As already mentioned during our study of the Cauchy distribution, when submitting a paper with Bayes Factors for publication, it is likely that the reviewers will ask the authors to justify their priors and to explicit it in their paper (otherwise a Bayes Factor may have been hacked!). Software such as JASP and the `R` package BayesFactor rely on the Cauchy distribution (with two parameters that are most of time very difficult to justify in practice) as a prior for many of the analyses.

Remark

To avoid hidden Bayes Factor hacking, softwares like JASP automatically provides a plot of the evidence for H_1 or H_0 for different width parameters of the Cauchy prior (named sometimes "sensitivity analysis"). In addition to the plot, JASP also provides a value denoted $\max$ BF10: this gives the Bayes Factor (for the alternative hypothesis) and the width parameter value of the Cauchy distribution (denoted r in JASP) where the largest Bayes Factor is found. Thus, conducting numerous analyses and reporting only the "best" one is a problem both for Frequentist and Bayesian inference. Bayes Factors do not provide a solution to this problem and also doesn't provide a solution to the false positive rate!!! So p-values (see page 948) and Bayes Factors share some of their pitfalls. Neither should be applied without some understanding of the underlying principles! Therefore a shift from Frequentist to Bayesian statistics is unlikely to be sufficient to alleviate the symptoms of the replication crisis...

Then in practice we just replace both numerator and denominator with Monte Carlo estimates. For the numerator we get:

$$\int P(D|\theta_1,\mathcal{M}_1)P(\theta_1|\mathcal{M}_1)\mathrm{d}\theta_1 = \mathrm{E}_{\mathcal{M}_1}\big(P(D|\theta,\mathcal{M}_1)\big) \cong \frac{1}{N}\sum_{j=1}^{N} P(D|\theta_1^{(j)},\mathcal{M}_1) \qquad (5.7.1637)$$

where the subscript $\mathcal{M}_1$ at the expectation indicates that θ in the expectation is distributed according to (the prior of) model 1 and, correspondingly, the $\theta_1^{(j)}$ on the right-hand side are independent and identically distributed samples from the prior of model 1. Using the same approximation for the denominator, we get:

$$\widehat{\mathrm{BF}}_{12} = \frac{\frac{1}{N}\sum_{j=1}^{N} P(D|\theta_1^{(j)},\mathcal{M}_1)}{\frac{1}{N}\sum_{j=1}^{N} P(D|\theta_2^{(j)},\mathcal{M}_2)} \qquad (5.7.1638)$$

The law of large numbers guarantees that this estimate converges to the correct value $\widehat{\mathrm{BF}}_{12}$ as the sample size N increases.

Caution! Their is some confusion between the frequentist and Bayesian paradigms because they use many of the same words to mean very different things. Name, "probability". Beyond Kolmogorov's axioms i would be a good idea to eliminate the word "probability" from the field of statistics. Under the frequentist paradigm, « *the probability...* » should only ever be referred to as, « *the long-run sampling proportion...* ». Likewise under the Bayesian paradigm, « *the probability...* » should only ever be referred as to as « *the unfalsifiable belief of the experimenter...* ». If the field of statistics makes this one simple change it can avoid a lot of nonsensical claims.

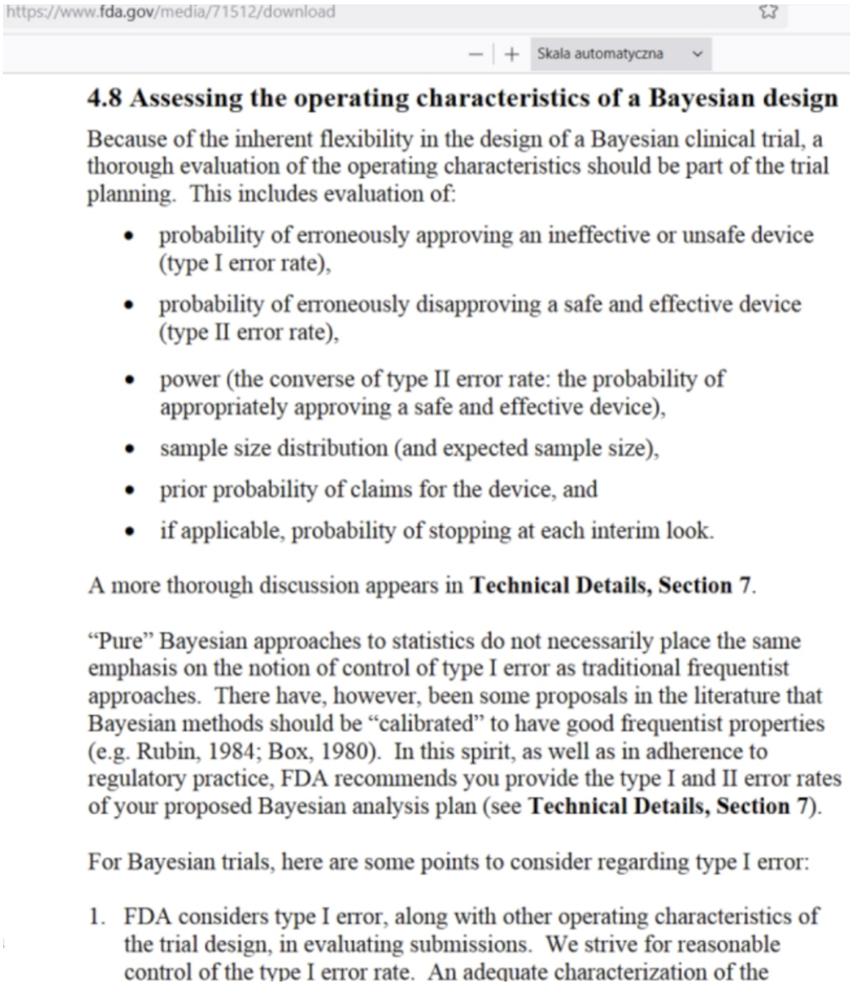
Interpretation: Those hypotheses ~~for which the observed result is within a 90% margin of error.~~
...for which I have 90% belief.
Wow, so what will this change allow us to do that we couldn't before?
Nothing, the results are pretty much the same except now the interpretation of probability is in terms of my personal belief.
Doesn't that make the results unfalsifiable? Wouldn't a falsifiable interpretation also provide us confidence?
What is falsifiable? Is that like a QC check? I can have someone QC my results.
Oh, brother. No, falsifiable/verifiable is not the same as QC-able.
The belief level of your credible interval is not a factual statement about the parameter, the hypothesis, nor the experiment. You can choose any prior and your resulting 90% posterior credible interval will always be "right."

Figure 5.169: **What it means to be "revolutionary" in statistics (author: Geoffrey Johnson)**

The Bayes Factor is used quite a lot in cutting edge fields of various sciences like: Social Science (to compare different models of behaviours), History (to quantify the existence of an individual), Cosmology (to compare various cosmological models), Particles Physics (to compare various models of fundamental particles). For more, see the excellent paper [307].

To close this topic let us provide a sample of the regulation of the FDA (Federal Drug Administration) relatively to clinical trials based on bayesian method because it's quite interesting (as a reader make your own conclusions...) :



4.8 Assessing the operating characteristics of a Bayesian design

Because of the inherent flexibility in the design of a Bayesian clinical trial, a thorough evaluation of the operating characteristics should be part of the trial planning. This includes evaluation of:

- probability of erroneously approving an ineffective or unsafe device (type I error rate),
- probability of erroneously disapproving a safe and effective device (type II error rate),
- power (the converse of type II error rate: the probability of appropriately approving a safe and effective device),
- sample size distribution (and expected sample size),
- prior probability of claims for the device, and
- if applicable, probability of stopping at each interim look.

A more thorough discussion appears in **Technical Details, Section 7**.

"Pure" Bayesian approaches to statistics do not necessarily place the same emphasis on the notion of control of type I error as traditional frequentist approaches. There have, however, been some proposals in the literature that Bayesian methods should be "calibrated" to have good frequentist properties (e.g. Rubin, 1984; Box, 1980). In this spirit, as well as in adherence to regulatory practice, FDA recommends you provide the type I and II error rates of your proposed Bayesian analysis plan (see **Technical Details, Section 7**).

For Bayesian trials, here are some points to consider regarding type I error:

1. FDA considers type I error, along with other operating characteristics of the trial design, in evaluating submissions. We strive for reasonable control of the type I error rate. An adequate characterization of the

5.7.10 Weak Law of Large Numbers (Khinchin's law)

We will now focus on a very interesting relation in statistics that can tell a lot of things while having little information and whatever the distribution (which is not bad!). This is a widely used property for example in statistical simulation in the context of the use of Monte Carlo techniques.

Given a random variable with values in $\mathbb{R}^+$. Then we will show the following relation named "Markov's inequality":

$$\boxed{\forall\lambda > 0 : P(X \geqslant \lambda) \leqslant \frac{\mathrm{E}(X)}{\lambda}} \tag{5.7.1639}$$

with in the particular context of probabilities $\mathrm{E}(X) \leq \lambda$.

In other words, we propose to prove that the probability that a random variable is greater than or equal to λ is less then or equal to its mean divided by the value λ considerated and regardless of the probability distribution of the random variable X!

Proof 5.47.10. Let us write the values of X by $(x_1, \ldots, x_n)$, where $0 \leq x_1 < x_2 < \ldots < x_n$ (that is to say sorted in ascending order) and let us also write $x_0 = 0$. We note first that the inequality is trivial in case where $\lambda \geq x_n \geq 0$. Indeed, as X can be included only between 0 and x_n by definition then the probability that it is greater to x_n is equal to zero. In other words:

$$P(X \geqslant \lambda) = 0 \tag{5.7.1640}$$

and X being positive, then $\mathrm{E}(X)$ is also positive, thus the inequality in this special case in a first time.

Otherwise, we have $0 < \lambda \leq x_n$ and then there exist one $k \in (1, \ldots, n)$ such that $x_{k-1} < \lambda \leq x_k$. Thus:

$$\mathrm{E}(X) = \sum_{i=1}^{n} x_i p_i \geqslant \sum_{i=k}^{n} x_i p_i \geqslant \sum_{i=k}^{n} p_i = \lambda P(X \geqslant \lambda) \tag{5.7.1641}$$

■ Q.E.D.

✍**Example:**

We assume that the number of outgoing parts of a given factory during one week is a random variable of mean 50. If we wish to estimate the cumulative probability that production exceeds 75 parts we will simply apply:

$$P(X \geqslant 75) \leqslant \frac{\mathrm{E}(X)}{\lambda} = \frac{50}{75} = 0.6666 = 66.66\% \tag{5.7.1642}$$

Consider now a kind of generalization of this inequality named "Bienayme-Chebyshev inequality" (abbreviated "BC inequality") that will allow us to get a very very interesting and important result a little bit later.

Consider a real random variable X (so we do not limit ourselves to the only cases where it is in $\mathbb{R}^+$). Then we will prove the following Bienayme-Chebyshev inequality:

$$\boxed{\forall\varepsilon>0:P(|X-\mathrm{E}(X)|\geqslant\varepsilon)\leqslant\frac{\mathrm{V}(X)}{\varepsilon^2}=\frac{\sigma^2}{\varepsilon^2}} \tag{5.7.1643}$$

which expresses the fact that the smaller the standard deviation is, more the probability that the random variable X moves away from its expectation is low.

Proof 5.47.11. We obtain this inequality by first writing:

$$\forall\varepsilon>0:P(|X-\mathrm{E}(X)|\geqslant\varepsilon)=P\left([X-\mathrm{E}(X)]^2\geqslant\varepsilon^2\right) \tag{5.7.1644}$$

where the choice of the square will serve us for a future simplification.

Then by applying Markov's inequality (as you see is something that can be useful ...) to the random variable $Y=[X-\mathrm{E}(X)]^2$ with $\lambda=\varepsilon^2$ it comes automatically:

$$P(Y\geqslant\varepsilon^2)=P\left([X-\mathrm{E}(X)]^2\geqslant\varepsilon^2\right)\leqslant\frac{\mathrm{E}(Y)}{\varepsilon^2}=\frac{\mathrm{E}\left([X-\mathrm{E}(X)]^2\right)}{\varepsilon^2} \tag{5.7.1645}$$

Then, using the definition of the variance:

$$\mathrm{E}\left([X-\mathrm{E}(X)]^2\right)=\mathrm{E}\left([X-\mu_X]^2\right)=\mathrm{V}(X)=\sigma^2 \tag{5.7.1646}$$

We get:

$$P(Y\geqslant\varepsilon^2)\leqslant\frac{\mathrm{E}\left([X-\mathrm{E}(X)]^2\right)}{\varepsilon^2}=\frac{\mathrm{V}(X)}{\varepsilon^2}=\frac{\sigma^2}{\varepsilon^2} \tag{5.7.1647}$$

■ Q.E.D.

If we put:

$$\varepsilon=t\sigma \tag{5.7.1648}$$

The equality will be written:

$$\boxed{P(|X-\mathrm{E}(X)|\geqslant t\sigma)\leqslant\frac{1}{t^2}} \tag{5.7.1649}$$

and expresses the cumulative probability in order that X moves away from the mean of more than t times its standard deviation, is below $1/t^2$. But for $t=2$, 3 and 4, we can deduce that there is, respectively, 75%, 89% and 94% of the data between the interval defined by 2, 3 and 4 standard deviations around the mean. There is, in particular, less than 1 chance on 9 that X moves away from its mean by more than three times the standard deviation. This is also this theorem that is used by the Basel Committee to define the Value at Risk correction factor used in finance (see section Economy page 7858).

✍**Example:**

We take the example where the number of outgoing parts of a given factory during one week is a random variable of mean 50. We assume in addition that the variance of the weekly production is 25. We seek to calculate the probability that the production of next week is between 40 and 60 pieces.

To calculate this we must first remember that the BT inequality is based partially on the term $|X - \text{E}(X)|$ so we have:

$$|40 - 50| = |60 - 50| = 10 \tag{5.7.1650}$$

Therefore the BT inequality allows us to work on equal intervals in absolute value which is also written:

$$-10 \leq X - \text{E}(X) \leq 10 \tag{5.7.1651}$$

Then we just have to apply numerical values to the inequality:

$$P(|X - \text{E}(X)| \geqslant \varepsilon) = P(|X - \text{E}(X)| \geqslant 10) = \frac{\text{V}(x)}{\varepsilon^2} = \frac{25}{10^2} = 0.25 = 25\% \tag{5.7.1652}$$

Because it can be applied to completely arbitrary distributions provided they have a known finite mean and variance, the inequality generally gives a poor bound compared to what might be deduced if more aspects are known about the distribution involved:

t	**Min. % within t standard deviations of mean**	**Max. % beyond t standard deviations from mean**
1	0%	100%
$\sqrt{2}$	50%	50%
1.5	55.56%	44.44%
2	75%	25%
$2\sqrt{2}$	87.5%	12.5%
3	88.8889%	11.1111%
4	93.75%	6.25%
5	96%	4%
6	97.2222%	2.7778%
7	97.9592%	2.0408%
8	98.4375%	1.5625%
9	98.7654%	1.2346%
10	99%	1%

Table 5.50: **Chebychev typical intervals to the mean**

There is another inequality sometimes useful in practice. Let us quickly prove it!

Defining $Y = X - \text{E}[X]$, it follows that $\text{E}[Y] = 0$ and $\text{V}(Y) = \text{V}(X) =: \sigma^2 = \text{E}\left[Y^2\right]$.

For $t, u > 0$, using Markov's inequality given for reminder by (see page 920):

$$\forall \lambda > 0 : P(X \geqslant \lambda) \leqslant \frac{\mathrm{E}(X)}{\lambda} \tag{5.7.1653}$$

we have:

$$\begin{aligned} P(Y \geq t) = P(Y + u \geq t + u) \leq P\left((Y+u)^2 \geq (t+u)^2\right) \\ \leq \frac{\mathrm{E}\left[(Y+u)^2\right]}{(t+u)^2} = \frac{\sigma^2 + u^2}{(t+u)^2} =: \varphi(u) \end{aligned} \tag{5.7.1654}$$

the last inequality being a consequence of Markov's inequality! Before we continue with the next steps a reader has asked us to explain how $P(Y + u \geq t + u) \leq P\left((Y+u)^2 \geq (t+u)^2\right)$? This is indeed not necessary trivial at first sight!

First, remember that we have $t, u > 0$. The first thing trivial is that $(Y+u)^2 \geq (Y+u)$. Now what you have to observe numerically is that for some values of $1 > t, u > 0$ we have $t + u < t^2 + 2tu + u^2$. Hence the width of the interval of the probability is bigger and that explains the inequality!

As the above holds for any choice of $u \in \mathbb{R}$, we can choose to apply it with the value that minimize: $\varphi'(u) = 0$, i.e.:

$$\varphi'(u) = 2\frac{u}{(t+u)^2} - 2\frac{\sigma^2 + u^2}{(t+u)^3} = 0 \tag{5.7.1655}$$

gives $u = \sigma^2/t$, and the result follows:

$$\boxed{P(X - \mathrm{E}(X) \geq t) \leq \frac{\sigma^2}{\sigma^2 + t^2}} \tag{5.7.1656}$$

and this is the "Cantelli's inequality" (also named the "Chebyshev-Cantelli inequality" or the "one-sided Chebyshev inequality").

The last two inequalities obtained before the example will allow us to obtain a very important and powerful relation that we call "weak law of large numbers" (WLLN) or "Khinchin theorem".

Consider a random variable X having a variance and $(X_n)_{n \in \mathbb{N}^*}$ a sequence of independent random variables (i.e. uncorrelated by pairs) of the same distribution as this of X and all having the same mean μ and the same standard deviations σ.

What we will show is that if we measure the same random quantity X_n of the same distribution in the process of a series of independent experiments (so in this case, we say technically that the sequence $(X_n)_{n \in \mathbb{N}^*}$ of random variables is defined on the same probability space) , then the arithmetic average of the observed values will stabilize on the mean of X when the number of measurements tends to infinity[50]:

$$\boxed{\forall \varepsilon > 0 : \quad \left(\left| \frac{1}{n} \sum_{i=1}^{n} X_i - \mu \right| \geqslant \varepsilon \right) \leqslant \frac{\sigma^2}{n\varepsilon^2} \underset{n \to +\infty}{\to} 0} \tag{5.7.1657}$$

---

[50] This explains for example why births, weddings, deaths display a fascinating regularity from one year to the other on huge independent - uncorrelated - population of individuals

when $n \rightarrow +\infty$ this is the very important result which we did mention above! The empirical estimator of the mean tends for any distribution to the true expected mean if n is large! So by this rule we assure that the sample average is a consistent estimator of mean! This result (quite intuitive) is sometimes named the "fundamental theorem of Monte Carlo" because it is central to the simulations principle of the same name (see section Numerical Methods page 6708), which are crucial in the study of advanced statistics.

Remark

This convergence property is also named "regression toward the mean" or simply "reversion to the mean". Implicitly meaning that if a variable is extreme on its first measurement, it will tend to be closer to the average on its second measurement - and if it is extreme on its second measurement, it will tend to have been closer to the average on its first. That's why measuring and individual performance (whatever what kind of performance), only once doesn't make sense scientifically speaking as that performance fluctuates more or less around its mean!!!

One of Galton's first examples was the average height of parents and their children. He found that tall parents had (on average) children who were smaller than them, and that short parents had (on average) children who were taller than them. In both cases the children with parents at the extreme ends of the distribution had heights closer to the population mean height.

So in other words, the cumulative probability that the difference between the arithmetic average and the expected of the observed random variables to be in a given range around the average tends to zero as the number of measured random variables tends to infinity (that which is ultimately intuitive).

This result allows us to estimate the expected mean value using the empirical mean (arithmetic average) calculated on a very large number of experiments.

Proof 5.47.12. We use the Chebyshev-Bienaymé inequality for the random variable (this relation is difficult to interpret but allows us to get the desired result):

$$Y=\frac{1}{n}\sum_{i=1}^{n}X_i \tag{5.7.1658}$$

And we first calculate using the mathematical properties of the mean that we proved earlier:

$$\mathrm{E}(Y)=\mathrm{E}\left(\frac{1}{n}\sum_{i=1}^{n}X_i\right)=\frac{1}{n}\mathrm{E}\left(\sum_{i=1}^{n}X_i\right)=\frac{1}{n}\sum_{i=1}^{n}\mathrm{E}(X_i)=\frac{1}{n}\sum_{i=1}^{n}\mu=\mu \tag{5.7.1659}$$

and in a second time using the mathematical properties of the variance as already proved above:

$$\mathrm{V}(Y)=\mathrm{V}\left(\frac{1}{n}\sum_{i=1}^{n}X_i\right)=\frac{1}{n^2}\mathrm{V}\left(\sum_{i=1}^{n}X_i\right)=\frac{1}{n^2}\left(\sum_{i=1}^{n}\mathrm{V}(X_i)+2\sum_{1\leqslant i<j\leqslant n}\mathrm{cov}(X_i,X_j)\right) \tag{5.7.1660}$$

and since we assumed uncorrelated variables then the covariance between them is zero therefore:

$$\mathrm{V}(Y)=\frac{1}{n^2}\left(\sum_{i=1}^{n}\mathrm{V}(X_i)\right)=\frac{1}{n^2}\left(\sum_{i=1}^{n}\sigma^2\right)=\frac{1}{n^2}n\sigma^2=\frac{\sigma^2}{n^2} \tag{5.7.1661}$$

So by injecting it into the BT inequality:

$$P\left([Y-\mathrm{E}(Y)]^2 \geqslant \varepsilon^2\right) \leqslant \frac{\mathrm{V}(Y)}{\varepsilon^2} \tag{5.7.1662}$$

that becomes:

$$P\left(\left[\frac{1}{n}\sum_{i=1}^{n} X_i-\mu\right]^2 \geqslant \varepsilon^2\right) \leqslant \frac{\sigma^2}{n\varepsilon^2} \tag{5.7.1663}$$

and the inequality tends effectively to zero as well n at the denominator tends to infinity.

■ Q.E.D.

Note that the latter relation is often denoted in some works, and according to what we saw at the beginning of this section:

$$P\left(|M_n-m_X|^2 \geqslant \varepsilon\right) \leqslant \frac{\sigma_X^2}{n\varepsilon^2} \tag{5.7.1664}$$

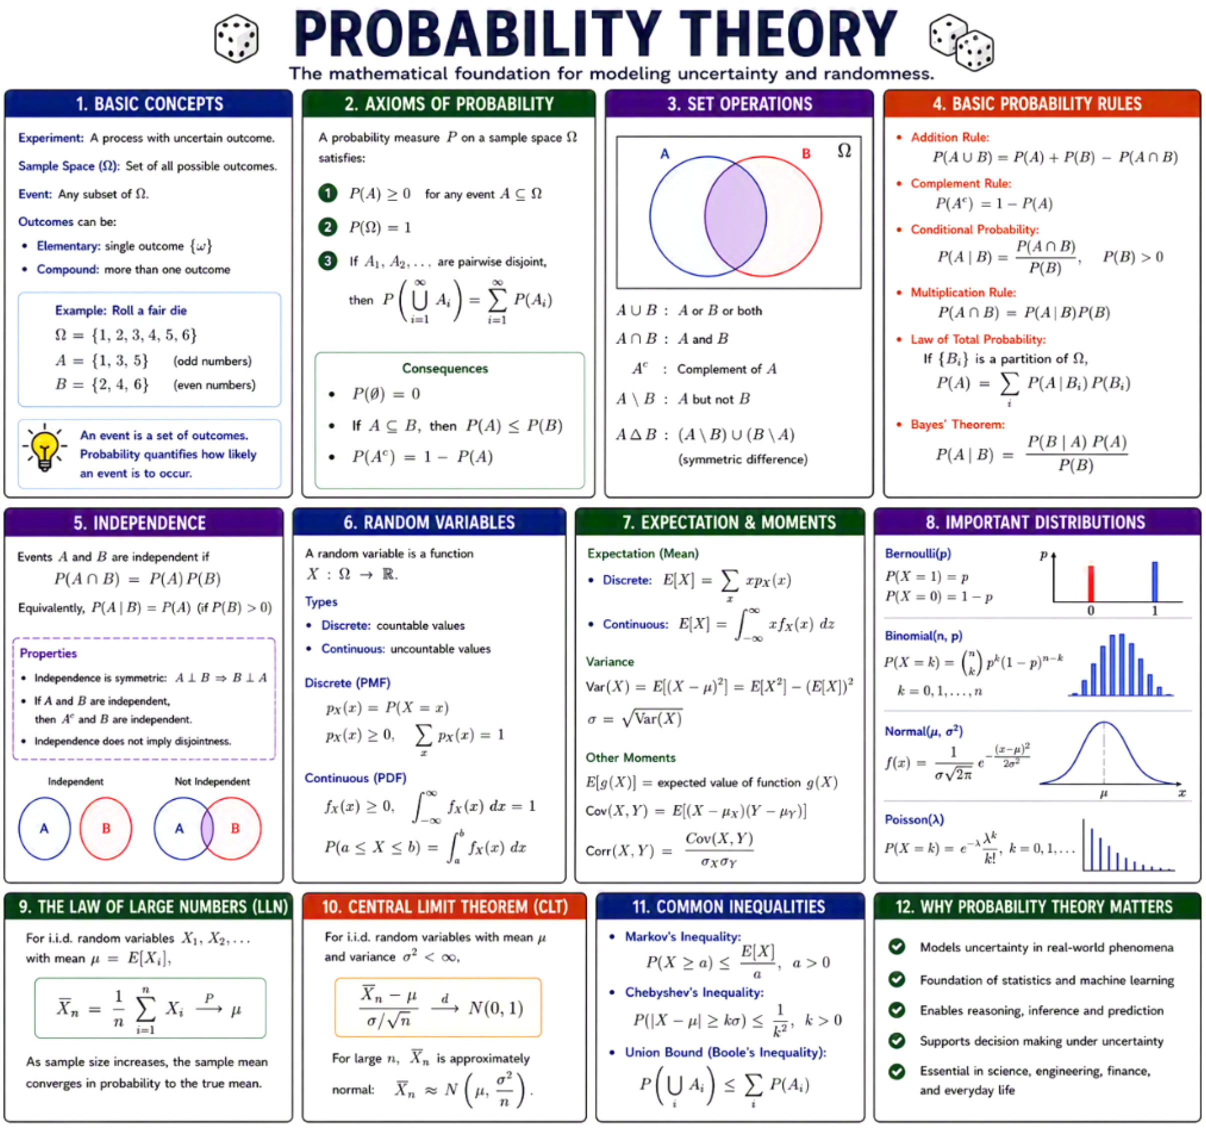
or:

$$P\left(|M_n-m_X| < \varepsilon\right) \geqslant 1-\frac{\sigma_X^2}{n\varepsilon^2} \tag{5.7.1665}$$

Therefore for $\forall\varepsilon > 0$:

$$\lim_{n\rightarrow+\infty} P\left(|M_n-m_X| < \varepsilon\right) = 1 \tag{5.7.1666}$$

A brief reminder of some of the most important elements seen so far about probabilities and statistics :



PROBABILITY THEORY

The mathematical foundation for modeling uncertainty and randomness.

1. BASIC CONCEPTS

Experiment: A process with uncertain outcome.

Sample Space (Ω): Set of all possible outcomes.

Event: Any subset of Ω.

Outcomes can be:

- **Elementary:** single outcome $\{\omega\}$
- **Compound:** more than one outcome

Example: Roll a fair die

$\Omega = \{1, 2, 3, 4, 5, 6\}$

$A = \{1, 3, 5\}$ (odd numbers)

$B = \{2, 4, 6\}$ (even numbers)

An event is a set of outcomes. Probability quantifies how likely an event is to occur.

2. AXIOMS OF PROBABILITY

A probability measure P on a sample space Ω satisfies:

① $P(A) \geq 0$ for any event $A \subseteq \Omega$

② $P(\Omega) = 1$

③ If $A_1, A_2, \ldots$ are pairwise disjoint, then $P\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} P(A_i)$

Consequences

- $P(\emptyset) = 0$
- If $A \subseteq B$, then $P(A) \leq P(B)$
- $P(A^c) = 1 - P(A)$

3. SET OPERATIONS

$A \cup B$: A or B or both

$A \cap B$: A and B

A^c : Complement of A

$A \setminus B$: A but not B

$A \,\Delta\, B$: $(A \setminus B) \cup (B \setminus A)$ (symmetric difference)

4. BASIC PROBABILITY RULES

- **Addition Rule:**
  $P(A \cup B) = P(A) + P(B) - P(A \cap B)$
- **Complement Rule:**
  $P(A^c) = 1 - P(A)$
- **Conditional Probability:**
  $P(A \mid B) = \dfrac{P(A \cap B)}{P(B)}, \quad P(B) > 0$
- **Multiplication Rule:**
  $P(A \cap B) = P(A \mid B)P(B)$
- **Law of Total Probability:**
  If $\{B_i\}$ is a partition of Ω,
  $P(A) = \sum_i P(A \mid B_i)\, P(B_i)$
- **Bayes' Theorem:**
  $P(A \mid B) = \dfrac{P(B \mid A)\, P(A)}{P(B)}$

5. INDEPENDENCE

Events A and B are independent if

$P(A \cap B) = P(A)\, P(B)$

Equivalently, $P(A \mid B) = P(A)$ (if $P(B) > 0$)

Properties

- Independence is symmetric: $A \perp B \Rightarrow B \perp A$
- If A and B are independent, then A^c and B are independent.
- Independence does not imply disjointness.

6. RANDOM VARIABLES

A random variable is a function $X : \Omega \to \mathbb{R}$.

Types

- **Discrete:** countable values
- **Continuous:** uncountable values

Discrete (PMF)

$p_X(x) = P(X = x)$

$p_X(x) \geq 0, \quad \sum_x p_X(x) = 1$

Continuous (PDF)

$f_X(x) \geq 0, \quad \int_{-\infty}^{\infty} f_X(x)\, dx = 1$

$P(a \leq X \leq b) = \int_a^b f_X(x)\, dx$

7. EXPECTATION & MOMENTS

Expectation (Mean)

- **Discrete:** $E[X] = \sum_x x p_X(x)$
- **Continuous:** $E[X] = \int_{-\infty}^{\infty} x f_X(x)\, dz$

Variance

$\mathrm{Var}(X) = E[(X-\mu)^2] = E[X^2] - (E[X])^2$

$\sigma = \sqrt{\mathrm{Var}(X)}$

Other Moments

$E[g(X)]$ = expected value of function $g(X)$

$\mathrm{Cov}(X,Y) = E[(X-\mu_X)(Y-\mu_Y)]$

$\mathrm{Corr}(X,Y) = \dfrac{\mathrm{Cov}(X,Y)}{\sigma_X \sigma_Y}$

8. IMPORTANT DISTRIBUTIONS

Bernoulli(p)

$P(X=1) = p$

$P(X=0) = 1-p$

Binomial(n, p)

$P(X=k) = \binom{n}{k} p^k (1-p)^{n-k}$

$k = 0, 1, \ldots, n$

Normal(μ, σ^2)

$f(x) = \dfrac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}}$

Poisson(λ)

$P(X=k) = e^{-\lambda}\dfrac{\lambda^k}{k!}, \ k = 0, 1, \ldots$

9. THE LAW OF LARGE NUMBERS (LLN)

For i.i.d. random variables $X_1, X_2, \ldots$ with mean $\mu = E[X_i]$,

$$\boxed{\overline{X}_n = \frac{1}{n}\sum_{i=1}^{n} X_i \xrightarrow{P} \mu}$$

As sample size increases, the sample mean converges in probability to the true mean.

10. CENTRAL LIMIT THEOREM (CLT)

For i.i.d. random variables with mean μ and variance $\sigma^2 < \infty$,

$$\boxed{\frac{\overline{X}_n - \mu}{\sigma/\sqrt{n}} \xrightarrow{d} N(0,1)}$$

For large n, $\overline{X}_n$ is approximately normal: $\overline{X}_n \approx N\left(\mu, \dfrac{\sigma^2}{n}\right)$.

11. COMMON INEQUALITIES

- **Markov's Inequality:**
  $P(X \geq a) \leq \dfrac{E[X]}{a}, \quad a > 0$
- **Chebyshev's Inequality:**
  $P(|X-\mu| \geq k\sigma) \leq \dfrac{1}{k^2}, \quad k > 0$
- **Union Bound (Boole's Inequality):**
  $P\left(\bigcup_i A_i\right) \leq \sum_i P(A_i)$

12. WHY PROBABILITY THEORY MATTERS

- ✓ Models uncertainty in real-world phenomena
- ✓ Foundation of statistics and machine learning
- ✓ Enables reasoning, inference and prediction
- ✓ Supports decision making under uncertainty
- ✓ Essential in science, engineering, finance, and everyday life

5.7.11 Characteristic Function

In probability theory and statistics, the "characteristic function" of any real-valued random variable completely defines its probability distribution. If a random variable admits a probability density function, we will prove further below that then the characteristic function is the inverse Fourier transform of the probability density function. Thus it provides the basis of an alternative route to analytical results compared with working directly with probability density functions or cumulative distribution functions.

Before giving an engineer proof of the famous central limit theorem, first let us introduce the concept of "characteristic function", which is central in statistics.

First, remember that the Fourier transform is given in its physicist version (see section Sequences and Series page 1758) by the relation:

$$\mathcal{F}(k)=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}f(x)e^{-\mathrm{i}xk}\mathrm{d}x \tag{5.7.1667}$$

Let us recall that the Fourier transform is an analogue of the Fourier series theory for non-periodic functions, and allows to associate them a frequencies spectrum. To a given factor, it is a "bilateral Laplace transform" given by (see section Analysis page 2337):

$$\mathcal{L}[f(x)]=\mathcal{F}(p)=\int\limits_{-\infty}^{+\infty}f(x)e^{-px}\mathrm{d}x \tag{5.7.1668}$$

where p is the complex variable given in the present case by (the real part is zero, because the Fourier transform is the particular case of a Laplace transform whose real part of the variable is zero: then make Fourier transform is like make a Laplace transform on the axis of imaginary numbers only):

$$p=\mathrm{i}k \tag{5.7.1669}$$

Now we want to prove that if:

$$g(x)=f'(x)\quad\Rightarrow\quad G(k)=\mathrm{i}k\mathcal{F}(k) \tag{5.7.1670}$$

In other words, we are looking for a simplified expression of the Fourier transform of the derivative of $f(x)$.

Proof 5.47.13. We start from:

$$G(k)=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}f'(x)e^{-\mathrm{i}xk}\mathrm{d}x \tag{5.7.1671}$$

An integration by parts gives (see section Differential and Integral Calculus page 1532):

$$\int\limits_{-\infty}^{+\infty}f'(x)e^{-\mathrm{i}xk}\mathrm{d}x=f(x)e^{-\mathrm{i}xk}\Big|_{x=-\infty}^{x=+\infty}+\mathrm{i}k\int\limits_{-\infty}^{+\infty}f(x)e^{-\mathrm{i}xk}\mathrm{d}x \tag{5.7.1672}$$

By imposing that f tends to zero at infinity, then we have:

$$f(x)e^{-\mathrm{i}xk}\Big|_{x=-\infty}^{x=+\infty}=0 \tag{5.7.1673}$$

and:

$$G(k)=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}f'(x)e^{-\mathrm{i}xk}\mathrm{d}x=\frac{\mathrm{i}k}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}f(x)e^{-\mathrm{i}xk}\mathrm{d}x=\mathrm{i}k\mathcal{F}(k) \tag{5.7.1674}$$

■ Q.E.D.

This is the first result we needed.

Now let us prove that if:

$$g(x)=xf(x)\quad\Rightarrow\quad G(k)=\mathrm{i}\mathcal{F}'(k) \tag{5.7.1675}$$

Proof 5.47.14. So we start from:

$$\begin{aligned}G(k)&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}xf(x)e^{-\mathrm{i}xk}\mathrm{d}x=\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}k}\left(\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}f(x)e^{-\mathrm{i}xk}\mathrm{d}x\right)=\mathrm{i}\mathcal{F}'(k)\\&=\mathrm{i}\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}f(x)\frac{\mathrm{d}}{\mathrm{d}k}e^{-\mathrm{i}xk}\mathrm{d}x=\mathrm{i}\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}f(x)(-\mathrm{i}x)e^{-\mathrm{i}xk}\mathrm{d}x=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}xf(x)e^{-\mathrm{i}xk}\mathrm{d}x\end{aligned} \tag{5.7.1676}$$

■ Q.E.D.

This is the second result we needed.

Now let us perform the calculation of the Fourier transform of the Normal centered-reduced distribution $\mathcal{N}(0,1)$ (this choice is not innocent...):

$$y=f_X(x)=\frac{1}{\sqrt{2\pi}}e^{-x^2/2} \tag{5.7.1677}$$

We know that this latter relation is trivially solution of the following differential equation (or it satisfies it in other words...):

$$y'=-xy \tag{5.7.1678}$$

taking the Fourier transform of both sides of the equality, we use the previous two results:

$$\begin{gathered}g(x)=f'(x)\text{ then }G(k)=\mathrm{i}k\mathcal{F}(k)\\g(x)=xf(x)\text{ then }G(k)=\mathrm{i}\mathcal{F}'(k)\end{gathered} \tag{5.7.1679}$$

We have:

$$\mathrm{i}k\mathcal{F}(k)=-\mathrm{i}\mathcal{F}'(k) \tag{5.7.1680}$$

Or:

$$-k\mathrm{d}k=\frac{1}{\mathcal{F}(k)}\mathrm{d}\mathcal{F}(k) \tag{5.7.1681}$$

Then after integration:

$$\begin{aligned}&\int\limits_0^k-k\mathrm{d}k=\int\limits_0^k\frac{1}{\mathcal{F}(k)}\mathrm{d}\mathcal{F}(k)\Rightarrow-\frac{1}{2}k^2\Big|_0^k=\ln(\mathcal{F}(k))\Big|_0^k\Rightarrow-\frac{1}{2}k^2=\ln(\mathcal{F}(k))-\ln(\mathcal{F}(0))\\&\qquad\Rightarrow-\frac{1}{2}k^2=\ln\left(\frac{\mathcal{F}(k)}{\mathcal{F}(0)}\right)\Rightarrow e^{-\frac{1}{2}k^2}=\frac{\mathcal{F}(k)}{\mathcal{F}(0)}\Rightarrow\mathcal{F}(k)=\mathcal{F}(0)e^{-\frac{1}{2}k^2}\end{aligned} \tag{5.7.1682}$$

As:

$$\mathcal{F}(k)=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} f(x)e^{-\mathrm{i}xk}\mathrm{d}k \tag{5.7.1683}$$

We therefore have:

$$\begin{aligned}\mathcal{F}(0)&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} f(x)e^{-\mathrm{i}kx}\mathrm{d}x=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} f(x)\mathrm{d}x=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}\frac{1}{\sqrt{2\pi}}e^{-x^2/2}\mathrm{d}x\\&=\frac{1}{2\pi}\int\limits_{-\infty}^{+\infty} e^{-x^2/2}\mathrm{d}x\end{aligned} \tag{5.7.1684}$$

We proved during our study of the Normal distribution that:

$$\int\limits_{-\infty}^{+\infty} e^{-x^2/2}\mathrm{d}x=\sqrt{2\pi} \tag{5.7.1685}$$

Therefore:

$$\mathcal{F}(0)=\frac{1}{2\pi}\int\limits_{-\infty}^{+\infty} e^{-x^2/2}\mathrm{d}x=\frac{1}{2\pi}\sqrt{2\pi}=\frac{1}{\sqrt{2\pi}} \tag{5.7.1686}$$

We then have (very important result!):

$$\mathcal{F}(k)=\frac{1}{\sqrt{2\pi}}e^{-k^2/2} \tag{5.7.1687}$$

Let us now introduce the characteristic function as defined by statisticians:

$$\boxed{\phi_X(\omega)=\mathrm{E}\left[e^{\mathrm{i}kX}\right]=\int\limits_{-\infty}^{+\infty} e^{\mathrm{i}kx}f_X(x)\mathrm{d}x} \tag{5.7.1688}$$

which is an important and powerful analytical tool for analysing a sum of independent random variables. In addition, this function contains all the information characteristic of the random variable X (all moments) as its Taylor development will show it to us just further below!

Remark

The notation is not innocent since the $\mathrm{E}[\ldots]$ represents an expected mean of the density function with respect to the complex exponential.

Therefore the characteristic function of the Normal reduced centered random variable of distribution law:

$$f_X(x)=\frac{1}{\sqrt{2\pi}}e^{-x^2/2} \tag{5.7.1689}$$

becomes easy to determine because:

$$\boxed{\phi_X(k)=\int\limits_{-\infty}^{+\infty} e^{\mathrm{i}kx} f_X(x)\mathrm{d}x=\sqrt{2\pi}\mathcal{F}(-k)} \tag{5.7.1690}$$

This is why the characteristic function of the reduced centered Normal distribution is often assimilated to a simple Fourier transform (see section Sequences and Series page 1758).

And thanks to the previous result:

$$\mathcal{F}(k)=\frac{1}{\sqrt{2\pi}}e^{-k^2/2}\Rightarrow F(-k)=\frac{1}{\sqrt{2\pi}}e^{-(-k)^2/2}=\frac{1}{\sqrt{2\pi}}e^{-k^2/2} \tag{5.7.1691}$$

Therefore:

$$\phi_X(k)=\frac{\sqrt{2\pi}}{\sqrt{2\pi}}e^{-k^2/2}=e^{-k^2/2} \tag{5.7.1692}$$

which is the result we will need for the central limit theorem that we will study just after. This characteristic function is equal, to a given constant, to the probability density of the law. Then we say that the characteristic function of a Gaussian function is Gaussian function....

But before that, let us look a little closer this characteristic function:

$$\phi_X(\omega)=\mathrm{E}\left[e^{\mathrm{i}kx}\right]=\int\limits_{-\infty}^{+\infty} f_X(x)\mathrm{d}x \tag{5.7.1693}$$

Using a Maclaurin development (see section Sequences and Series page 1696) and changing some notations we get:

$$\phi_X(\omega)=\int\limits_{-\infty}^{+\infty}\left[\sum_{k=0}^{+\infty}\frac{(\mathrm{i}\omega)^k}{k!}x^k f_X(x)\mathrm{d}x\right] \tag{5.7.1694}$$

and by inverting the sum and the integral, we have:

$$\phi_X(\omega)=\sum_{k=0}^{+\infty}\frac{(\mathrm{i}\omega)^k}{k!}\left[\int\limits_{-\infty}^{+\infty} x^k f_X(x)\mathrm{d}x\right]=\sum_{k=0}^{+\infty}\frac{(\mathrm{i}\omega)^k}{k!}M_X^k \tag{5.7.1695}$$

This characteristic function contains therefore all the moments (general term used for the mean, variance, skewness and kurtosis) of X.

✍**Examples:**

Let us see another famous example with the Poisson distribution (interesting case as it is a discrete distribution function!)!

Proof. Using the definition of characteristic function:

$$\begin{aligned}\varphi_X(t) &= \mathrm{E}\left[\exp(\mathrm{i}tX)\right]\\ &= \sum_{x\in\mathbb{R}_X}\exp(\mathrm{i}tx)P_X(x)\\ &= \sum_{x\in\mathbb{R}_X}[\exp(\mathrm{i}t)]^x\exp(-\lambda)\frac{1}{x!}\lambda^x\\ &= \exp(-\lambda)\sum_{x=0}^{+\infty}\frac{(\lambda\exp(\mathrm{i}t))^x}{x!}\\ &= \exp(-\lambda)\exp(\lambda\exp(\mathrm{i}t))\\ &= \exp(\lambda[\exp(\mathrm{i}t)-1])\end{aligned}$$

where:

$$\exp(\lambda\exp(\mathrm{i}t))=\sum_{x=0}^{+\infty}\frac{(\lambda\exp(\mathrm{i}t))^x}{x!}$$

is the usual Taylor series expansion of the exponential function as proved in the section Sequences and Series page 1703 (note that the series converges for any value of t).

5.7.11.1 Moment generating function and cumulants

In probability theory and statistics, the moment-generating function of a real-valued random variable is an alternative specification of its probability distribution. Thus, it provides the basis of an alternative route to analytical results compared with working directly with probability density functions or cumulative distribution functions. There are particularly simple results for the moment-generating functions of distributions defined by the weighted sums of random variables. However, not all random variables have moment-generating functions.

As its name implies, the moment generating function can be used to compute a distribution's moments: the nth moment about 0 is the nth derivative of the moment-generating function, evaluated at 0.

In addition to real-valued distributions (univariate distributions), moment-generating functions can be defined for vector- or matrix-valued random variables, and can even be extended to more general cases.

The moment-generating function of a real-valued distribution does not always exist, unlike the characteristic function. There are relations between the behaviour of the moment-generating function of a distribution and properties of the distribution, such as the existence of moments.

The moment-generating function of a random variable X is:

$$M_X(t):=\mathrm{E}\left(e^{tX}\right),\quad t\in\mathbb{R} \tag{5.7.1696}$$

wherever this expectation exists. In other words, the moment-generating function of X is the expectation of the random variable e^{tX}.

$M_X(0)$ always exists and is equal to 1 (see proof just below). However, a key problem with moment-generating functions is that moments and the moment generating function may not exist, as the integrals need not converge absolutely. By contrast, the characteristic function or Fourier transform always exists (because it is the integral of a bounded function on a space of finite measure), and for some purposes may be used instead.

The moment-generating function is so named because it can be used to find the moments of distributions. The series expansion of e^{tX} is:

$$e^{tX}=1+tX+\frac{t^2X^2}{2!}+\frac{t^3X^3}{3!}+\ldots+\frac{t^nX^n}{n!}+\ldots \tag{5.7.1697}$$

Hence:

$$\begin{aligned}M_X(t)=\mathrm{E}\left(e^{tX}\right)&=1+t\mathrm{E}(X)+\frac{t^2\mathrm{E}\left(X^2\right)}{2!}+\frac{t^3\mathrm{E}\left(X^3\right)}{3!}+\ldots+\frac{t^n\mathrm{E}\left(X^n\right)}{n!}+\ldots\\&=1+tm_1+\frac{t^2m_2}{2!}+\frac{t^3m_3}{3!}+\ldots+\frac{t^nm_n}{n!}+\ldots\end{aligned} \tag{5.7.1698}$$

where m_n is the n th moment. Differentiating $M_X(t)$ a number i times with respect to t and setting $t=0$, we obtain the ith moment about the origin, m_i.

If it exists for t in a neighbourhood of 0, then all "moments" of X exist, and:

$$\boxed{\left.\frac{\partial^k}{\partial t^k}M_X(t)\right|_{t=0}=\mathrm{E}\left(X^k\right)} \tag{5.7.1699}$$

The "cumulant generating function" is the log of the moment generating function:

$$c_X(t)=\log\left(M_X(t)\right) \tag{5.7.1700}$$

It generates the "cumulants", which are defined by what the cumulant generating function generates, i.e., for a random variable, the k^{th} cumulant is:

$$\boxed{\gamma_k=\left.\frac{\partial^k}{\partial t^k}c_X(t)\right|_{t=0}=\left.\frac{\partial^k}{\partial t^k}\log\left(M_X(t)\right)\right|_{t=0}=\left.\frac{\partial^k}{\partial t^k}\log\left(\mathrm{E}(e^{tX})\right)\right|_{t=0}} \tag{5.7.1701}$$

Cumulants are slightly easier to work with than moments. The first four are:

$$\begin{aligned}\gamma_1&=\mathrm{E}(X)=\mu_1=\mu\\\gamma_2&=\mathrm{V}(X)=\mu_2=\sigma^2\\\gamma_3&=\mathrm{E}\left[(X-\mathrm{E}[X])^3\right]=\mu_3\\\gamma_4&=\mathrm{E}\left[(X-\mathrm{E}[X])^4\right]-3\mathrm{V}[X]^2=\mu_4-3\mu_2^2=\mu_4-3\sigma^4\end{aligned} \tag{5.7.1702}$$

The skewness and kurtosis (see page 636) are then simple functions of the cumulants:

$$\text{Skewness}\,[X]=\frac{\gamma_3}{\sigma^3}\qquad\text{and}\qquad\text{Kurtosis}\,[X]=\frac{\gamma_4}{\sigma^4} \tag{5.7.1703}$$

If X is a continuous random variable, the following relation between its moment-generating function $M_X(t)$ and the two-sided Laplace transform of its probability density function $f_X(x)$ holds:

$$M_X(t)=\mathcal{L}\left\{f_X\right\}(-t) \tag{5.7.1704}$$

since the PDF's two-sided Laplace transform (see section Analysis page 2337) is given as:

$$\mathcal{L}(f(X)) = \int\limits_{-\infty}^{+\infty} e^{-sx} f_X(x)\mathrm{d}x \tag{5.7.1705}$$

and the "moment-generating function's" (MGF) definition expands (by the law of the unconscious statistician) to:

$$\boxed{M_X(t) = \mathrm{E}(e^{tX}) = \int\limits_{-\infty}^{+\infty} e^{tx} f_X(x)\mathrm{d}x} \tag{5.7.1706}$$

The moment-generating function is the expectation of a function of the random variable, it can be written as:

- For a discrete probability mass function, $M_X(t) = \sum_{i=1}^{+\infty} e^{tx_i} p_i$
- For a continuous probability density function, $M_X(t) = \int_{-\infty}^{+\infty} e^{tx} f(x)\mathrm{d}x$

✍**Examples:**

E1. Let us take the case of the Normal distribution.

Suppose $X = \mathcal{N}(\mu, \sigma^2)$ (with $\sigma^2 > 0$). Then its MGF is:

$$M_X(t) = \mathrm{E}\left(e^{tX}\right) = \frac{1}{\sqrt{2\pi}\sigma} \int\limits_{-\infty}^{+\infty} e^{tx} e^{-\frac{1}{2}\frac{(x-\mu)^2}{\sigma^2}} \mathrm{d}x = \frac{1}{\sqrt{2\pi}\sigma} \int\limits_{-\infty}^{+\infty} e^{tx-\frac{1}{2}\frac{1}{\sigma^2}\left(x^2-2\mu x+\mu^2\right)} \mathrm{d}x$$

$$= \frac{1}{\sqrt{2\pi}\sigma} \int\limits_{-\infty}^{+\infty} e^{-\frac{1}{2}\frac{1}{\sigma^2}\left(x^2-2\left(\mu+t\sigma^2\right)x+\mu^2\right)} \mathrm{d}x$$

In the exponent, complete the square with respect to the x:

$$x^2 - 2\left(\mu + t\sigma^2\right)x = \left(x - \left(\mu + t\sigma^2\right)\right)^2 - \left(\mu + t\sigma^2\right)^2$$

Then:

$$M_X(t) = e^{\frac{1}{2}\frac{1}{\sigma^2}\left(\left(\mu+t\sigma^2\right)^2-\mu^2\right)} \int\limits_{-\infty}^{+\infty} \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{1}{2}\frac{1}{\sigma^2}\left(x-\left(\mu+t\sigma^2\right)\right)^2} \mathrm{d}x$$

Notice that the integrand is the probability density function of a $\mathcal{N}(\mu + t\sigma^2, \sigma^2)$, which means the integral is 1. Expanding the $\left(\mu + t\sigma^2\right)^2$ and simplifying a bit yields:

$$M_X(t) = e^{t\mu + \frac{1}{2}\sigma^2 t^2}, t \in \mathbb{R}$$

The cumulant generating function is then a simple quadratic:

$$c_X(t) = t\mu + \frac{1}{2}\sigma^2 t^2$$

and it is easy to see that:

$$c'_X(0) = \mu, \quad c''(0) = \sigma^2, \quad c'''(t) = 0$$

Thus the mean is μ and variance is σ^2 (not surprisingly), and all other cumulants are 0. In particular, the skewness and kurtosis are both 0 .

E2. Let us see now an example with the Gamma distribution.

The Gamma distribution has as we know two parameters: $\alpha > 0$ is the shape parameter, and $\lambda > 0$ is the scale parameter. Its space is $\mathcal{X} = [0, +\infty[$, and its probability density function is $cx^{\alpha-1}\exp(-\lambda x)$, where:

$$\frac{1}{c} = \int\limits_0^{+\infty} x^{\alpha-1}e^{-\lambda x}\mathrm{d}x = \int\limits_0^{+\infty} (u/\lambda)^{\alpha-1}e^{-u}\mathrm{d}u/\lambda = \frac{1}{\lambda^\alpha}\int\limits_0^{+\infty} u^{\alpha-1}e^{-u}\mathrm{d}u = \frac{1}{\lambda^\alpha}\Gamma(\alpha)$$

The gamma function is defined to be that very integral, i.e., for $\alpha > 0$ (see section Differential and Integral Calculus page 1574):

$$\Gamma(\alpha) = \int\limits_0^{+\infty} u^{\alpha-1}e^{-u}\mathrm{d}u$$

It generally has no closed-form value, but there are some convenient facts that we have already proven during it's study:

$$\begin{aligned}\Gamma(\alpha+1) &= \alpha\Gamma(\alpha) \text{ for } \alpha > 0\\ \Gamma(n) &= (n-1)! \text{ for } n = 1, 2, \ldots;\\ \Gamma\left(\frac{1}{2}\right) &= \sqrt{\pi}\end{aligned}$$

The probability density function for a $\Gamma(\alpha, \lambda)$ is then:

$$f(x \mid \alpha, \lambda) = \frac{\lambda^\alpha}{\Gamma(\alpha)}x^{\alpha-1}e^{-\lambda x}, x \in (0, \infty)$$

If $\alpha = 1$, then we fall back on the "exponential distribution" (λ), with probability density function:

$$g(x \mid \lambda) = \lambda e^{-\lambda x}, x \in \mathcal{X} = [0, +\infty[$$

The MGF is:

$$M_X(t) = \mathrm{E}\left(e^{tX}\right) = \frac{\lambda^\alpha}{\Gamma(\alpha)}\int\limits_0^{+\infty} e^{tx}x^{\alpha-1}e^{-\lambda x}\mathrm{d}x = \frac{\lambda^\alpha}{\Gamma(\alpha)}\int\limits_0^{+\infty} x^{\alpha-1}e^{-(\lambda-t)x}\mathrm{d}x$$

That integral needs $(\lambda - t) > 0$ to be finite, so we need $t < \lambda$, which means the MGF is finite for a neighbourhood of zero, since $\lambda > 0$. Now the integral at the end of the previous relation is the same as that the one just earlier above:

$$\int\limits_0^{+\infty} x^{\alpha-1}\exp(-\lambda x)\mathrm{d}x$$

except that $\lambda - t$ is in place of λ. Thus we have:

$$\mathrm{E}\left(e^{tX}\right)=\frac{\lambda^\alpha}{\Gamma(\alpha)}\frac{\Gamma(\alpha)}{(\lambda-t)^\alpha}=\left(\frac{\lambda}{\lambda-t}\right)^\alpha, t<\lambda$$

We will use the cumulant generating function $c_X(t)=\log\left(M_X(t)\right)$ to obtain the mean and variance, because it is slightly easier. Thus:

$$c'_X(t)=\frac{\partial}{\partial t}\alpha(\log(\lambda)-\log(\lambda-t))=\frac{\alpha}{\lambda-t}\Longrightarrow \mathrm{E}(X)=c'_X(0)=\frac{\alpha}{\lambda}$$

and:

$$c''_X(t)=\frac{\partial^2}{\partial t^2}\alpha(\log(\lambda)-\log(\lambda-t))=\frac{\alpha}{(\lambda-t)^2}\Longrightarrow \mathrm{V}(X)=c''_X(0)=\frac{\alpha}{\lambda^2}$$

In general, the k^{th} cumulant is:

$$\gamma_k=\left.\frac{\partial^k}{\partial t^k}c_X(t)\right|_{t=0}=(k-1)!\frac{\alpha}{\lambda^k}$$

and in particular:

$$\begin{aligned}\text{Skewness }(X)&=\frac{2\alpha/\lambda^3}{\alpha^{3/2}/\lambda^3}=\frac{2}{\sqrt{\alpha}}\\ \text{Kurtosis }(X)&=\frac{6\alpha/\lambda^4}{\alpha^2/\lambda^4}=\frac{6}{\alpha}\end{aligned}$$

Thus the skewness and kurtosis depends on just the shape parameter α. Also, they are positive, but tend to 0 as α increases.

E3. Let us see now an example with the binomial distribution.

The Binomial is as we already know a model for counting the number of successes in n trials, e.g., the number of heads in ten flips of a coin, where the trials are independent and have the same probability p of success:

$$X=\mathcal{B}(n,p)\Longrightarrow f_X(x)=\begin{pmatrix}n\\x\end{pmatrix}p^x(1-p)^{n-x},\quad x\in\mathcal{X}=\{0,1,\ldots,n\}$$

The fact that the probability density function sums to 1 relies on the binomial theorem (see section Calculus page 1364):

$$(a+b)^n=\sum_{x=0}^{n}a^xb^{n-x}$$

with $a=p$ and $b=1-p$. This theorem also helps in finding the MGF:

$$\begin{aligned}M_X(t)=\mathrm{E}\left(e^{tX}\right)&=\sum_{x=0}^{n}e^{tx}f_X(x)=\sum_{x=0}^{n}e^{tx}\begin{pmatrix}n\\x\end{pmatrix}p^x(1-p)^{n-x}\\&=\sum_{x=0}^{n}\begin{pmatrix}n\\x\end{pmatrix}\left(pe^t\right)^x(1-p)^{n-x}=\left(pe^t+1-p\right)^n\end{aligned}$$

It is finite for all $t \in \mathbb{R}$, as is the case for any bounded random variable. The first two moments are:

$$\mathrm{E}(X)=M_X'(0)=n\left(pe^t+1-p\right)^{n-1}pe^t\Big|_{t=0}=np$$

and:

$$\begin{aligned}\mathrm{E}\left(X^2\right)=M_X''(0)&=\left[n(n-1)\left(pe^t+1-p\right)^{n-2}\left(pe^t\right)^2+n\left(pe^t+1-p\right)^{n-1}pe^t\right]\Big|_{t=0}\\&=n(n-1)p^2+np\end{aligned}$$

Thus:

$$\mathrm{V}(X)=\mathrm{E}\left(X^2\right)-\mathrm{E}(X)^2=n(n-1)p^2+np-(np)^2=np-np^2=np(1-p)$$

E4. Let us see now an example with the Poisson distribution.

$$\begin{aligned}M_X(t)=\mathrm{E}\left(e^{tX}\right)=\sum_{x=0}^{n}e^{tx}f_X(x)&=\sum_{x=0}^{+\infty}e^{tx}e^{-\lambda}\frac{1}{x!}\lambda^x\\&=e^{-\lambda}\sum_{x=0}^{+\infty}\frac{\left(\lambda e^t\right)^x}{x!}\\&=e^{-\lambda}e^{\lambda e^t}=e^{\lambda\left(e^t-1\right)}\end{aligned}$$

where:

$$e^{\lambda e^t}=\sum_{x=0}^{+\infty}\frac{\left(\lambda e^t\right)^x}{x!}$$

is the usual Taylor series expansion of the exponential function (see section Sequences and Series page 1703). Furthermore, since the series converges for any value of t, the moment generating function of a Poisson random variable exists for any $t \in \mathbb{R}$.

E5. Let us see now an example with the ex-Gaussian distribution (see section Statistics page 806).

Then, the moment generating function of X is:

$$M_X(t)=\left(\frac{\lambda}{\lambda-t}\right)\exp\left[\mu t+\frac{1}{2}\sigma^2t^2\right] \tag{5.7.1707}$$

Indeed, suppose X follows an ex-Gaussian distribution. Then, $X=A+B$ where A and B are independent A is normally distributed with mean μ and variance σ^2, and B is exponentially distributed with rate λ. We have already proven above that the moment generating function for A (Normal distribution) is given by:

$$M_A(t)=\exp\left[\mu t+\frac{1}{2}\sigma^2t^2\right] \tag{5.7.1708}$$

and we also have already proven the moment generating function for B (Poisson distribution) is given by:

$$M_B(t)=\frac{\lambda}{\lambda-t} \tag{5.7.1709}$$

By definition, X is a linear combination of independent random variables A and B, so the moment generating function of X is the product of $M_A(t)$ and $M_B(t)$. That is:

$$\begin{aligned}M_X(t) &= M_A(t)\cdot M_B(t)\\ &= \exp\left[\mu t+\frac{1}{2}\sigma^2t^2\right]\cdot\left(\frac{\lambda}{\lambda-t}\right)\\ &= \left(\frac{\lambda}{\lambda-t}\right)\exp\left[\mu t+\frac{1}{2}\sigma^2t^2\right]\end{aligned}\tag{5.7.1710}$$

Theorem 5.48. The limiting distribution of a Poisson (λ) distribution as $\lambda\rightarrow+\infty$ is Normal (this will be useful to us in the section of Quality Engineering).

Proof 5.48.1. Let $X_n\sim\text{Poisson}(n)$, for $n=1,2,\ldots$ The probability mass function of X_n is:

$$f_{X_n}(x)=\frac{n^xe^{-n}}{x!}\quad x=0,1,2,\ldots\tag{5.7.1711}$$

The moment generating function of X_n is as proved in the example just above:

$$M_{X_n}(t)=E\left[e^{tX_n}\right]=e^{n\left(e^t-1\right)}\tag{5.7.1712}$$

for $-\infty<t<+\infty$. Taking the limit gets us nowhere because:

$$\lim_{n\rightarrow+\infty}M_{X_n}(t)=\lim_{n\rightarrow\infty}e^{n\left(e^t-1\right)}=\infty\tag{5.7.1713}$$

So now consider a "standardized" Poisson random variable:

$$\frac{X_n-n}{\sqrt{n}}\tag{5.7.1714}$$

which has limiting moment generating function:

$$\begin{aligned}\lim_{n\rightarrow+\infty}M_{(X_n-n)/\sqrt{n}}(t) &= \lim_{n\rightarrow+\infty}\text{E}\left[\exp\left(t\cdot\frac{X_n-n}{\sqrt{n}}\right)\right]\\ &= \lim_{n\rightarrow+\infty}\exp(-t\sqrt{n})\text{E}\left[\exp\left(\frac{tX_n}{\sqrt{n}}\right)\right]\\ &= \lim_{n\rightarrow+\infty}\exp(-t\sqrt{n})\exp\left(n\left(e^{t/\sqrt{n}}-1\right)\right)\\ &= \lim_{n\rightarrow+\infty}\exp\left(-t\sqrt{n}+n\left(tn^{-1/2}+t^2n^{-1}/2+t^3n^{-3/2}/6+\cdots\right)\right)\\ &= \lim_{n\rightarrow+\infty}\exp\left(t^2/2+t^3n^{-1/2}/6+\cdots\right)\\ &= \exp\left(t^2/2\right)\qquad-\infty<t<+\infty\end{aligned}\tag{5.7.1715}$$

by using the moment generating function of a Poisson random variable and expanding the exponential function as a series. This can be recognized as the moment generating function of a standard Normal random variable! This implies that the associated unstandardized random variable X_n has a limiting distribution that is Normal with mean n and variance n. This result is the basis for the "normal approximation to the Poisson distribution"! In practice most people consider the approximation valid enough if $n>20$ (i.e. $\lambda>20$).

5.7.12 Central Limit Theorem

The central limit theorem is a set of results from the early 120th century (holocene calendar) on the weak convergence in probability of a sequence of random variables. Intuitively, from these results, any sum (implicitly: the average of these variable) of independent random variables identically distributed tends to some given random variable. The best known and most important result is simply named "central limit theorem" concerning a sum of independent random variables with existing variance whose number tends to infinity and it is this that we will prove heuristically here.

In the simplest case, considered below for the proof of the theorem, these variables are continuous, independent and have the same mean and the same variance. To try to get a finite result, we should center this sum by subtracting its average and reduce it by dividing it by its standard deviation. Under fairly broad conditions, the probability distribution (of the average) converges to a Normal centered reduced distribution. The ubiquity of the Normal distribution is explained by the fact that many considered random phenomena are due to the superposition of an infinity of many small causes.

This probability theorem has an interpretation in mathematical statistics. The latter associates a probability distribution to a population. Each element extracted from the population is considered as a random variable and by bringing together a number n of these supposed independent variables, we get a sample. The sum of these random variables divided by n gives a new variable named the "empirical mean". This, once reduced, tends to a Normal reduced variable as n approaches infinity as we know.

The central limit theorem tells us what we should expect in terms of sums of independent random variables. But what about the products? Well, the logarithm of a product (strictly positive factors) is the sum of logarithms of factors, so that the logarithm of a product of random variables (with strictly positive values) tends to a Normal distribution, resulting a log-Normal distribution for the product itself (see our study of the Log-Normal distribution earlier above).

In itself, the convergence to the Normal distribution ("asymptotic normality") of many random variables when their number tends to infinity only interests the mathematician. For the practitioner, it is worth stopping shortly before the limit: the sum of a large number of these variables is nearly Gaussian, which often provides a more usable approximation than the exact law.

Moving further away from theory, we can say that a good number of natural phenomena are due to the superposition of numerous causes, more or less independent. As a result, the Normal law represents them reasonably effectively.

Conversely, we can say that no concrete phenomenon is really Gaussian because it can not exceed certain limits, especially if its values are all positive (or all negative).

Proof 5.48.2. Given $\{X_i\}_{i=1...+\infty}$ a suite (sample) of continuous random variables (in our simplified proof...), independent (independent measures of physical or mechanical phenomena for example) and identically distributed, for which the average μ_X and standard deviation σ_X exist (this means that the central limit theorem works for finite variance phenomena only as far as we know!!!).

We saw earlier in this section (see page 940) that:

$$\boxed{Z_n=\frac{S_n-n\mu}{\sigma\sqrt{n}}=\frac{M_n-\mu}{\sigma/\sqrt{n}}=\frac{\textbf{signal}}{\text{estimated noise}}} \tag{5.7.1716}$$

are the same expressions of centered reduced variable generated using a sequence of n identically distributed random variables that by construction therefore has a zero mean and unit variance:

$$\mathrm{E}(Z_n)=0 \quad \text{and} \quad \mathrm{V}(Z_n)=1 \tag{5.7.1717}$$

Let us develop the first form of the prior-previous equality (the both are anyway equal!):

$$Z_n=\frac{1}{\sqrt{n}\sigma}\left[\sum_{i=1}^{n}(X_i-\mu)\right]=\frac{1}{\sqrt{n}\sigma}\left[\sum_{i=1}^{n}X_i-n\mu\right] \tag{5.7.1718}$$

Now using the characteristic function of the Normal centered-reduced distribution (we simplify at the same time the notations of the estimators of the average and standard deviation):

$$\phi_{Z_n}(\omega)=\mathrm{E}[e^{\mathrm{i}\omega Z_n}]=\mathrm{E}\left[\exp\left(\mathrm{i}\omega\frac{\sum_{i=1}^{n}(X_i-\mu)}{\sqrt{n}\sigma}\right)\right] \tag{5.7.1719}$$

As the random variables X_i are independent and identically distributed, we get:

$$\phi_{Z_n}(\omega)=\mathrm{E}\left[\exp\left(\mathrm{i}\omega\frac{X_1-\mu}{\sqrt{n}\sigma}\right)\right]\cdot\ldots\cdot\mathrm{E}\left[\exp\left(\mathrm{i}\omega\frac{X_n-\mu}{\sqrt{n}\sigma}\right)\right]=\left(\mathrm{E}\left[\exp\left(\mathrm{i}\omega\frac{X-\mu}{\sqrt{n}\sigma}\right)\right]\right)^n \tag{5.7.1720}$$

A Taylor expansion (see section Sequences and Series page 1696) of the term between braces gives at the third order (Maclaurin series expansion of the exponential):

$$\mathrm{E}\left[\exp\left(\mathrm{i}\omega\frac{X-\mu}{\sqrt{n}\sigma}\right)\right]\cong\mathrm{E}\left[1+\mathrm{i}\frac{\omega}{\sqrt{n}\sigma_{\bar{X}}}(X-\mu)-\frac{\omega^2}{n\sigma^2}(X-\mu)^2\right] \tag{5.7.1721}$$

Finally:

$$\begin{aligned}
\phi_{Z_n}(\omega)&\cong\left(\mathrm{E}\left[1+\mathrm{i}\frac{\omega}{\sqrt{n}\sigma}(X-\mu)-\frac{\omega^2}{n\sigma^2}(X-\mu)^2\right]\right)^n\\
&=\left[\int_{-\infty}^{+\infty}\left(1+\mathrm{i}\frac{\omega}{\sqrt{n}\sigma}(X-\mu)-\frac{\omega^2}{n\sigma_{\bar{X}}^2}(X-\mu)^2\right)f_X(x)\mathrm{d}x\right]^n\\
&=\left[\int_{-\infty}^{+\infty}f_X(x)\mathrm{d}x+\int_{-\infty}^{+\infty}\frac{\mathrm{i}X\omega}{\sqrt{n}\sigma}f_X(x)\mathrm{d}x-\int_{-\infty}^{+\infty}\frac{\mathrm{i}\mu\omega}{\sqrt{n}\sigma}f_X(x)\mathrm{d}x-\frac{\omega^2}{n\sigma^2}\int_{-\infty}^{+\infty}(X-\mu)^2f_X(x)\mathrm{d}x\right]^n\\
&=\left[1+\frac{\mathrm{i}\omega}{\sqrt{n}\sigma_{\bar{X}}}\int_{-\infty}^{+\infty}Xf_X(x)\mathrm{d}x-\frac{\mathrm{i}\mu\omega}{\sqrt{n}\sigma_{\bar{X}}}\int_{-\infty}^{+\infty}f_X(x)\mathrm{d}x-\frac{\omega^2}{n\sigma_{\bar{X}}^2}\int_{-\infty}^{+\infty}(X-\mu)^2f_X(x)\mathrm{d}x\right]^n\\
&=\left[1+\frac{\mathrm{i}\omega}{\sqrt{n}\sigma_{\bar{X}}}\mu-\frac{\mathrm{i}\mu\omega}{\sqrt{n}}-\frac{\omega^2}{n\sigma^2}\int_{-\infty}^{+\infty}(X-\mu)^2f_X(x)\mathrm{d}x\right]^n\\
&=\left[1-\frac{\omega^2}{n\sigma^2}\int_{-\infty}^{+\infty}(X-\mu)^2f_X(x)\mathrm{d}x\right]^n=\left[1-\frac{\omega^2}{n\sigma_{\bar{X}}^2}\mathrm{V}(X)\right]^n=\left[1-\frac{\omega^2}{2n}\right]^n
\end{aligned} \tag{5.7.1722}$$

Let us put:

$$-\frac{\omega^2}{2n}=\frac{1}{x} \tag{5.7.1723}$$

Then we have:

$$\phi_{Z_n}(\omega)\cong\left[1+\frac{1}{x}\right]^{-\frac{\omega^2 x}{2}}=\left[\left(1+\frac{1}{x}\right)^x\right]^{-\frac{\omega^2}{2}} \tag{5.7.1724}$$

So as x approaches infinity (see section Functional Analysis page 2226):

$$\boxed{\phi_{Z_n}(\omega)\cong\lim_{n\rightarrow+\infty}\left[\left(1+\frac{1}{x}\right)^x\right]^{-\frac{\omega^2}{2}}=\left[\lim_{n\rightarrow+\infty}\left(1+\frac{1}{x}\right)^x\right]^{-\frac{\omega^2}{2}}=e^{-\frac{\omega^2}{2}}} \tag{5.7.1725}$$

We find back the characteristic function of the reduced centered Normal distribution!

In two words, the Central Limit Theorem (CLT) said that for large samples, the centered and reduced sum of n random variables independent ad identically distributed follow a Normal centered and reduced distribution. And so we have verbatim to the empirical mean:

$$\frac{M_n-\mu}{\sigma/\sqrt{n}}=\mathcal{N}(0,1)\Leftrightarrow M_n=\mathcal{N}\left(\mu,\frac{\sigma}{\sqrt{n}}\right) \tag{5.7.1726}$$

Or more elegantly the CLT will be written:

$$\boxed{\sqrt{n}\left(\left(\frac{1}{n}\sum_{i=1}^{n}X_i\right)-\mu\right)\xrightarrow{d}\mathcal{N}\left(0,\sigma^2\right)} \tag{5.7.1727}$$

■ Q.E.D.

Caution! In facts there are three central limits theorem (CLT) nowadays... The "Lindeberg-Levy CLT" proven just above that isn't very useful because of the need for identically distributed variables. The "Lyapunov's and Lindeberg CLT" which is much more flexible relaxing the requirement of identically distributed variables at the cost of the necessity of higher moments like skewness and kurtosis to disappear sufficiently quickly (being just finite and quickly go towards zero). The "Gnedenko-Kolmogorov CLT" that is even better as it handles also heavy-tails (but there are also traps as many things in life are not as easy as they seem to...!).

Now we will illustrate the central limit theorem in the case of a sequence $\{X_i\}$ of discrete random variables following a Bernoulli distribution with parameter equal to $1/2$.

We can imagine that XN represents the result obtained in the n-th launch of a coin (assigning the number 1 for head and 0 for tail). Let us write:

$$\bar{X}_n=\frac{1}{n}\sum_{k=1}^{n}X_k \tag{5.7.1728}$$

the average. We obviously have for all n in this special case:

$$\mathrm{E}(X_n)=\frac{1}{2} \qquad \mathrm{V}(X_n)=\frac{1}{4} \tag{5.7.1729}$$

and therefore:

$$\mathrm{E}(\bar{X}_n)=\sum_{k=1}^{n}\frac{1}{2}=\frac{1}{2} \qquad \mathrm{V}(\bar{X}_n)=\frac{1}{n^2}\sum_{k=1}^{n}\frac{1}{4}=\frac{1}{4n} \tag{5.7.1730}$$

After having centered and reduced $\bar{X}_n$ we get:

$$\frac{\bar{X}_n-\mathrm{E}(\bar{X}_n)}{\sqrt{\mathrm{V}(\bar{X}_n)}}=2\sqrt{n}\left(\bar{X}_n-\frac{1}{2}\right) \tag{5.7.1731}$$

Let us note Φ as always the cumulative Normal reduced centered distribution.

The central limit theorem says that for any $t\in\mathbb{R}$:

$$\lim_{n\rightarrow+\infty}P\left(2\sqrt{n}\left(\bar{X}_n-\frac{1}{2}\right)\leq t\right)=\Phi(t) \tag{5.7.1732}$$

Using Maple™ 4.00b we have plot in blue some graphs of the function:

$$t\mapsto F_n(t)=P\left(2\sqrt{n}\left(\bar{X}_n-\frac{1}{2}\right)\leq t\right) \tag{5.7.1733}$$

for different values of n. We have Represented in red the function Φ.

For $n=1$:

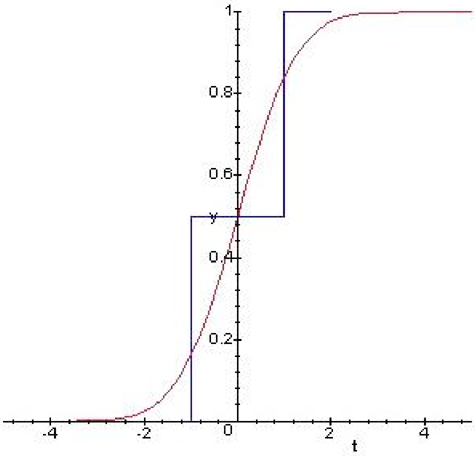


Figure 5.170: First approach of the Bernoulli distribution by the Normal distribution according to the CLT

For $n=2$:

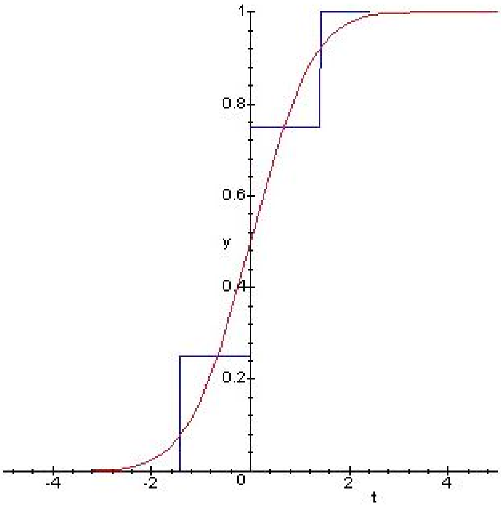

Figure 5.171: Second approach of the Bernoulli distribution by the Normal distribution according to the CLT

For $n = 5$:

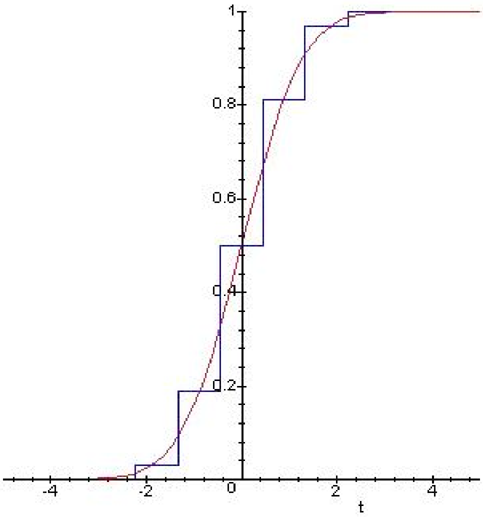

Figure 5.172: Fifth approach of the Bernoulli distribution by the Normal distribution according to the CLT

For $n = 30$:

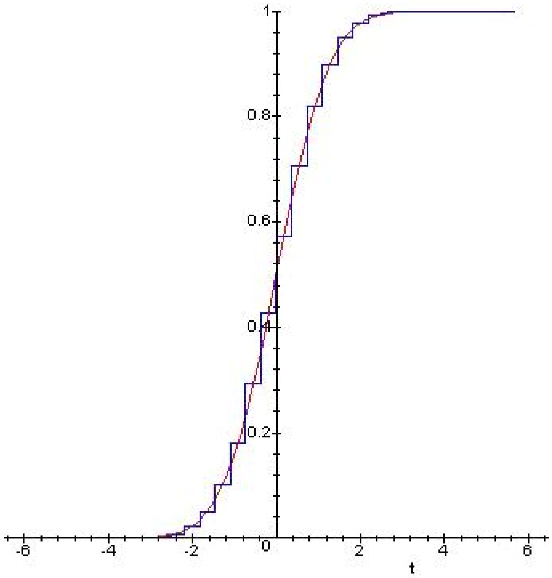

Figure 5.173: **Thirteenth approach of the Bernoulli distribution by the Normal distribution according to the CLT**

These graphs were obtained with Maple™ 4.00b using the following commands:

```
>with(stats):
>with(plots):
>e1:=plot(Heaviside(t+1)*statevalf[dcdf,binomiald[1,0.5]](trunc((t+1)/2))
,t=-2..2,y=0..1,color=blue):
>e2:=plot(Heaviside(t+sqrt(2))*statevalf[dcdf,binomiald[2,0.5]]
(trunc((t*sqrt(2)+2)/2)),t=-sqrt(2)-1..sqrt(2)+1,y=0..1,color=blue):
>e3:=plot(Heaviside(t+sqrt(5))*statevalf[dcdf,binomiald[5,0.5]]
(trunc((t*sqrt(5)+5)/2)),t=-sqrt(5)-1..sqrt(5)+1,y=0..1,color=blue):
>e4:=plot(statevalf[cdf,normald](t),t=-5..5):
>e5:=plot(Heaviside(t+sqrt(30))*statevalf[dcdf,binomiald[30,0.5]]
(trunc((t*sqrt(30)+30)/2)),t=-sqrt(30)-1..sqrt(30)+1,y=0..1,color=blue):
>display(e1,e4);
>display(e2,e4);
>display(e4,e3);
>display(e5,e4);
```

clearly show the convergence of F_n to Φ.

In fact we see that convergence is downright uniform which is confirmed by the "Moivre-Laplace central limit theorem":

Given X_n a sequence of independent random variables with the same Bernoulli parameter p, $0 < p < 1$. Therefore:

$$F_n(t) = P\left(2\sqrt{n}\left(\bar{X}_n - \frac{1}{2}\right) \leq t\right) = \Phi(t) \tag{5.7.1734}$$

tends uniformly to $\Phi(t)$ on $\mathbb{R}$ when $n \rightarrow +\infty$.

5.7.13 Univariate Hypothesis and Adequation Tests (NHST)

Definition (#5.7.142): A "statistical model" is a mathematical tool that embodies a set of statistical assumptions concerning the generation of sample data (and similar data from a larger population), often in considerably idealized form. It is usually specified as a mathematical relationship between one or more random variables and other non-random variables named "parameters". All statistical hypothesis tests and all statistical estimators are derived via statistical models!

During our study of confidence intervals, remember that we get the below few relations (it is only a sample of the most important one proved above!):

$$\bar{X}-Z_{\alpha/2}\frac{\sigma}{\sqrt{n}}\leq\mu\leq\bar{X}+Z_{\alpha/2}\frac{\sigma}{\sqrt{n}} \tag{5.7.1735}$$

and:

$$\frac{nS_*^2}{\chi^2_{\alpha/2}(n)}\leq\sigma^2\leq\frac{nS_*^2}{\chi^2_{1-\alpha/2}(n)} \tag{5.7.1736}$$

and:

$$\frac{(n-1)S^2}{\chi^2_{\alpha/2}(n-1)}\leq\sigma^2\leq\frac{(n-1)S^2}{\chi^2_{1-\alpha/2}(n-1)} \tag{5.7.1737}$$

and finally:

$$\bar{X}-\frac{S}{\sqrt{n}}T_{\alpha/2}(n-1)\leq\mu\leq\bar{X}+\frac{S}{\sqrt{n}}T_{\alpha/2}(n-1) \tag{5.7.1738}$$

that allowed to do statistical inference based on the knowledge or not of the true mean or variance of the whole or on a sample of the population. In other words, under in what range stood a given moment (mean or variance) as a function of the chosen confidence level α.

We will also prove in details later the following two intervals:

$$\frac{1}{F_{\alpha/2}(n,m)}\frac{S^2_{*X}}{S^2_{*Y}}\leq\frac{\sigma^2_X}{\sigma^2_Y}\leq\frac{1}{F_{1-\alpha/2}(n,m)}\frac{S^2_{*X}}{S^2_{*Y}} \tag{5.7.1739}$$

and:

$$\frac{1}{F_{\alpha/2}(n-1,m-1)}\frac{S^2_{X}}{S^2_{Y}}\leq\frac{\sigma^2_X}{\sigma^2_Y}\leq\frac{1}{F_{1-\alpha/2}(n-1,m-1)}\frac{S^2_{*X}}{S^2_{*Y}} \tag{5.7.1740}$$

These are only a few of the more than 500 parametric and non-parametric confidence intervals - and their respective tests - that exist at the beginning of the 121st century (for more see the Data Science mind map at page 6770)!!!

Definition (#5.7.143): When we want to know if we can trust the value of a statistic (mean, median, variance, correlation coefficient, etc.) with some certainty, we speak of "hypothesis testing" and especially of "conformity test" (we speak of "adequation test" when the purpose is to check that measures will follow a particular distribution law).

Formally, a statistical hypothesis is a statement about the parameters of a distribution describing a population from which observations can be sampled as measured data. More precisely, let m be a generative model describing measured data y in terms of a distribution $\mathcal{D}(\theta)$ with model parameters $\theta \in \Theta$. Then, a statistical hypothesis is formally specified as:

$$H : \theta \in \Theta^* \quad \text{where: } \Theta^* \subset \Theta \tag{5.7.1741}$$

Let H be a statistical hypothesis. Then:

- H is named a "point hypothesis" or "exact hypothesis", if it specifies an exact parameter value:

$$H : \theta = \theta^* \tag{5.7.1742}$$

- H is named a "set hypothesis" or "inexact hypothesis", if it specifies a set of possible values with more than one element for the parameter value (e.g. a range or an interval):

$$H : \theta \in \Theta^* \tag{5.7.1743}$$

The statement which is tested in a statistical hypothesis test is named the "null hypothesis", denoted as H_0. The test is designed to assess the strength of evidence against H_0 and possibly reject it. The opposite of H_0 is named the "alternative hypothesis". Usually, H_0 is a statement that a particular parameter is zero, that there is no effect of a particular treatment or that there is no difference between particular conditions. More precisely, let m be a generative model describing measured data y using model parameters $\theta \in \Theta$. Then, a null hypothesis is formally specified as:

$$H_0 : \theta \in \Theta_0 \quad \text{where: } \Theta_0 \subset \Theta \tag{5.7.1744}$$

Let H_0 be a null hypothesis of a statistical hypothesis test. Then, the corresponding alternative hypothesis, denoted as H_1, is either the negation of H_0 or an interesting sub-case in the negation of H_0, depending on context. The test is designed to assess the strength of evidence against H_0 and possibly reject it in favor of H_1. Usually, H_1 is a statement that a particular parameter is non-zero, that there is an effect of a particular treatment or that there is a difference between particular conditions.

More precisely, let m be a generative model describing measured data y using model parameters $\theta \in \Theta$. Then, null and alternative hypothesis are formally specified as:

$$\begin{aligned} H_0 &: \theta \in \Theta_0 \quad \text{where: } && \Theta_0 \subset \Theta \\ H_1 &: \theta \in \Theta_1 \quad \text{where: } && \Theta_1 = \Theta \setminus \Theta_0 \end{aligned} \tag{5.7.1745}$$

Remark

The reader must also remember, as already said earlier in this section, that we have put many other confidence interval techniques detailed proofs related for example for regression techniques in the section of Theoretical Computing.

Hypothesis testing are intended to check whether the sample can be considered as extracted from a given population or be representative of this population vis-a-vis of parameter such as a mean, variance or the observed frequency. This implies that the theoretical distribution of the parameter is known at the population level. The hypothesis tests are not made to prove the null hypothesis (usually expressing equality or uniformity between different populations), but to eventually reject it (to be exact the rejection of the null hypothesis is more robust). In terms of the communication of statistical tests a number of experts recommend:

1. To always communicate the p-value (see page 948) with four decimal places (we will come back later on this concept).
2. Never say that a low p-value shows a significant magnitude of the effect studied because it is not necessary true (to check you just take a phenomenon of very small amplitude on a large sample and then the p-value will become very small by construction). Once again will discuss this more deeply later.
3. To always give the confidence interval of the test whether it is unilateral or bilateral.
4. To be careful to not to set a rejection threshold to the test except if a standard (norm) or legislation requires it (in which case we will specify which one).
5. To never say that the test is "proved" or "significant" or even "statistically significant". Just say that the result is "statistical" or that we have the "likelihood of the data knowing the null hypothesis" and that's it (in bayesian terms: «*the likelihood of the data is not the credence of the model*»)!
6. If the interest is to show the null hypothesis and that it is not rejected, since often its statistical power is low, you will need to repeat the experience to reinforce the conclusion.
7. If the interest is to reject the null hypothesis and that this is true, a good scientific practice is to look for additional studies that would faulty conclusion.
8. If there is for example no statistical difference between two values, therefore this does not mean that there is presence of statistical equivalence. It is then necessary to proceed to "equivalence tests".
9. The rejection of the null hypothesis does not mean that the mechanism of the phenomenon has been highlighted but just indicates, for refresh, an information about the size of the dataset a posteriori.
10. We communicate the posteriori power of the test.

To summarize, the studies must be communicated respecting the principle of truthfulness, after having been the subject of appropriate controls, and must be exposed, described and presented with impartially (some people say "a-theoric"). We must not confuse between objectives and speculatives results! The conclusions should be the most faithful expression of the content of facts and datas.

The reader has to know that Null Hypothesis Significance Testing (NHST) is the result of the evolution of two hypothesis testing theories, i.e. the Fisher's approach to data testing and the Neyman-Pearson's approach tests of acceptance. The final procedure is the incongruent combination of the previous two theories into the current approach: NSHT. We may also consider that Bayesian Hypothesis Testing (BHT) is itself a kind (...) of evolution of NHST. All these four hypothesis testing theories (Fisher, Neyman-Pearson, NHST, BHT) are complementary and the scientist should avoid to use only one of them when doing analyzing an experiment outcome. As already mentioned at the beginning of the book, different analytical approach are or first importance to compare the results by minimizing the practitioner bias. For more details see [435].

For example, if we want to know with some confidence whether a given mean of a population sample is realistic about the true unknown theoretical mean we will use the "Z-test" which is simply:

$$\bar{X} - Z_{\alpha/2}\frac{\sigma}{\sqrt{n}} \leq \mu \leq \bar{X} + Z_{\alpha/2}\frac{\sigma}{\sqrt{n}} \tag{5.7.1746}$$

Now remember that we have proved that if we have two random variables of law:

$$\mathcal{N}(\mu_1,\sigma_1) \qquad \mathcal{N}(\mu_2,\sigma_2) \tag{5.7.1747}$$

then subtracting (differentiate) the averages gives:

$$\mathcal{N}\left(\mu_2-\mu_1,\sqrt{\sigma_1^2+\sigma_2^2}\right) \tag{5.7.1748}$$

So for the difference of two average of random variables from two independent population samples we obtain directly:

$$\mathcal{N}\left(\bar{X}_2-\bar{X}_1,\sqrt{\frac{\sigma_1^2}{n_1}+\frac{\sigma_2^2}{n_2}}\right) \tag{5.7.1749}$$

We can then adapt the Z-test as:

$$Z^{\text{calc}} = \frac{\bar{X}-\mu}{\sigma/\sqrt{n}} = \frac{\bar{X}-\mu}{\sqrt{\dfrac{\sigma^2}{n}}} = \frac{(\bar{X}_2-\bar{X}_1)-(\mu_2-\mu_1)}{\sqrt{\frac{\sigma_1^2}{n_1}+\frac{\sigma_2^2}{n_2}}} \tag{5.7.1750}$$

The relation that is very useful when for two samples of two populations, we want check if there is a statistically significant difference of the mean to a given fixed level of confidence level α and the associated probability for this difference:

$$\bar{X}_2-\bar{X}_1-Z\sqrt{\frac{\sigma_1^2}{n_1}+\frac{\sigma_2^2}{n_2}} \leqslant \mu_2-\mu_1 \leqslant \bar{X}_2-\bar{X}_1+Z\sqrt{\frac{\sigma_1^2}{n_1}+\frac{\sigma_2^2}{n_2}} \tag{5.7.1751}$$

Therefore:

$$|Z^{\text{calc}}| \leqslant |Z_{\alpha/2}| \tag{5.7.1752}$$

We then speak of "two-sample Z-test" and it is used lost in the industry to ensure the equality of two averages of two measurements of populations when standard deviation is known.

And if the theoretical standard deviation is not known, we use the "Student T-test" (used a lot in pharmacoeconomics) proved above:

$$\bar{X}-\frac{S}{\sqrt{n}}T_{\alpha/2}(n-1)\leq\mu\leq\bar{X}+\frac{S}{\sqrt{n}}T_{\alpha/2}(n-1) \tag{5.7.1753}$$

In the same idea for standard deviation, we use the "Chi-square variance test" as already proved above:

$$\frac{(n-1)S^2}{\chi^2_{\alpha/2}(n-1)}\leq\sigma^2\leq\frac{(n-1)S^2}{\chi^2_{1-\alpha/2}(n-1)} \tag{5.7.1754}$$

And when we want to test for the equality of variance of two populations we use "Fisher F-test" (that will be proved below during our study of the analysis of variance):

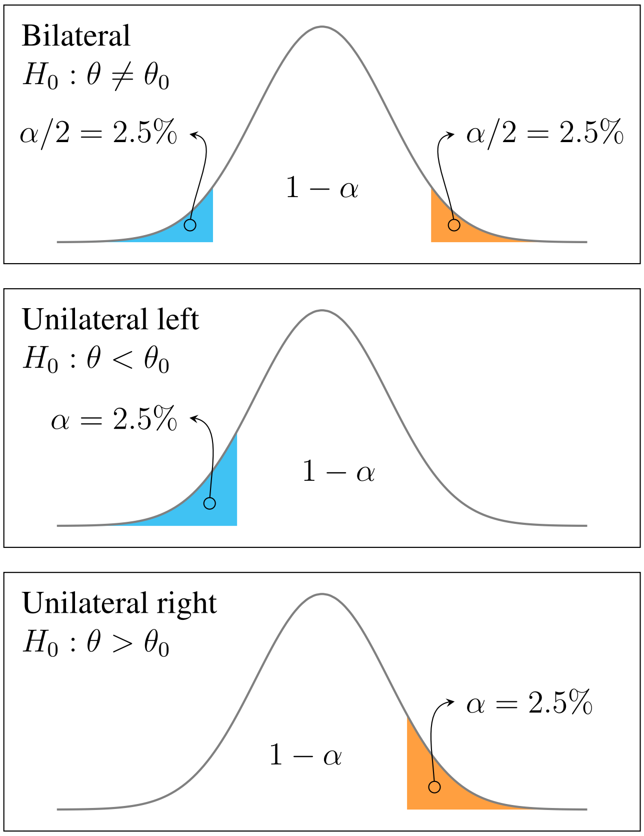
$$\frac{1}{F_{\alpha/2}(n-1,m-1)}\frac{S_X^2}{S_Y^2}\leq\frac{\sigma_X^2}{\sigma_Y^2}\leq\frac{1}{F_{1-\alpha/2}(n-1,m-1)}\frac{S_{*X}^2}{S_{*Y}^2} \tag{5.7.1755}$$

In practice we must be aware that the purpose of a test is very often to show that the effect is significant. It is then customary to say that the test is successful if the null hypothesis is rejected in favour of the alternative hypothesis! When the practitioner knows that the effect is significant and his test fails to reject the null hypothesis H_0 this is sometimes named the "dilemma of not rejecting the null hypothesis". As we will see a little further, the idea is then to calculate an "a posteriori test power" (it is then named by some softwares like SPSS, "observed power") and adapt the sample size accordingly to have an acceptable power according to tradition.

5.7.13.1 Direction of hypothesis tests and p-values

The fact that we get all values satisfying a right bounded test AND (!) left bounded is what we name in the general case a "two-tailed test" as it includes the left sided and right sided unilateral tests. Thus, all the above tests are in a bilateral form, but we could make a unilateral use too! We use one-tailed test when the expected difference (or difference to highlight) can only go in one direction (typically in the case of clinical trials or during a corrective quality action in the industry for which we expect a improvement going in one single direction). Unilateral tests are sometimes named "non-inferiority tests" (left-sided) or "non-superiority test" (right-sided).

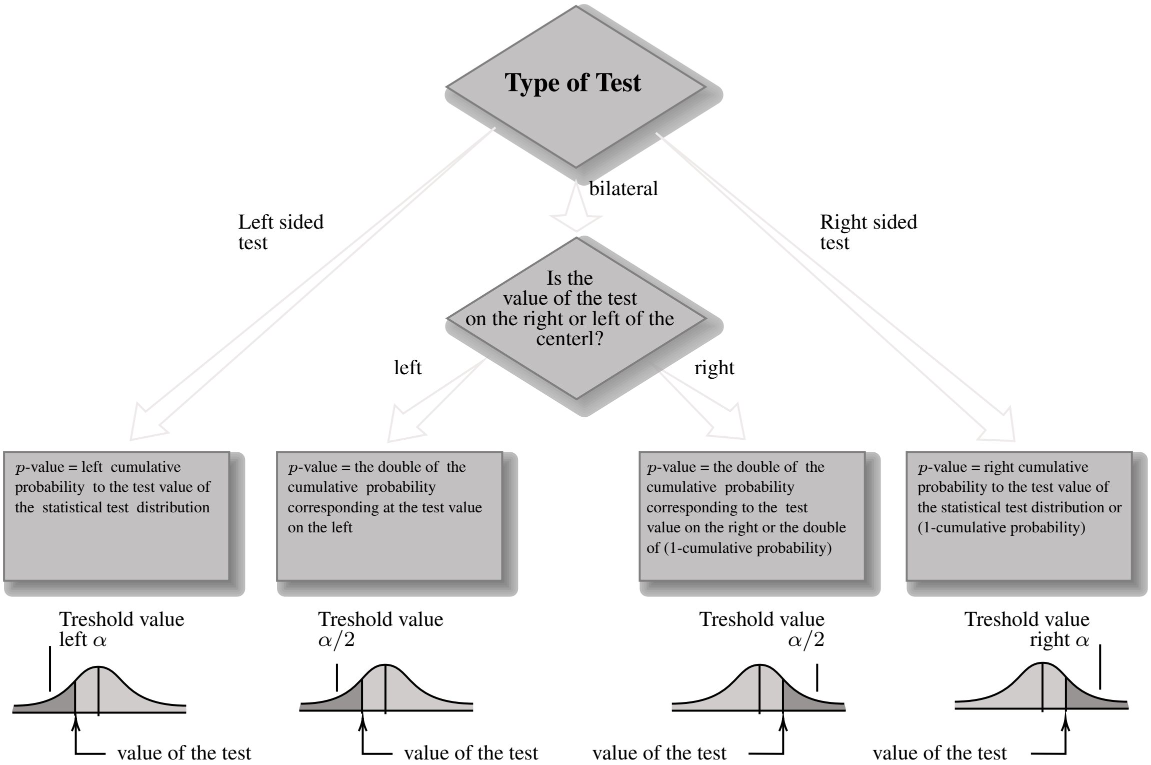
Below we presented for example a right unilateral test (since the rejection region is on the right and therefore the cumulative probability is left-sided) and a two-sided test of 5% (since the beginning of the 121st century (holocene calendar), more and more practitioners recommend to take a value of 1%):



Bilateral
$H_0 : \theta \neq \theta_0$
$\alpha/2 = 2.5\%$
$\alpha/2 = 2.5\%$
$1-\alpha$
Unilateral left
$H_0 : \theta < \theta_0$
$\alpha = 2.5\%$
$1-\alpha$
Unilateral right
$H_0 : \theta > \theta_0$
$\alpha = 2.5\%$
$1-\alpha$

Figure 5.174: **Illustration of a test (or confidence level) unilateral and bilateral (author: Walmes Zeviani)**

We can also summarize how to determine the p-value (which will be discussed more in detail further below) with the following diagram:



Type of Test
bilateral
Left sided test
Right sided test
Is the value of the test on the right or left of the centerl?
left
right
p-value = left cumulative probability to the test value of the statistical test distribution
p-value = the double of the cumulative probability corresponding at the test value on the left
p-value = the double of the cumulative probability corresponding to the test value on the right or the double of (1-cumulative probability)
p-value = right cumulative probability to the test value of the statistical test distribution or (1-cumulative probability)
Treshold value left α
Treshold value $\alpha/2$
Treshold value $\alpha/2$
Treshold value right α
value of the test
value of the test
value of the test
value of the test

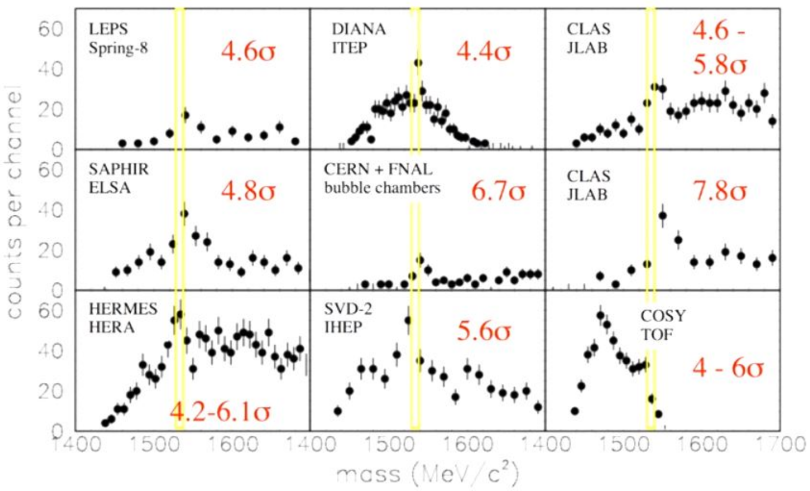
Figure 5.175: Summary figure to determine the p-value of parametrical test with symmetrical distributions

Definition (#5.7.144): The "p-value" is the likelihood of obtaining an effect at least as extreme as the one in your sample data, assuming the truth of the null hypothesis. In other words, if the null hypothesis is true, the p-value is the probability of obtaining your sample data. It answers the question, are your sample data unusual if the null hypothesis is true? If you are thinking that the p-value is the probability that the null hypothesis is true, the probability that you are making a mistake if you reject the null, or anything else along these lines, this is the most common misunderstanding of practitioners.

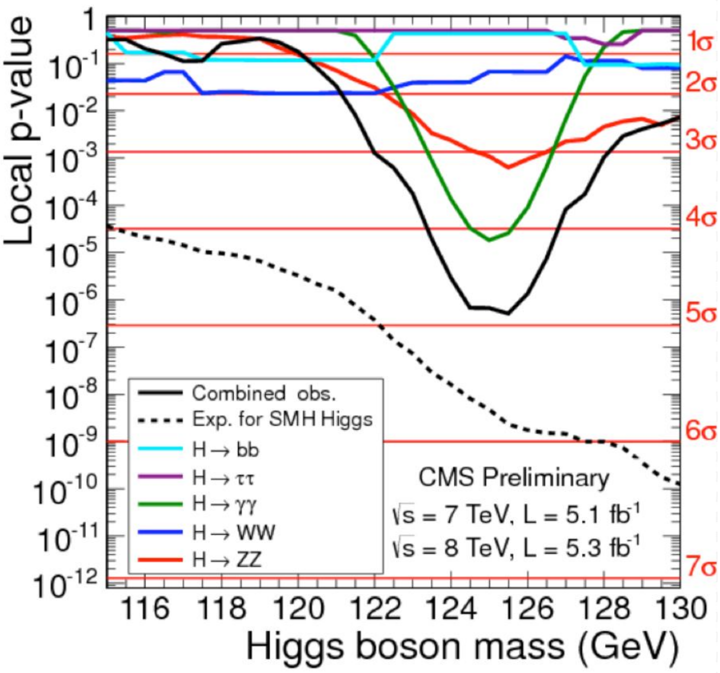
Remark

As the American Statistical Association - ASA wrote in its 12016 (holocene calendar) statement (see `https://www.tandfonline.com/doi/full/10.1080/00031305.2016.1154108`): «*p-values do not measure the probability that the studied hypothesis is true, or the probability that the data were produced by random chance alone.*» Instead if we are looking for a non-technical description, the ASA offers this statement: «*p-values can indicate how incompatible the data are with a specified statistical model.*»

As already mentioned, the p-value is often considered as significant if it is less than 5% or even better when... below 1%. In particle physics, according to the Gauss distribution (for which it is easy to convert percentages into standard deviation as we already know!), the p-value is often communicated in σ as shown in the random example below of pentaquark discovery studies in 12003 (holocene calendar):



or another random (well-known random...) example is that of the Higgs Boson confirmation discovery at the LHC/CERN in 12012[51] (holocene calendar):



The common misconception is what we'd really like to know. We would loooove to know the probability that a hypothesis is correct, or the probability that we're making a mistake. What we get instead with these frequentist methods is the probability of our observation given the null hypothesis, which just isn't as useful.

It would be great if we could take evidence solely from a sample and determine the probability that the sample is wrong. Unfortunately, that seems not possible with the frequentist methods and this for logical reasons when you think about it. Without outside information, a sample can't tell you whether it's representative of the population.

---

[51] The standard of certainty that particle physicists require at the beginning of the 121st century (holocene calendar) for a discovery is roughly 1 in 3.5 million, i.e. 5σ.

Sigma (unilateral Normal Law)/ Z	p-value	Field

5	99.9999427%	Used in particle physics

Table 5.52: **Conversion sigma to p-value in bilateral**

The p-values are based exclusively on information contained within a sample. Consequently, p-values can't answer the question that we most want answered, but there seems to be an irresistible temptation towards interpreting it that way.

Let us also note that the hypothesis tests on the standard deviation (variance), the mean or correlation are named "parametric tests" in reverse of the nonparametric tests that we will see much further below.

Remarks

R1. There is also another definition of the concept of parametric and nonparametric tests that we will see further below (a bit different because more precise).

R2. Warning! Some authors or teachers sometimes talk about "left-sided" for a "right-sided test"... In fact it is simply a choice of vocabulary. If the reference of teaching is not the rejection area but the acceptance area, then it is clear that the right and left are concepts that are reversed...

Finally, many software calculate what we name therefore the "p-value" which is the limit calculated risk (probability threshold) α that might have set the statistician to be at the border between acceptance of the null hypothesis and its rejection (remember that a successful test does not prove anything and a rejection is better but still do not prove anything!). So the p-value is a fundamental value in statistics because it gives the possibility to quantify the likelihood of the null hypothesis H_0 (acceptance or rejection).

Definition (#5.7.145): But strictly speaking the "p-value" is the conditional (Bayesian) probability, that our data satisfy the null hypothesis (that H_0 is true[52]), i.e. the likelihood of results:

$$\boxed{p\text{-value}=P(\text{data}|H_0)} \tag{5.7.1756}$$

and (sadly...) not the probability of the null hypothesis knowing the data (plausibility of H_0, i.e. $P(H_0|\text{data})$)!:

$$p\text{-value}\neq P(H_0|\text{data}) \tag{5.7.1757}$$

While the difference may be small as we saw in the section Probabilities, it is not zero! So in reality the p-value says nothing about the hypothesis itself, but it provides information on the experimental data if the experiment is conducted infinite number of times and all relevant assumptions hold! So as a p-value simply gives information only in the case we would repeat the experiment a large number of times we understand better why p-values are often decried in single experiment studies...

As Ronald Fisher famously said: «*A scientific fact should be regarded as experimentally established only if a properly designed experiment rarely fails to give this level of significance*». What this means is p-value less than 0.05 (or as applicable) only tells you that one should repeat the experiment!

It is true that the smaller the p-value, the more unusual the data would be if every single assumption were correct; but a very small p-value does not tell us which assumption is incorrect. For example, the p-value may be very small because the targeted hypothesis is false; but it may instead (or in addition) be very small because the study protocols were violated, or because it was selected for presentation based on its small size. Conversely, a large p-value indicates only that the data are not unusual under the model, but does not imply that the model or any aspect of it (such as the targeted hypothesis) is correct; it may instead (or in addition) be large because (again) the study protocols were violated, or because it was selected for presentation based on its large size!

The general definition of a p-value may help one to understand why statistical tests tell us much less than what many think they do: Not only does a p-value not tell us whether the hypothesis targeted for testing is true or not; it says nothing specifically related to that hypothesis unless we can be completely assured that every other assumption used for its computation is correct, an assurance that is lacking in far too many studies.

Especially keep in mind (because we have a natural cognitive bias about this...) that in general:

$$P(\text{data}|H_0)\neq P(H_0|\text{data}) \tag{5.7.1758}$$

But these two probabilities (likelihood on the left and plausibility on the right) are however linked by the Bayes theorem (see section Probabilities page 492):

$$P(H_0|\text{data})=\frac{P(\text{data}|H_0)P(H_0)}{P(\text{data})} \tag{5.7.1759}$$

---

[52] Equivalently we can say that it is the conditional probability of obtaining data as extreme as the one that was actually observed, assuming that the null hypothesis is true! Another nice way to describe, it is to say that the p-value is the proportion of times that you would see evidence stronger than what was observed, against the null hypothesis, if the null hypothesis were true and you hypothetically repeated the experiment (sampling of individuals from a population) a large number of times!

But the both terms $P(H_0)$ (prior probability of the observed phenomenon) and $P(\text{data})$ are in practice difficult or even impossible to know.

For hypothesis testing, for example, the 5% risk threshold α is the risk to reject the null hypothesis H_0 even though it is true. If the risk imposed/chosen is 5% and the calculated p-value is less (in most tests but be careful because this is not a generality!!!), the test fails (rejection of the null hypotheses) in favour of an alternative hypothesis denoted by H_1 or H_a. Never forget that reject the test is always better in term of power than accepting it. In other words we can say that the p-value is the smallest α at which we would reject H_0.

In a paper published the March 7, 12016 (holocene calendar) by the American Statistical Association we have a list of principles to improve the conduct and interpretation of quantitative science relatively to the usage of the p-value! The statement's six principles, many of which address misconceptions and misuse of the p- value, are the following:

1. p-values can indicate how incompatible the data are with a specified statistical model.
2. p-values do not measure the probability that the studied hypothesis is true, or the probability that the data were produced by random chance alone.
3. Scientific conclusions and business or policy decisions should not be based only on whether a p-value passes a specific threshold.
4. Proper inference requires full reporting and transparency.
5. A p-value, or statistical significance, does not measure the size of an effect or the importance of a result.
6. By itself, a p-value does not provide a good measure of evidence regarding a model or hypothesis.

The alternative hypothesis H_1 has of course itself its own risk that we denote by β and its own p-value. So when the null hypothesis is not rejected, the risk associated with this decision is a "risk of the second kind". To assess this, we should calculate the power of the test considered (see proofs further below).

Perhaps, to better understand, here is an illustration of a particular case of an bilateral hypothesis test of the average for a typical random variable following a Normal distribution (basically it's almost the same principle for all tests...):

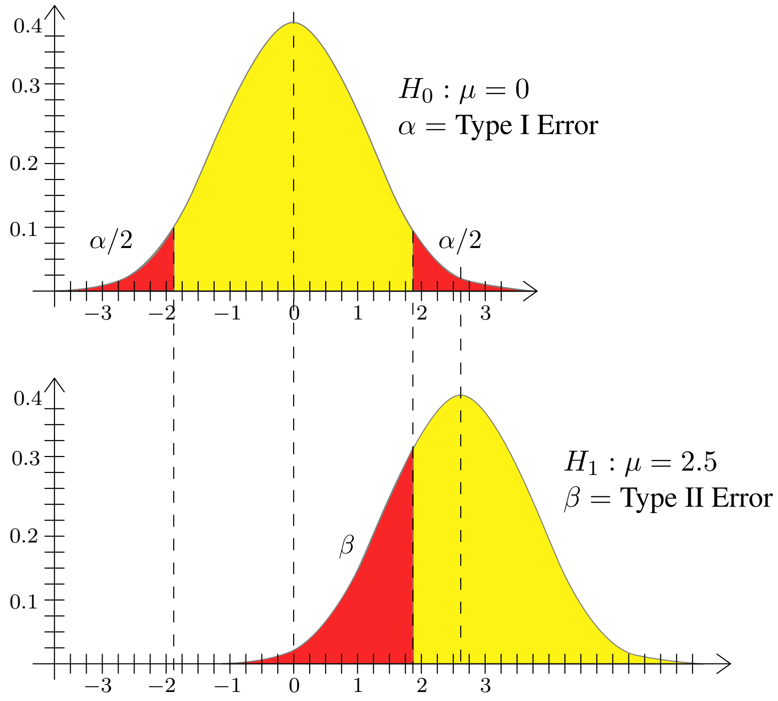

Figure 5.176: Null and alternative hypothesis of a special case of two-sided test

Thus, in the case presented above, we see better why the null hypothesis can be accepted or rejected in favour of the alternative hypothesis (which is of the same law that the null hypothesis but just shifted) depending on the reference value measured that will be used for the test (in the special case of the above figure it is the arithmetic mean of measurements).

We also note that the red area of the alternative hypothesis, corresponding to the cumulated probability β, is partially merged with the yellow part of the null hypothesis. This is why we can sometimes accept the null hypothesis wrongly. However, we see that smaller is β, more the alternative hypothesis would be far from the red boundary zone of the null hypothesis (this would correspond to a translation to the right in this case) and less the likelihood of a false conclusion is big. This is why we talk about "risk β" because smaller it is, the better. Verbatim more $1-\beta$ is big, then smaller is the risk of confusing the null and alternative hypothesis. This is why $1-\beta$ is named "power of the test" (see below the subsection that is devoted to this concept).

We (sadly) do not reject the null hypothesis if the p-value is by tradition greater than 5% (0.05). In fact, bigger is the p-value, the better it is because for the people interested in the null hypothesis because the confidence interval is becoming smaller. If the confidence interval is becoming huge (very close to 100%) because the p-value is very small then the analysis does not really make sense physically speaking anymore in the point of view of the null hypothesis!

Thus, if the p-value is small, that mean we should take a low risk α of error, therefore accept (i.e. do not reject) in almost all cases the tested hypothesis (H_0)...

Remarks

R1. We should never say that we "accept" a hypothesis or that it is "true" or "false" as these terms are too strong and might suggest a scientific proof. We should say if we "reject" or "does not reject" the null hypothesis and it may be possibly "correct" or "incorrect".

R2. For bilateral test hypotheses, we can for example say that we have (or not have) a significant difference between the measured reference value and the expected value. For one-sided tailed, we can say that the measured reference value is significantly bigger or smaller than the expected value.

R3. Moreover if the reader has well understand the construction of hypothesis testing, the fact of wrongly reject a hypothesis ("Type I error" or "Error of the first kind") is more robust than accept it wrongly ("Type II error" or "Error of the second kind").

R4. The reader will also have noticed with the help of the previous figure that a one sided test has a higher power than a one-sided test (for a same risk threshold of course!). Thus, a statistically insignificant difference in bilateral test, can be statistically significant in a one sided test.

R5. If the p-value is close to the limit threshold (rejection) value we say that the "effect is marginally significant".

A big issue with hypothesis testing[53] is what we name "p-hacking": the underlying idea consists of replicating a test dozens of times until it provides the conclusion that the experimenter wants... or try all possible combinations of variables until we found something significant or even just take big samples (as we know that NHST tests fail systemically when samples are big).

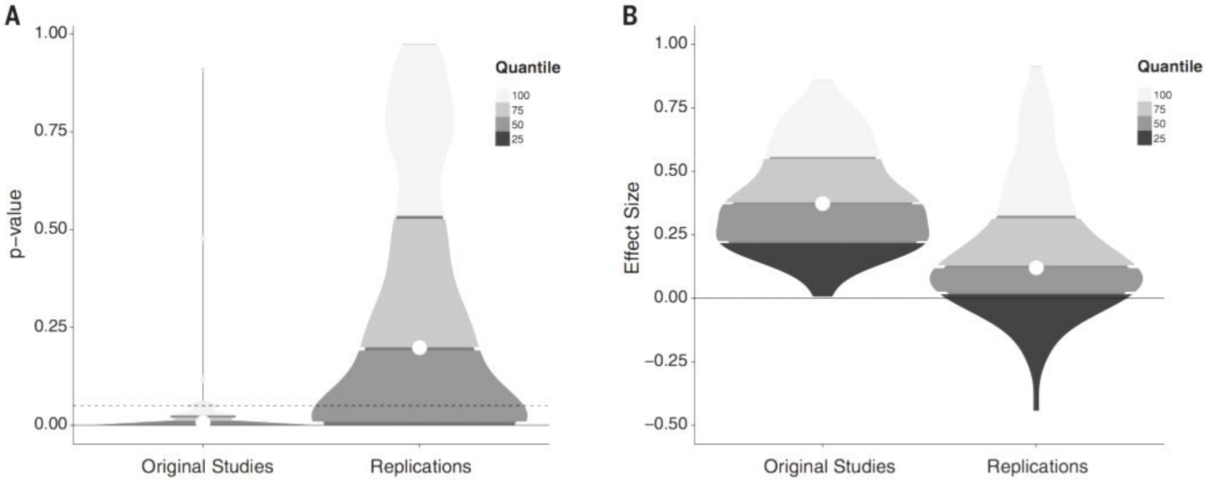

Figure 5.177: p-hacking Open Science Collaboration, *Estimating the reproducibility of physiological science*, Science, 349 (12015)

p-hacking is generally thought of as cheating, but what if we made it compulsory instead? If the purpose of studies is to push the frontiers of knowledge, then perhaps playing around with different methods shouldn't be thought of as a dirty trick, but encouraged as a way of exploring boundaries. A recent project spearheaded by Brian Nosek, a founder of the non-profit Center for Open Science, offered a clever way to do this.

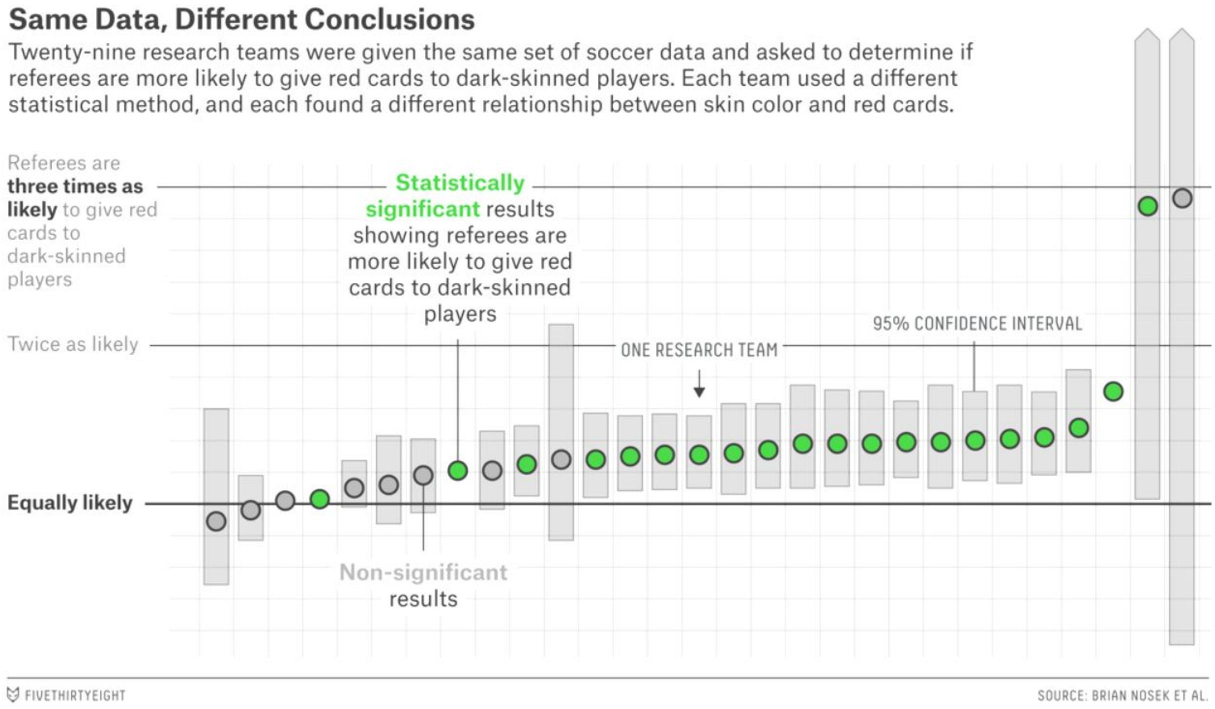
---

[53] A second one is the "significance filter curse" quite well documented in [602].

Nosek's team invited researchers to take part in a crowd-sourcing data analysis project. The setup was simple. Participants were all given the same data set and prompt: Do soccer referees give more red cards to dark-skinned players than light-skinned ones? They were then asked to submit their analytical approach for feedback from other teams before diving into the analysis.

Twenty-nine teams with a total of 61 analysts took part. The researchers used a wide variety of methods, ranging - for those of you interested in the methodological gore - from simple linear regression techniques to complex multilevel regressions and Bayesian approaches. They also made different decisions about which secondary variables to use in their analyses.

Despite analysing the same data, the researchers got a variety of results. Twenty teams concluded that soccer referees gave more red cards to dark-skinned players, and nine teams found no significant relationship between skin color and red cards.



Same Data, Different Conclusions

Twenty-nine research teams were given the same set of soccer data and asked to determine if referees are more likely to give red cards to dark-skinned players. Each team used a different statistical method, and each found a different relationship between skin color and red cards.

SOURCE: BRIAN NOSEK ET AL.

The variability in results wasn't due to fraud or sloppy work. These people are assumed to be highly competent analysts who were motivated to find the evidence, said Eric Luis Uhlmann, a psychologist at the Insead business school in Singapore and one of the project leaders. Even the most skilled researchers must make subjective choices that have a huge impact on the result they find.

But these disparate results don't mean that studies can't inch us toward strong evidence. The important lesson here is that a single analysis is not sufficient to find a definitive answer.

However generally the reader must keep in mind that if there are multiple statistical tests that apply for exactly the same thing and work differently (quite common in statistics like the multiple homogeneity of variance tests, the multiple normality tests, the multiple unit root tests, the multiple stationarity tests, etc.), then a single significant result leads to rejection!

Caution! Furthermore statistical significance has literally zero connection with "practical significance" also named "scientific importance" or "relevance". It will never tell you if something is important or not! Indeed, it's not an indicator knowing the context! That a null hypothesis is rejected or not only means that the hypothesis test has not met the pre-set significance level α and not that the results are significant or not significant for practical applications (they very likely are to the scientist spending nights in the lab collecting the data)! The test statistics typically just looks at the effect (difference, ratio, covariance, etc) and the variance. In other words, it just looks if the signal is visible enough on the background of the noise. It takes the current condition - sample size - into consideration. More data means that smaller effects will be indicated as statistically significant.

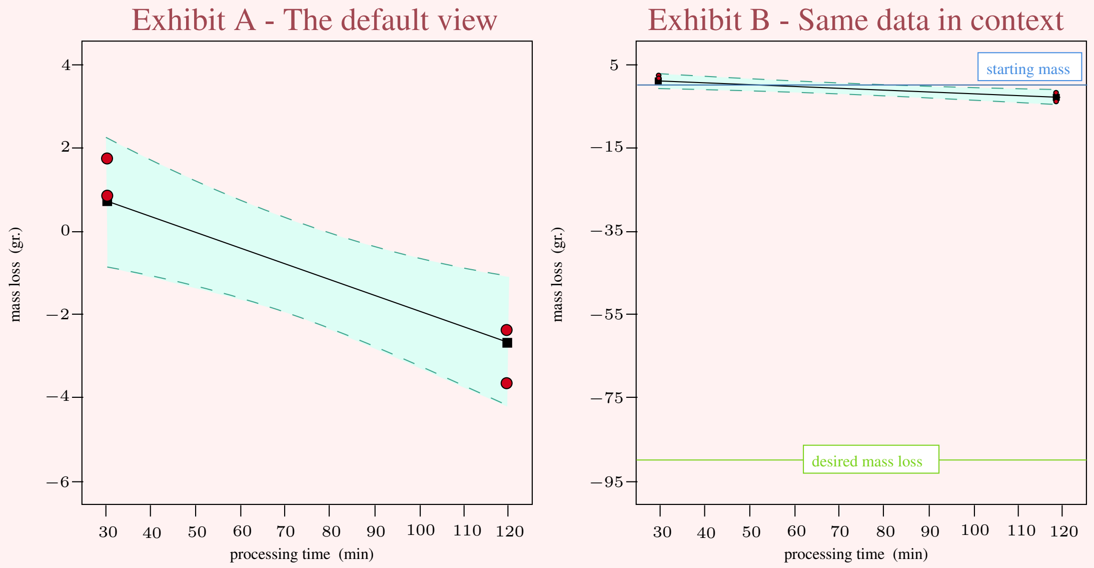


Exhibit A - The default view
Exhibit B - Same data in context

Figure 5.178: High statistical significance which contextualized has low practical significance (source: Danish Technological Institute)

To decide whether something is practically significant, we need the minimal meaningful difference threshold! It doesn't come from some "blind" mathematical procedure, ignoring the context, but rather from the domain knowledge: experts, literature review, your experience, pilot studies, etc. In medicine we name it MCID for "minimum clinically important difference". And we can embed it into statistical hypothesis testing via interval hypothesis, like in non-inferiority, superiority or equivalence clinical studies.

> *Evidence based medicine has taken centuries to advance humans to the point where people are so healthy and living so long that they can deny that science, statistics and medicine is what got us here.*

quote 5.7:958.#48

Keep in mind that as we said in the introduction: What makes science so powerful is that it's self-correcting. Sure, false findings get published, but eventually new studies come along to overturn them, and new evidence is revealed. At least, that's how it's supposed to work. But scientific publishing doesn't have a great track record when it comes to self-correction, but this is changing with new technologies that facilitates such tracking with computer databases.

So the scientific method is still a posteriori far away the most reliable method (less worst) that any other way of knowing that we have TODAY (but it's not an argument however to not try to find a better one)!

Remark

By the way... the reader can try to remember an adage named after economist Charles Goodhart, which has been phrased by Marilyn Strathern as: «*When a measure becomes a target, it ceases to be a good measure.*» But the original formulation was: «*Any observed statistical regularity will tend to collapse once pressure is placed upon it for control purposes.*»

Definitions (#5.7.146):

D1. The "probability α of Type I error" (error of the first kind / false negative[54]) is the probability of rejecting the null hypothesis when in reality it is likely to be true[55]. In statistics, the "size of a test" is the probability of falsely rejecting the null hypothesis. That is, it is the probability of making a type I error. It is denoted by the Greek letter α (alpha). For a simple null hypothesis, the size is determined by the following conditional probability:

$$P\left(\text{ test rejects } H_0 \mid H_0\right) \tag{5.7.1760}$$

D2. The "probability β of Type II error" (error of the second kind / false positive) is the probability of maintaining the null hypothesis when it is likely to be false. Since, by definition, power is equal to $1-\beta$, the power of a test will get smaller as beta gets bigger. The "power of a test" is the probability of rejecting H_0, given that H_1 is actually true. That is, for given null and alternative hypothesis, the power is determined by the following conditional probability:

$$P\left(\text{ test doesn't reject } H_0 \mid H_1\right) \tag{5.7.1761}$$

	State of Nature	
Test outcome	H_0 **false**	H_0 **true**
Reject H_0	Correctly rejected null hypothesis ($1-\beta$: power of the test)	Type I Error (false negative) (Risk α)
Fail to reject H_0	Type II Error (false positive) (Risk β)	Correctly accepted null hypothesis ($1-\alpha$: confidence level)

---

[54] Notice that depending on the point of view of the scientist, a "false negative" can be named "false positive", this is why many textbooks avoid using this specific vocabulary!

[55] Please keep in mind that as already mentioned in the introduction of this textbook, we are speaking here not about the "philosophical truth", but the "truth" as the best explanation at our actual level of knowledge!!!

Or in a more mathematical form:

	State of Nature	
Test outcome	H_0 **false**	H_0 **true**
Reject H_0	Correctly rejected null hypothesis $P(\text{reject } H_0 \vert H_0 \text{ is false}) = 1-\beta$	Type I Error (false negative) $P(\text{reject } H_0 \vert H_0 \text{ is true}) = \alpha$
Fail to reject H_0	Type II Error (false positive) $P(\text{fail reject } H_0 \vert H_0 \text{ is false}) = \beta$	Correctly accepted null hypothesis $P(\text{fail reject } H_0 \vert H_0 \text{ is true}) = 1-\alpha$

Thus a traditional criteria selection is to use the following principle: among all the tests that have the same size of Type I error, choose one that has the smallest size of the value of the Type II error.

Thus, it can be said that a hypothesis test simply has for purpose to minimize α the error of Type I and, on the contrary, to maximize $1-\beta$, the power of the test.

In general, the magnitude of the Type II error increases when that of the Type I error decreases. We can not, as far as we know, minimize the two errors at the same time. For this reason, we often take a fixed value of α, size of the type I error, and we minimize β, magnitude of the Type II error (i.e. we increase the power $1-\beta$).

Remark

In 12017 (holocene calendar) the false negative rate in the general U.S.A. population for HIV test is around 0.003%, or three times out of every $100,000$ tests.

False positive rates are far lower, between 0.0004% and 0.0007% due to the practice by which the initial positive result is confirmed with a secondary test.

Other example, false negatives occur in 1 of every $2,500$ women screened (NHS Breast Screening Programme – *Helping you decide* leaflet of July 12013 according to holocene calendar) and occur more often in younger women than in older women because the breast tissue of younger women is denser.

To close this subject, here are the three types of situations testing hypotheses on the statistics that is the average in the framework of an underlying Normal distribution and whose mean is in this particular case zero and of unit variance (because we can often come back to this particular case by centering and reducing the underlying random variable or by doing special transformations):

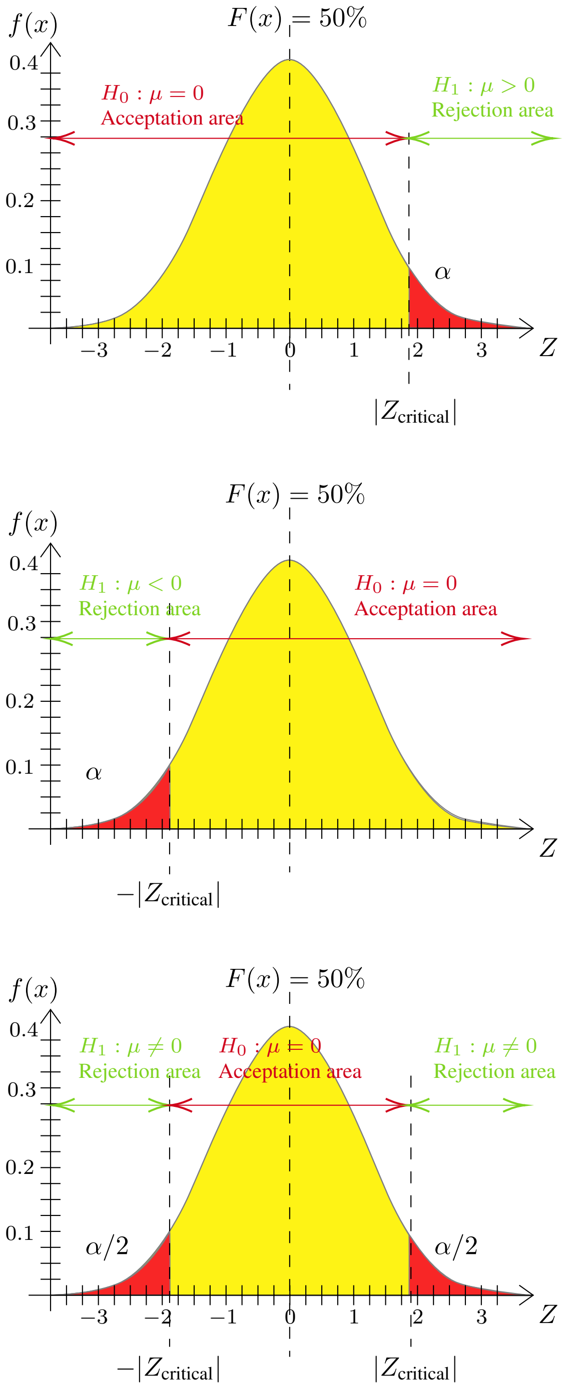

Figure 5.179: **The three possible scenarios for a hypothesis test on the average**

Let us indicate that it makes no sense (as opposed to what we can sometimes read in some paper or electronic media) to have the following null hypotheses in the special case shown above:

$$\begin{gathered} H_0 : \mu \leq 0 \\ H_0 : \mu \geq 0 \\ H_0 : \mu \neq 0 \end{gathered} \tag{5.7.1762}$$

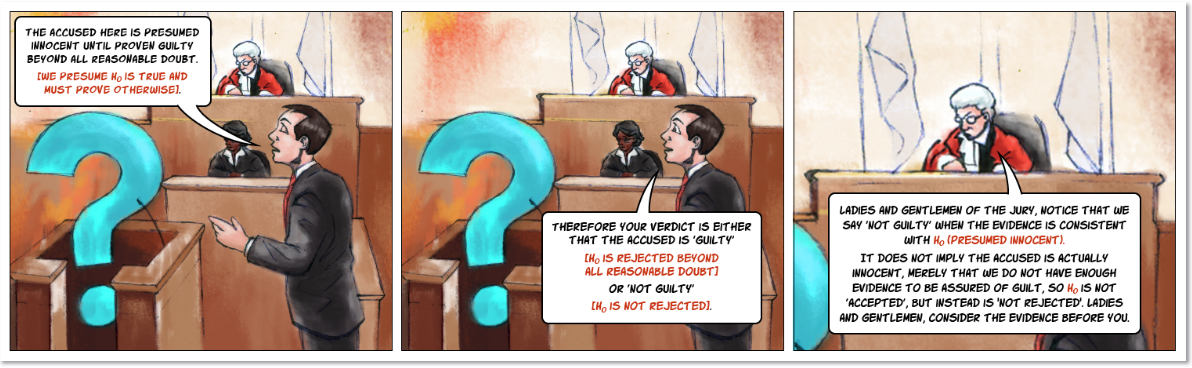
with the alternative hypothesis that automatically follows (we did not write it because it is useless and obvious). The reason is simple: how could you position your reduced centered

Normal distribution if the mean is not fixed ... ??? This is why the null hypothesis in the context of the tests on the mean (and some other tests) are always written with an equality!

Obviously the reader has very likely noticed that:

- If the confidence interval contains the parameter of interest relatively to H_0 the test is not significant
- If the confidence interval excluded the parameter of interest relatively to H_0 the test is significant

To summarize, we can say that if we make a decision, we can make an error and it is best not to make mistakes often. Clearly, the probability of saying something stupid must be known and preferably small.

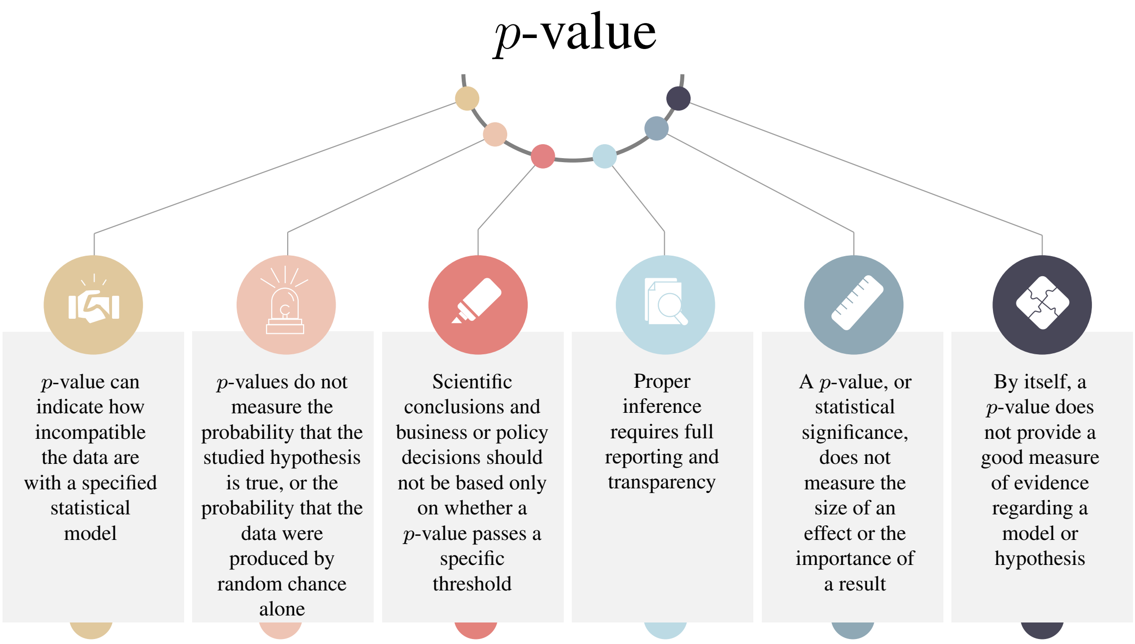


THE ACCUSED HERE IS PRESUMED INNOCENT UNTIL PROVEN GUILTY BEYOND ALL REASONABLE DOUBT. [WE PRESUME H_0 IS TRUE AND MUST PROVE OTHERWISE].
THEREFORE YOUR VERDICT IS EITHER THAT THE ACCUSED IS 'GUILTY' [H_0 IS REJECTED BEYOND ALL REASONABLE DOUBT] OR 'NOT GUILTY' [H_0 IS NOT REJECTED].
LADIES AND GENTLEMEN OF THE JURY, NOTICE THAT WE SAY 'NOT GUILTY' WHEN THE EVIDENCE IS CONSISTENT WITH H_0 (PRESUMED INNOCENT). IT DOES NOT IMPLY THE ACCUSED IS ACTUALLY INNOCENT, MERELY THAT WE DO NOT HAVE ENOUGH EVIDENCE TO BE ASSURED OF GUILT, SO H_0 IS NOT 'ACCEPTED', BUT INSTEAD IS 'NOT REJECTED'. LADIES AND GENTLEMEN, CONSIDER THE EVIDENCE BEFORE YOU.

Figure 5.180: **Comics illustrating Null and Alternative hypothesis (author: ?)**

But keep in mind that a better understanding of the p-value will not take away the human impulse (cognitive bias) to use statistics to create an impossible level of confidence. Most people want something that they can't really get, and that they don't really understand because of a lack of education and critical thinking. They want certainty! And even if you try to explain them you will have a backfire effect as they suffer from the anti-intellectualism syndrome.

Caution! In some high level statistical softwares the p-value may not match the confidence interval. For example, in R with the proportion test (see page 872), the p-value is computed using the Rao score test (based on pooled variance), the one-sided interval is computed with the Wilscon score and the two sided confidence interval is computer with the Wald (normal) non-pooled variance. The same kind of scenario in R (and other statistical softwares) happens with the Fisher's exact test (see page 1254).



p-value can indicate how incompatible the data are with a specified statistical model

p-values do not measure the probability that the studied hypothesis is true, or the probability that the data were produced by random chance alone

Scientific conclusions and business or policy decisions should not be based only on whether a p-value passes a specific threshold

Proper inference requires full reporting and transparency

A p-value, or statistical significance, does not measure the size of an effect or the importance of a result

By itself, a p-value does not provide a good measure of evidence regarding a model or hypothesis

5.7.13.2 Fisher's method for multiple p-values

In statistics, "Fisher's method, also known as "Fisher's combined probability test", is a technique for data fusion or "meta-analysis" (analysis of analyses). It was developed by and named for Ronald Fisher. In its basic form, it is used to combine the results from several independent tests bearing upon the same overall hypothesis (H_0).

Consider a set of k independent tests, each of these to test a certain null hypothesis $H_{0|i}, i = \{1, 2, \ldots, k\}$. For each test, a significance level p_i, i.e., a p-value, is obtained. All these p-values can be combined into a joint test whether there is a global effect, i.e., if a global null hypothesis H_0 can be rejected.

There are a number of ways to combine these independent, partial tests. The Fisher method is one of these, and is perhaps the most famous and most widely used. The test was presented in Fisher's now classical book, *Statistical Methods for Research Workers* (11932 according to holocene calendar).

The test is based on the fact that the probability of rejecting the global null hypothesis is related to intersection of the probabilities of each individual test, $\prod_i p_i$. However, $\prod_i p_i$ is not uniformly distributed (but each p_i is assumed to be uniformly distributed!), even if the null is true for all partial tests, and cannot be used itself as the joint significance level for the global test. To remediate this fact, some interesting properties and relationships among distributions of random variables were exploited by Fisher and embodied in the succinct excerpt above. The proof is given below:

Proof 5.48.3. So we are looking for the distribution law of:

$$X = \prod_i p_i \tag{5.7.1763}$$

but this seems quite difficult to do as we are dealing with a product. Then we take first logarithm (the natural one as we know in statistics that most of time in is the $\ln$ that appears:

$$\ln(X)=\ln\left(\prod_i p_i\right)=\sum_i \ln(p_i) \tag{5.7.1764}$$

Therefore we have now a sum of the natural logarithm of uniform distribution $\mathcal{U}_{0,1}$. It's a bit better but now we have the problem of the $\ln\left(\mathcal{U}_{0,1}\right)$.

But now let us see something nice! Remember that the cumulative distribution function of an exponential distribution is:

$$F(x)=1-e^{-\lambda x} \tag{5.7.1765}$$

The inverse is then given by:

$$x=-\frac{1}{\lambda}\ln(1-F(x)) \tag{5.7.1766}$$

If P is a random variable uniformly distributed in the interval $[0,1]$, so is $1-P$. As consequence the previous relation can be equivalently written as:

$$x=-\frac{1}{\lambda}\ln(P) \tag{5.7.1767}$$

where once again: $P=\mathcal{U}_{0,1}$. Therefore we have just found that the natural logarithm of a uniform random variable in the interval $[0,1]$ follows an exponential distribution with parameter $\lambda=1$!

But now we have a small a problem. As we have a sum of exponential laws we have never proved if the exponential law is stable by addition...

Let us now recall that the chi-squared distribution with k degrees of freedom is given by:

$$\chi^2_k(x)=\frac{1}{2^{\frac{k}{2}}\Gamma(k/2)}x^{\frac{k}{2}-1}e^{-\frac{x}{2}}\cdot 1_{[0,+\infty[} \tag{5.7.1768}$$

If $k=2$ we get:

$$\chi^2_2(x)=\frac{1}{2^{2/2}\Gamma(2/2)}x^{\frac{2}{2}-1}e^{-\frac{x}{2}}\cdot 1_{[0,+\infty[}=\frac{1}{2\cdot 1}x^0e^{-x/2}=\frac{1}{2}e^{-x/2} \tag{5.7.1769}$$

In other words, chi-squared distribution with two degrees of freedom is equal to a exponential distribution with $\lambda=1/2$!

And remember now during our study of the Gamma distribution we have proved that it was stable by addition. And as we have proved that the chi-square distribution follows from a special case of the Gamma distribution, and just now that the exponential distribution follows from a special case of the chi-squared distribution, then that latter is also stable by addition with degrees of freedom!!!!

Therefore multiplying the sum of logarithms by -2 to get rid of the $-$ coming from the exponential law and the $1/2$ coming from what bounds the chi-squared law to the exponential law, we get:

$$\chi^2_{2k}=-2\sum_{i=1}^{k}p_i \tag{5.7.1770}$$

from which a p-value for the global hypothesis can be easily obtained.

■ Q.E.D.

Under Fisher's method, two small p-values p_1 and p_2 combine to form a smaller p-value. The yellow-green boundary in the figure below defines the region where the meta-analysis p-value is below 0.05. For example, if both p-values are around 0.10, or if one is around 0.04 and one is around 0.25, the meta-analysis p-value is around 0.05:

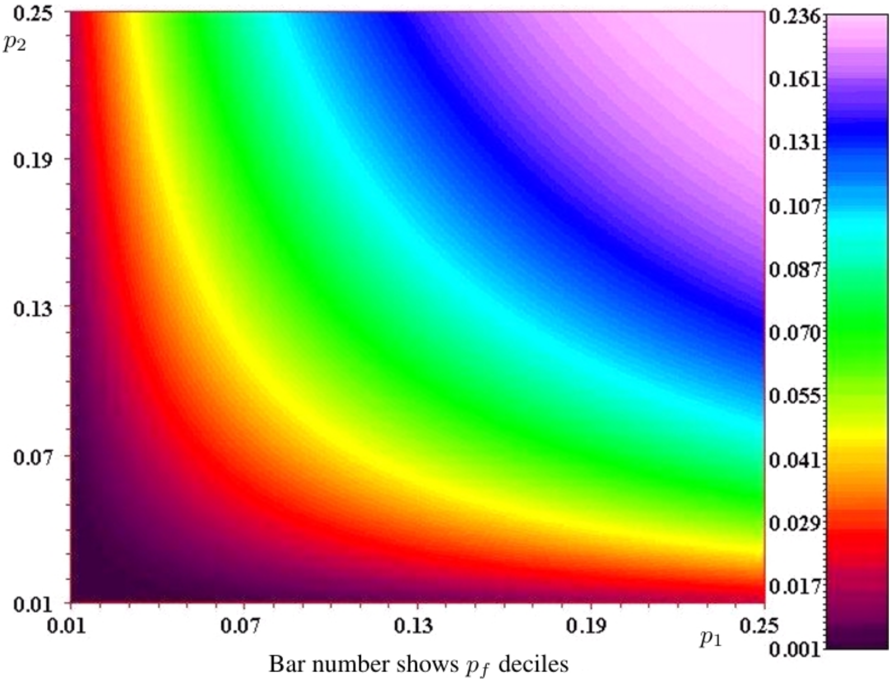


Figure 5.181: Fisher's method for multiple p-values (source: Wikipedia)

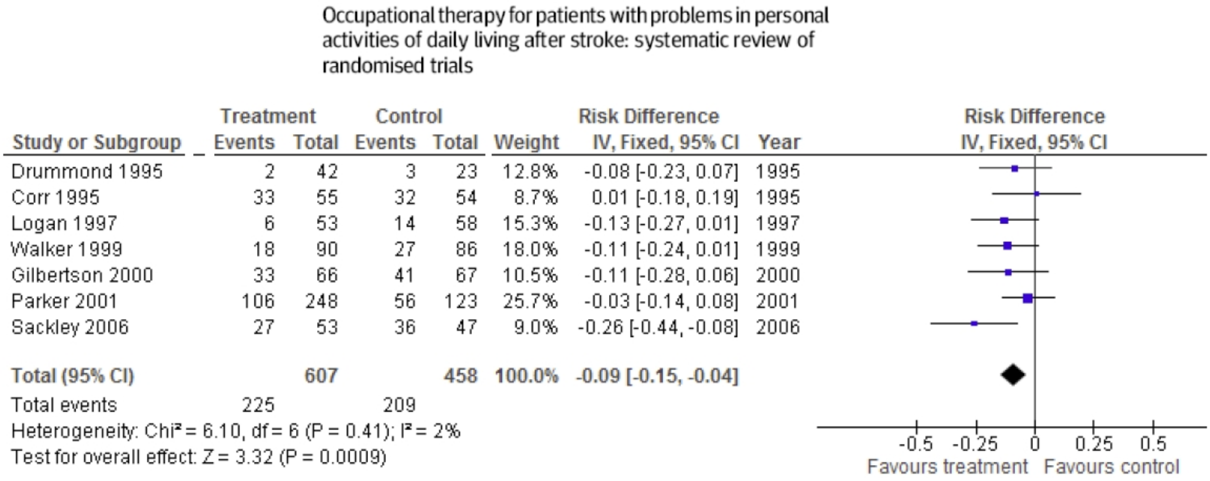
Remark

In the famous judgement case of Lucia de Berk the court made heavy use of statistical calculations to achieve its conviction. In a 12003 (holocene calendar) TV special of NOVA, Dutch professor of Criminal Law Theo de Roos stated: «*In the Lucia de Berk case statistical evidence has been of enormous importance. I do not see how one could have come to a conviction without it*». The law psychologist Henk Elffers, who was used by the courts as expert witness on statistics both in the original case and on appeal, was also interviewed on the programme and stated that the chance of a nurse working at the three hospitals being present at the scene of so many unexplained deaths and resuscitation is one in 342 million. But sadly, this value was wrongly calculated (this is why any important statistical calculations should be peer-reviewed always at least by three other independent people) by making a simple calculations of the multiplication of the p-values... Furthermore, always in the context of Lucai de Berk the statisticians Richard D. Gill and Piet Groeneboom calculated a chance of one in twenty-five that a nurse could experience a sequence of events of the same type as Lucia de Berk.

The use of probability arguments in the De Berk case was discussed in a 12007 (holocene calendar) *Nature* article by Mark Buchanan. He wrote: « *The court needs to weigh up two different explanations: murder or coincidence. The argument that the deaths were unlikely to have occurred by chance (whether* 1 *in* 48 *or* 1 *in* 342 *million) is not that* *meaningful on its own - for instance, the probability that ten murders would occur in the same hospital might be even more unlikely. What matters is the relative likelihood of the two explanations! However, the court was given an estimate for only the first scenario. »*

So we see here that using simple multiplication of Fisher multiplication inference is not the point in such a situation!

Notice that the use of Fisher's method works only if the studies included in a meta-analysis are comparable (sample size). If they aren't we have to use other techniques permitting the usage of weights like illustrated in the figure below that we have already encountered in the Introduction of this textbook:



Occupational therapy for patients with problems in personal activities of daily living after stroke: systematic review of randomised trials

	Treatment		Control			Risk Difference	
Study or Subgroup	Events	Total	Events	Total	Weight	IV, Fixed, 95% CI	Year
Drummond 1995	2	42	3	23	12.8%	-0.08 [-0.23, 0.07]	1995
Corr 1995	33	55	32	54	8.7%	0.01 [-0.18, 0.19]	1995
Logan 1997	6	53	14	58	15.3%	-0.13 [-0.27, 0.01]	1997
Walker 1999	18	90	27	86	18.0%	-0.11 [-0.24, 0.01]	1999
Gilbertson 2000	33	66	41	67	10.5%	-0.11 [-0.28, 0.06]	2000
Parker 2001	106	248	56	123	25.7%	-0.03 [-0.14, 0.08]	2001
Sackley 2006	27	53	36	47	9.0%	-0.26 [-0.44, -0.08]	2006
Total (95% CI)		**607**		**458**	**100.0%**	**-0.09 [-0.15, -0.04]**	
Total events	225		209				

Heterogeneity: Chi² = 6.10, df = 6 (P = 0.41); I² = 2%
Test for overall effect: Z = 3.32 (P = 0.0009)

Figure 5.182: Special example of a meta-analysis in the field of clinical trials with concepts that we will detail without exception in this entire book (source: [344])

The risk difference (R.D.) being simply the difference of two proportions, we use the famous following Wald interval (see page 880) for the calculation of the confidence interval:

$$(\hat{p}_X-\hat{p}_Y)-Z_{\alpha/2}\sqrt{\frac{\hat{p}_X(1-\hat{p}_X)}{n_1}+\frac{\hat{p}_Y(1-\hat{p}_Y)}{n_2}}\leq p_X-p_Y\leq(\hat{p}_X-\hat{p}_Y)+Z_{\alpha/2}\sqrt{\frac{\hat{p}_X(1-\hat{p}_X)}{n_1}+\frac{\hat{p}_Y(1-\hat{p}_Y)}{n_2}} \tag{5.7.1771}$$

where by definition R.D. $:=p_X-p_Y$.

We see above that the width of the 95% confidence interval of the common risk difference is smaller than the width of the 95% confidence interval of the estimated effect in each of the trials. That's obviously because the pooled effect is more precise than the effect estimated in the trials.

It is also very important to notice that in a meta-analysis (like the example above), even if no trial detects an effect of the experimental intervention (as you can see above in every trial zero is in the confidence interval), the synthesis of the results of the trials (Risk Difference as above) can make it possible to detect an overall effect (the reader can see that in the total confidence interval, the zero is outside the confidence interval). We gain in power of the test!

The reader may ask where does the -0.09 comes from in the "Total (95% CI)" line? It comes from the simple following weighted average of all the risk differences:

$$\widehat{\text{R.D.}}_{\text{weighted}} = 0.128 \cdot (-0.08) + 0.087 \cdot (0.01) + 0.153 \cdot (-0.13) + \ldots = -0.09$$

5.7.13.2.1 Simpson's Paradox (sophism)

The "Simpson's paradox" (in fact it's a sophism and not a paradox because it is just a special case of omitted variable bias), also named "Yule-Simpson effect", is a paradox in probability and statistics, in which a trend appears in different groups of data but disappears or reverses when these groups are combined[56].

This result is often encountered especially in social-science (Human Resources, Marketing, Psychology), and medical-science statistics and is particularly confounding when frequency data are unduly given causal interpretations. Simpson's paradox disappears when causal relations are brought into consideration.

Let us see a famous real example for a real medical study (there is also another famous case with the *Nation at Risk* report, if the reader is interested, just search for it on Internet!):

The table below shows the success rates and numbers of treatments for treatments involving both small and large kidney stones, where Treatment A includes all open surgical procedures and Treatment B is percutaneous nephrolithotomy (which involves only a small puncture). The numbers in parentheses indicate the number of success cases over the total size of the group (for example, 93% equals 81 divided by 87):

	Treatment A	**Treatment B**
Small stones	Group 1 93% $(81/87)$	Group 2 87% $(234/270)$
Large stones	Group 3 73% $(192/263)$	Group 4 69% $(55/88)$
Both	78% $(273/350)$	83% $(289/350)$

The paradoxical conclusion is that treatment A is more effective when used on small stones, and also when used on large stones, yet treatment B is more effective when considering both sizes at the same time. In this example the "lurking" variable (or "confounding variable") of the stone size was not previously known to be important until its effects were included.

Formally, if we denote (we change the notations!!!!) A the result, B the treatment, and C the stones, in the general case, with the Simpson paradox it is possible to have using Bayesian probabilities:

$$P(A|B,C) < P(A|B^c,C) \text{ and } P(A|B,C^c) < P(A|B^cC^c) \text{ yet also: } P(A|B) > P(A|B^c) \tag{5.7.1772}$$

---

[56] Edward H. Simpson first described this phenomenon in a technical paper in 11951 (holocene calendar), but the statisticians Karl Pearson et al., in 11899 (holocene calendar), and Udny Yule, in 11903 (holocene calendar), had mentioned similar effects earlier. The name Simpson's paradox was introduced by Colin R. Blyth in 11972 (holocene calendar).

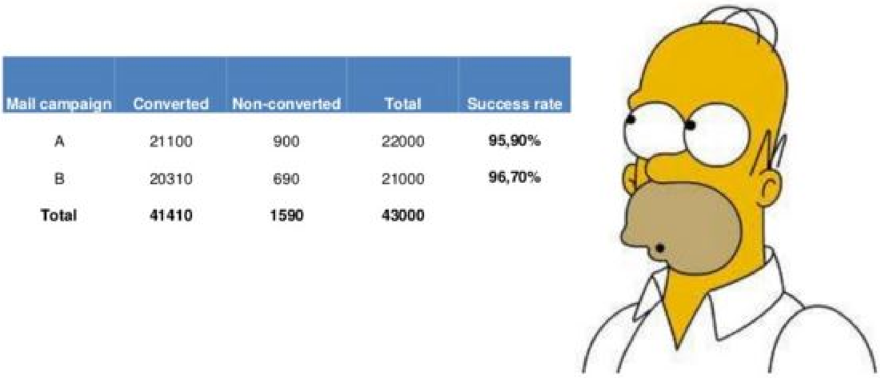
Which treatment is considered better is determined by an inequality between two ratios (successes/total). The reversal of the inequality between the ratios, which creates Simpson's paradox, happens because two effects occur together:

1. The sizes of the groups, which are combined when the lurking variable is ignored, are very different. Doctors tend to give the severe cases (large stones) the better treatment A, and the milder cases (small stones) the inferior treatment B. Therefore, the totals are dominated by groups 3 and 2, and not by the two much smaller groups 1 and 4.
2. The lurking variable has a large effect on the ratios, i.e. the success rate is more strongly influenced by the severity of the case than by the choice of treatment. Therefore, the group of patients with large stones using treatment A (group 3) does worse than the group with small stones, even if the latter used the inferior treatment B (group 2).

Based on these effects, the paradoxical result is seen to arise by suppression of the causal effect of stone size on successful treatment. The paradoxical result can be rephrased more accurately as follows: When the less effective treatment (B) is applied more frequently to easier cases, it can appear to be a more effective treatment.

Simpson's paradox usually fools us on tests of performance. In a famous example, researchers concluded that a newer treatment for kidney stones was more effective than traditional surgery, but it was later revealed that the newer treatment was more often being used on small kidney stones. More recently, on elementary school tests, minority students in Texas outperform their peers in Wisconsin, but Texas has so many minority students that Wisconsin beats it in state rankings. It would be a shame if Simpson's paradox led doctors to prescribe ineffective treatments or Texas schools to waste money copying Wisconsin.

Consider another funny illustrated example in Marketing! Consider we have the following information:



Mail campaign	Converted	Non-converted	Total	Success rate
A	21100	900	22000	95,90%
B	20310	690	21000	96,70%
Total	41410	1590	43000	

Figure 5.183: **Marketing Campaign performance**

Obviously the campaign B perform the best into converting an e-mail to click ("conversion rate")!

But now splitting in clicking high valuable links (costly products: high ticket conversion) or low valuable links (low ticket conversion) we get:

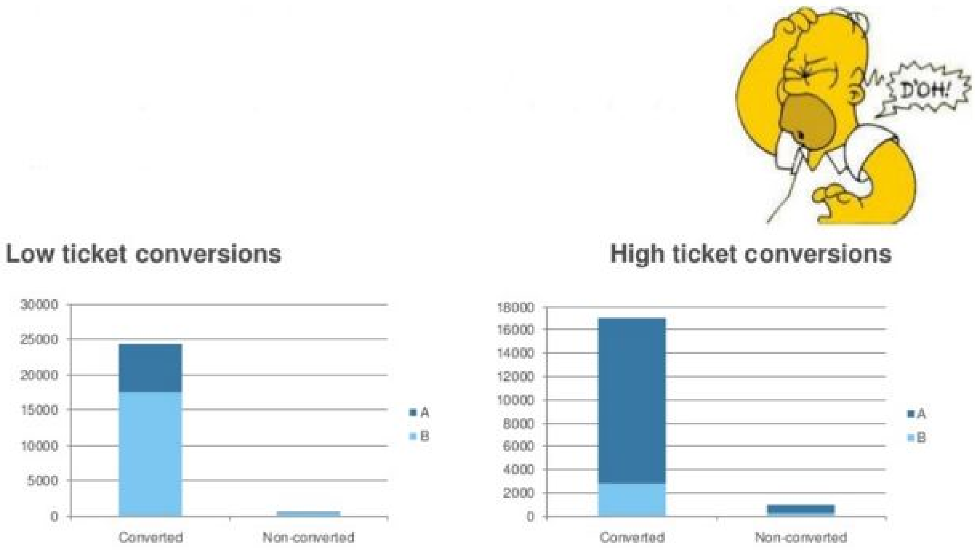


Figure 5.184: **Marketing Campaign performance in ticket conversion covariate**

Or for people that are more visual (with plots) here is an example from our R companion book. This is a simple regression of the IRIS dataset. The linear regression trend seem negative:

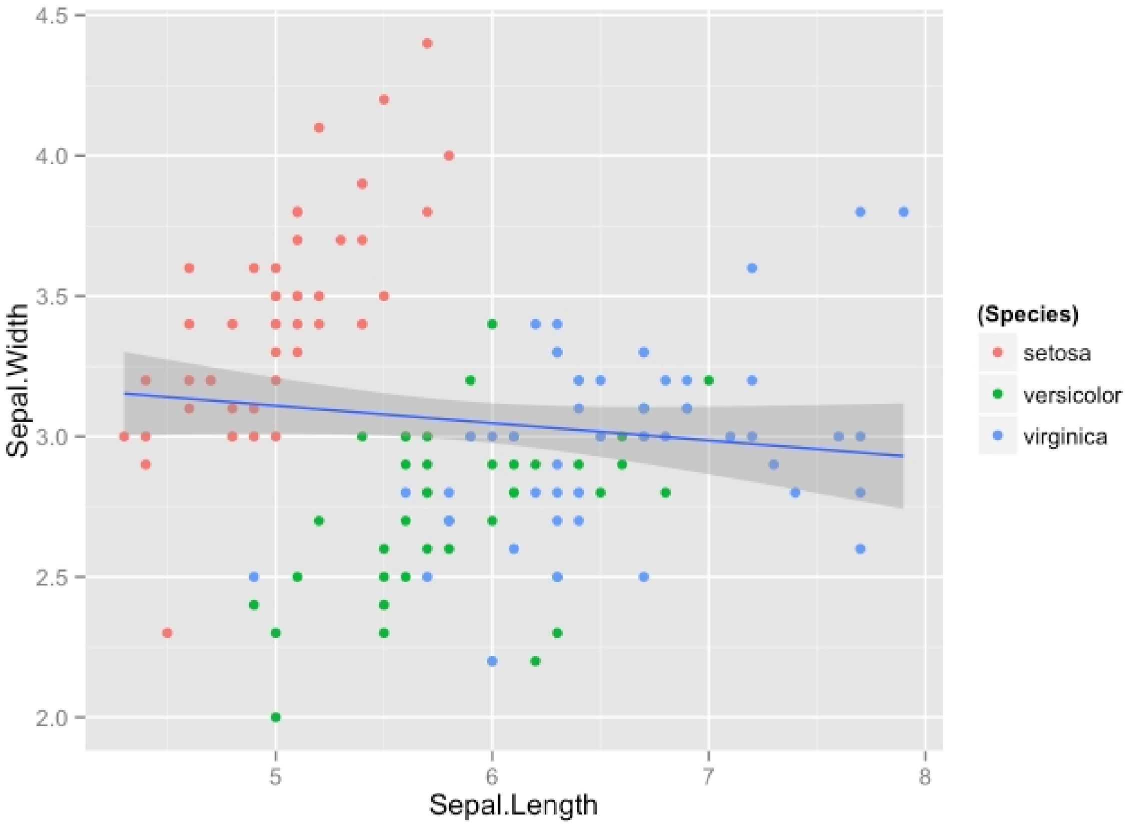

Figure 5.185: **IRIS dataset non-clustered regression in R to illustrate Simpson paradox**

Now if we cluster the regression.... all the trends are positive...:

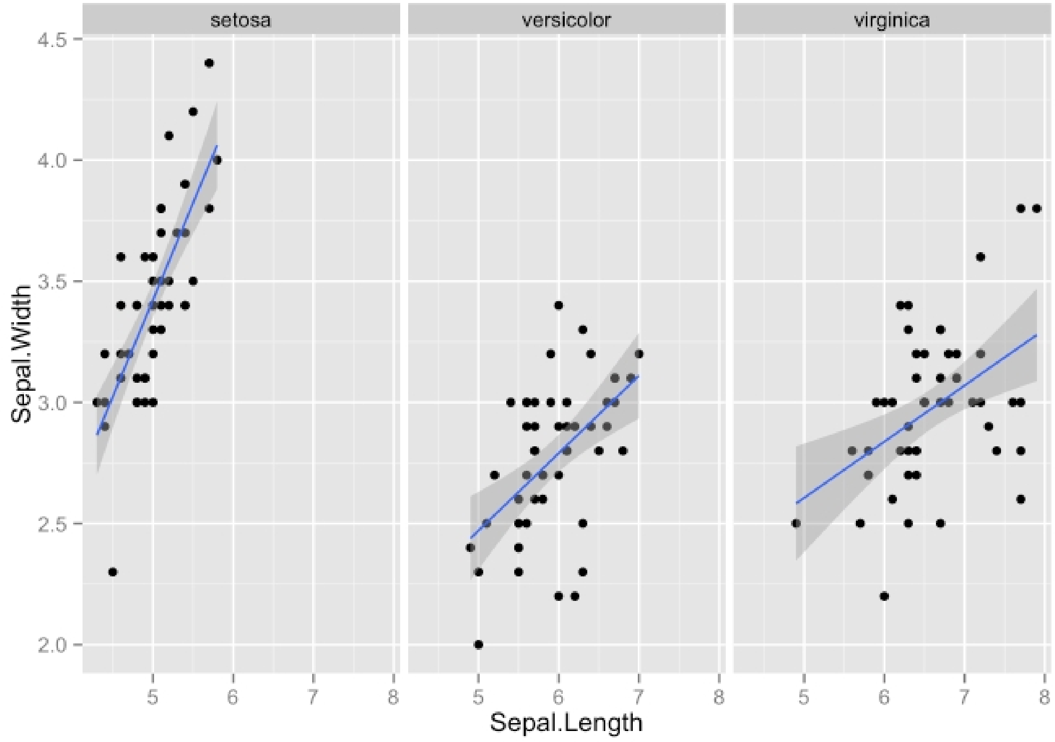

Figure 5.186: **IRIS dataset clustered regression in R to illustrate Simpson paradox**

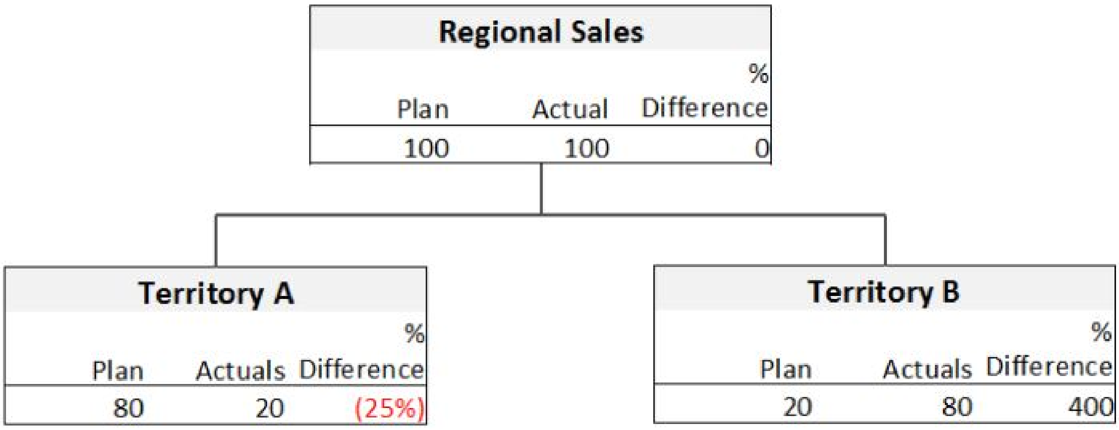
Some people may argue that this is not business oriented... So here is an example of Simpson's paradox typical in business intelligence reports or dashboards:



Regional Sales

Plan	Actual	% Difference
100	100	0

Territory A

Plan	Actuals	% Difference
80	20	(25%)

Territory B

Plan	Actuals	% Difference
20	80	400

We see above that aggregated regional Sales look like they are on plan. But at the next level of detail (at the Territory level), we can see that Territory A is doing very poorly (25% of plan) and Territory B is doing exceptionally well (400% of plan). This is a major challenge in the world of BI. It's easy to feel content with what the BI reports and dashboards are telling us without having an easy, automated way to delve into the minutiae to find those areas of the business that are significantly over- or under-performing.

Definition (#5.7.147): In the academic literature on information systems and business communication, a "report" is generally defined as a structured layout that systematically presents information, data, analyses, findings, and conclusions regarding a specific subject for the purpose of informing, documenting, evaluating, or supporting decision-making for a specific target audience eventually in an interactive way.

Definition (#5.7.148): In the academic literature on information systems and business communication, a "dashboard" is generally defined as a visual information system that in almost real-time consolidates, organizes, and presents the most important performance indicators, metrics, graphs or data from various reports needed to achieve one or more objectives, displayed on a single screen so that information can be monitored and understood at a glance for a specific target audience in a non-interactive way.

Remark

Another kind of quite famous similar case in statistics is named the "Lord's paradox" (that is also only a sophism in reality!). It just highlights the obvious fact that under some conditions an ANOVA (ANalysis Of VARiance) won't give the same result as an ANCOVA (ANalysis of CoVAriance). These are two different kind of tools that we will see further below.

5.7.13.3 Power of a Test

When the effect is actually large, we can expect that we need less observations to demonstrate it that when the effect is small ... but how much exactly? Did we have the possibility to do this, in terms of number of measures, to "prove" what we seek? Should we go about it differently and change the device to do the observation/experiment?

We have seen earlier that we can never "prove" the null hypothesis[57]; all we can do is reject or fail to reject it. However, there are times when it is necessary to try to "prove" (i.e. get evidence) the non-existence of a difference between groups. This most often happens within the context of comparing a new treatment against an established one and showing that the new intervention is not inferior to the standard (in some circumstances, we need many more subjects to get evidence of non-inferiority than we need to show a difference). Can we do something like this?

To answer all questions above, we need now to study in more detail the concept of "power of a test" that we have so far only mentioned, remember the following figure that we have already seen just a little bit earlier:

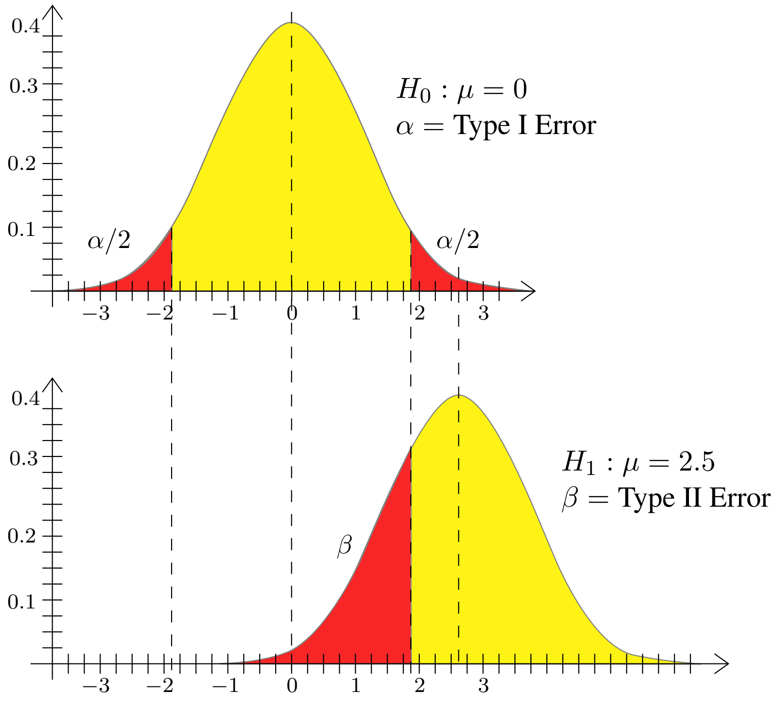


Figure 5.187: Null and alternative hypothesis of a special case of two-sided test

In the particular example above, we will obviously reject the null hypothesis H_0 if $\bar{X} > 1.96$ or $\bar{X} < -1.96$. Imagine that under the alternative hypothesis H_1, if we measured 2.5 for $\bar{X}$, we will have for power of the test:

$$1 - \beta = 1 - P\left(Y_{\mathcal{N}(2.5,1)} \leq 1.96\right) = 1 - P\left(Y_{\mathcal{N}(\bar{X},1)} \leq Z_{1-\alpha/2}\right) = 1 - 0.2946 \cong 0.705 \tag{5.7.1773}$$

---

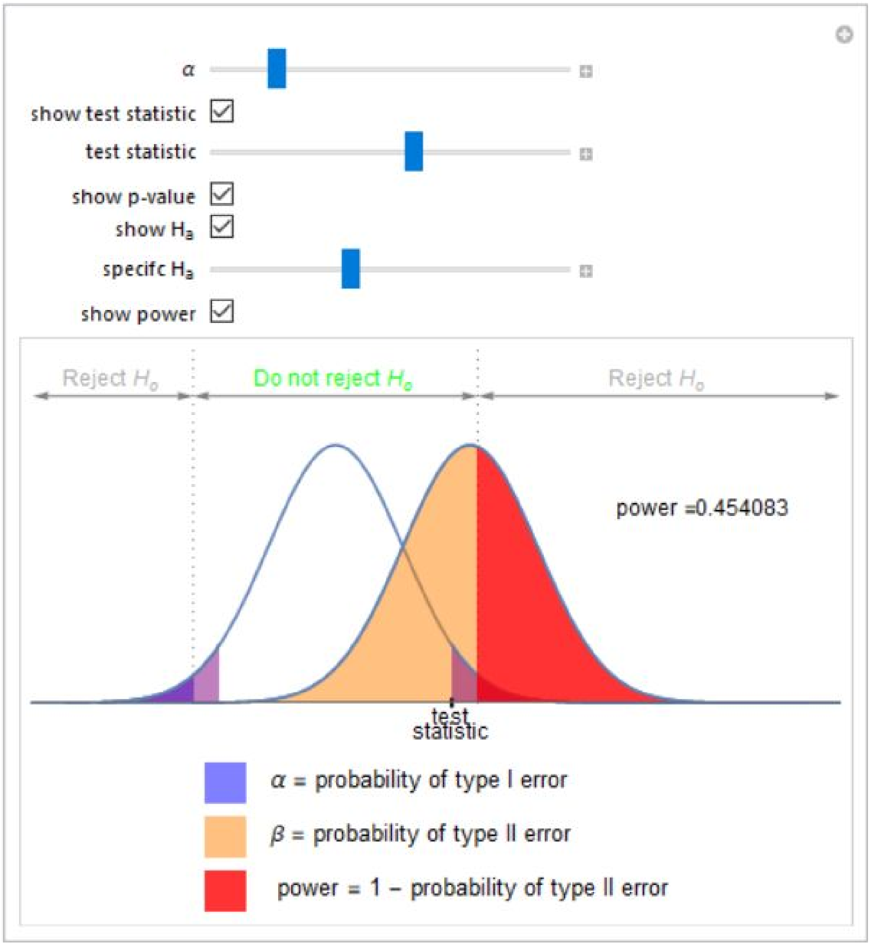
[57] Remember that with NHST, if the p-value is greater than a given threshold, we do should not say that we can accept (or "prove") the null hypothesis; rather, we use the convoluted locution that « *We have failed to disprove the null*».

So the test is relatively strong/powerful (in practice, we consider a test to be powerful if its value is above of 80% - that is to say the $\beta \leq 20\%$). Thus, we see that the (a posteriori!) power $1-\beta$ is even larger than the p-value is small (and respectively the power will be a posteriori even smaller than the p-value is great). Therefore the a posteriori power is in decreasing correspondence with the p-value (in practice it is however a bit absurd to make these calculations a posteriori but some scientific paper require this information).

So in general:

$$\boxed{\text{power} = 1 - \beta = 1 - P\,(\text{not rejecting a false } H_0)} \qquad (5.7.1774)$$

A great way to play with these concepts and visualize them is to take a look at the Wolfram widget available on http://demonstrations.wolfram.com/StatisticalPower/:



α

show test statistic ☑

test statistic

show p-value ☑

show H$_a$ ☑

specifc H$_a$

show power ☑

Reject H_0
Do not reject H_0
Reject H_0
power =0.454083
test statistic
🟦 α = probability of type I error
🟧 β = probability of type II error
🟥 power = 1 – probability of type II error

Before continuing, let us inform you that many don't understand why the probability of getting a type I error when performing a hypothesis test, isn't affected by the sample size?!

If we were using standard hypothesis testing, we may set the confidence level α and the compare the test p-value to it. In this case the sample size will not impact the probability of Type I error because your confidence level α is the probability of Type I error, pretty much by definition. In other words, you set the probability of Type I error by choosing the confidence level! The probability of Type I error is only impacted by your choice of the confidence level and nothing else!

But yes, we could also fix Type II error rate (but this is not the purpose of science as we know to "prove" the null hypothesis as it is practically quite hard most of times!), the Type I error rate usually becomes the unknown parameter and it is dependent on the sample size, the variance and the effect size (delta).

Remark

Many people say that if a Person A posits the existence of some phenomenon, it is incumbent on Person A to prove its existence rather than it being Person B's job to disprove it. For example, if we assert that there are pink unicorns with purple polka dots hiding deep in the forest, I cannot simply say, «*Well, prove that they don't exist*». For the scientific world to accept my claim, I have to bring one back, dead or alive. Is it ever legitimate to violate this injunction and try to prove the non-existence of something? In the text above we then have taken a look at trying to "prove" (i.e. get "enough evidence") that something does not exist[a].

---

[a] Obviously if we are sure that we have investigated ALL possible combinations, places and that the huge majority properties of the unicorn are proven wrong or impossible, then it's very highly likely that the unicorn itself doesn't exist

5.7.13.3.1 Evidence ("proof") of a negative

Georgia minister Nelson L. Price asserts on his website (and many other science popularizer on YouTube and scientifically illiterate social networks users) that « *one of the laws of logic is that you can't prove a negative* » (also named "argumentum ad ignorantium"). The fact is, however, that this supposed "law of logic" is no such thing!

Notice, for a start, that « *You cannot prove a negative* » is itself a negative. So, if it were true, it would itself be unprovable. Notice that any claim can be transformed into a negative by a little rephrasing - most obviously, by negating the claim and then negating it again. « *I exist* is logically equivalent to « *I do not not exist* », which is a negative. Yet here is a negative it seems we might perhaps be able to prove (in the style of Descartes: « *I think, therefore I do not not exist!* »).

Of course, those who say « *You cannot prove a negative* », or who say we do an « *argumentum ad ignorantium* », will insist that we have misunderstood their point. As Steven D. Hales notes, when people say, « *You can't prove a negative* », what they really mean is that you cannot prove that something does not exist. If this point were correct, it would apply not just to supernatural beings lying beyond the cosmic veil but also to things that might be supposed to exist on this side of the veil, such as unicorns, Martians, rabbits with 20 heads, and so on. We would not be able to prove the non-existence of any of these things either.

But is the point correct? Is it true that we can never prove that something does not exist? Again, it depends **IF** you have sufficiently defined the scope of what you are looking at and the level of evidence[58]. If someone claims there's a unicorn in the tool shed (see [519] for a deep treatment of this subject), we can quickly establish this person is mistaken by going and taking a look. We could similarly establish there's no Loch Ness monster by draining the loch. But what of the claim that unicorns once existed? We can't travel back in time and directly observe all of the past as we can every corner of the tool shed or Loch Ness. Does it follow that we can't prove unicorns never existed?

It depends in part, as we already know it, on what we mean by "prove". The word has a variety of meanings. By saying something is "prove", we might mean that it is established beyond all possible doubt. Or we might mean it has been established beyond reasonable doubt (this is the kind of proof in experimental science). Can we establish beyond reasonable doubt that unicorns have never inhabited the Earth? True, the history of our planet has been and gone, so we can no longer directly inspect it. But surely, if unicorns did roam the Earth, we would expect to find some evidence of their presence, such as fossils of unicorns or at least of closely related animals from which unicorns might plausibly have evolved. There is none. We also have plenty of evidence that unicorns are a fictional creation, in which case, it's surely reasonable for us to conclude that there never were any unicorns. Indeed, we would suggest we can give evidence of this beyond reasonable doubt (especially if all inherent properties of unicorns have already been broken down).

In response, it might be said, « *But you can't prove conclusively, beyond all possible doubt, that unicorns never roamed the Earth*[59] ». This is undeniably true! However, this point is not peculiar to negatives. It can be made about any claim about the unobserved, and thus any scientific theory at all, including scientific theories about what does exist. We can prove beyond reasonable doubt that dinosaurs existed, but not beyond all possible doubt!

Despite the mountain of evidence that dinosaurs roamed the Earth, it's still possible that, say, all those dinosaur fossils are fakes placed there by alien pranksters long ago.

Let's sum up. If « *you can't prove a negative* » means you can't prove beyond reasonable doubt that certain things don't exist, then the claim is just false. We prove the non-existence of things on a regular basis. If, on the other hand, "you can't prove a negative" means you cannot prove beyond all possible doubt that something does not exist, well, that may, arguably, be true. But so what? That point is irrelevant so far as defending beliefs in supernatural entities against the charge that science and/or reason have established beyond reasonable doubt that they don't exist.

Let us now consider something has a finite number of observable (i.e. refutable) properties/characteristics in a finite volume. So say we have a bowl. We can prove (i.e. get evidence) the non-existence of milk in our bowl with a photo (or more complex apparatus) of an empty bowl. But this photo does not depict negative milk. It depicts a positive bottom of the bowl, and from that positive, we can deduce the impossibility of milk being there, knowing, from other evidence, what milk looks like. So we are using positive evidence to prove impossibility.

---

[58] For example the huge majority of properties and acts that define some divinities have been showed with strong evidence as wrong. This lead us to the very likely conclusion that there are no divinities - especially divinities that have become mythologies give us a strong evidence for this.

[59] A "conclusive evidence" is evidence that cannot be contradicted by any other evidence. It is so strong as to overbear any other evidence to the contrary. The evidence is of such a nature that it compels a fact-finder to come to a certain conclusion.

Impossibility is the exhaustion of exclusive possibilities. Possibilities are zero or positive. In this case, milk and empty are mutually exclusive, where the likelihood of milk is 0, and the likeliness of empty is 1. This is different from proving a negative. Now as most religions have holy books that depicts quite precisely some properties and actions of their gods on Earth (finite volume), then if we found evidence in that closed volume (Earth) that disprove at least one of the properties (i.e. characteristic) of their god, then that latter very likely doesn't exist beyond any reasonable doubt (B.A.R.D.)... Technically this is denoted:

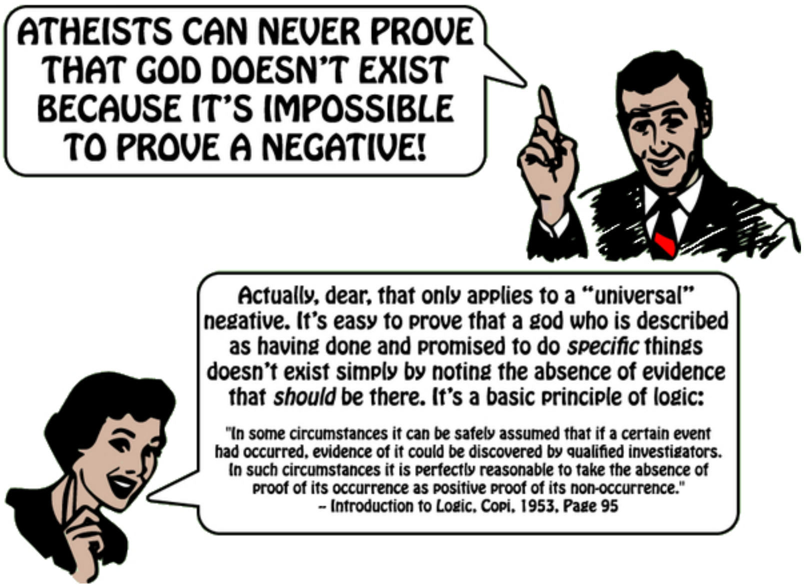
$$\begin{gathered}\forall\ H_{0,i} \in \mathcal{H}_0 = \{H_{0,1}, H_{0,2} \ldots, H_{0,n} | H_{0,j} \cap H_{0,i} = \varnothing \wedge \cap_{i=1}^{n} H_{0,i} \neq \varnothing\ \forall i, j\} \\ \text{if } \exists H_{0,i} = \texttt{FALSE B.A.R.D.} \Rightarrow \mathcal{H}_0 = \texttt{FALSE B.A.R.D.}\end{gathered} \tag{5.7.1775}$$

and named the "Stenger-Neyman-Pearson supernatural falsification method". So applying this relation to religious books (vedas, bible, torah, quran, etc.) knowing that the bible has (without counting the contradictions and historical errors) at least 21 scientific errors, the quran has (without counting the contradictions and historical errors) at least 73 scientific errors, the torah has (without counting the contradictions and historical errors) at least 20 scientific errors, the vedas have (without counting the contradictions and historical errors) at least 26 scientific errors bring us to quite an obvious conclusion about the perfection - and hence existence - of their supposed respective deities...

quote
5.7:976.#49

> *Science doesn't tell us what to think but sometimes it tells us what we can no longer believe.*
>
> Etienne Klein

The old adage «You cannot prove a negative» (the correct formulation should be «You cannot get evidence of a negative») is a typical evidence level 02 (see page 60) argument from scientifically illiterate people.



ATHEISTS CAN NEVER PROVE THAT GOD DOESN'T EXIST BECAUSE IT'S IMPOSSIBLE TO PROVE A NEGATIVE!
Actually, dear, that only applies to a "universal" negative. It's easy to prove that a god who is described as having done and promised to do *specific* things doesn't exist simply by noting the absence of evidence that *should* be there. It's a basic principle of logic:
"In some circumstances it can be safely assumed that if a certain event had occurred, evidence of it could be discovered by qualified investigators. In such circumstances it is perfectly reasonable to take the absence of proof of its occurrence as positive proof of its non-occurrence." -- Introduction to Logic, Copi, 1953, Page 95

So proving (i.e. get evidence) the non-existence depends how tightly defined the thing are checking for does not exist. If we can define some attribute the thing absolutely must have in a finite volume or time range, then we may be able to have strong evidence that the thing with that attribute does not exist. But as soon as there is any vagueness in the description, we cannot do so. So, again in order to prove (i.e. get evidence) something does not exist we must establish the properties of that thing in a finite volume to the point of being able to test its negation.

5.7.13.3.1.1 Two-One-Sided T-test procedure (TOST)

If we want to test the equality of two values $\hat{\theta}_1 = \hat{\theta}_2$ (mean, proportion or other), meaning the non-existence of an effect (or a "negative"), as alternative hypothesis H_A we can't do that with classical hypothesis and alternative test (as it is quite hard to build the statistics of the null hypothesis H_0, i.e. the statistical distribution of $\hat{\theta}_1 \neq \hat{\theta}_2$)!

A well known approach we then use in practice (considering the case with means!) is the "Two One-Sided Tests (TOST) procedure". This involves looking at the difference between the mean values for the two populations then testing a joint null hypothesis: that this difference is less than or equal to $+\delta$ AND that this difference is greater than or equal to $-\delta$ (for some sufficiently small and positive δ). If we can reject this joint null hypothesis, then you can conclude that the absolute value of the difference between the means is less than δ (see [300] for an analysis on how to choose δ).

In other words, the Two-One-Sided T-test procedure (TOST) is used to show that two samples are similar, in contrast to classical statistical tests which check for dissimilarity. The TOST relies on a parameter called delta, which has to be set by the researcher using their intuition. Doing so can be difficult, because of complex interactions of relevant parameters.

In some fields there may be industry standards to use as a guide for δ. If not, the equivalence acceptance criterion is best developed from a consensus among stakeholders such as decision makers, system engineers, operators, and subject matter experts (SMEs). Deciding what difference in SUT performance is "good enough" and determining δ for the equivalence test is not a trivial task and adequate time should be allotted for this in the planning phase. The value of δ should be based on how big a difference is practically important to consider the means not equivalent. Δ is similar to the difference to detect when we size a traditional designed experiment. Once δ is derived, the hypothesis can be stated as:

$$\begin{aligned} &H_0 : |\mu_1 - \mu_2| > \delta\text{: The difference in means is greater than the equivalence acceptance criterion}\\ &H_A : |\mu_1 - \mu_2| \leq \delta\text{: The difference in means is less than or equal to } \delta \text{ (the means are equivalent)} \end{aligned} \tag{5.7.1776}$$

A one-sided test similarity T-test (OST) is appropriate if the test team only cares if the response differs in one direction. For example, if a new rubber compound is used to make a tire with a mileage guarantee the producers may only care if the tire gets fewer miles of use. This is often named a "test for non-inferiority". In these situations, the null hypothesis is often termed the "inferiority" hypothesis and the alternate is the "non inferiority" hypothesis. The following equation is used to compare the t-ratio to the critical value.

As always we no longer use μ, because it represents the true population parameter, which we will likely never know. Instead we use $\hat{\mu}$, which denotes the sample mean. The critical value

$T_{\alpha,\text{df}}$ can be calculated with software or looked up in statistics tables.

We reject H_0 if:

$$\frac{|\hat{\mu}_1 - \hat{\mu}_2| + \delta}{\sqrt{\frac{\hat{\sigma}_1^2}{n_1} + \frac{\hat{\sigma}_2^2}{n_2}}} > T_{\alpha,n_1+n_2-2} \tag{5.7.1777}$$

In similarity testing, there is no two-sided test. Instead, we conduct two non inferiority tests from both sides:

$$\begin{array}{ll} H_0 : |\mu_1 - \mu_2| > \delta \longrightarrow \begin{cases} H_0 : \mu_1 - \mu_2 > \delta & \text{Null hypothesis expanded for the upper side test} \\ H_0 : \mu_1 - \mu_2 < -\delta & \text{Null hypothesis expanded for the lower side test} \end{cases} \\ H_A : |\mu_1 - \mu_2| \leq \delta \longrightarrow H_A : -\delta \leq \mu_1 - \mu_2 \leq \delta \; \text{The alternate hypothesis is expanded} \end{array} \tag{5.7.1778}$$

When the hypotheses are expanded to create the test statistics we get the following criterion. We reject H_0 if:

$$\frac{|\hat{\mu}_1 - \hat{\mu}_2| + \delta}{\text{SE}} > T_{\alpha,n_1+n_2-2} \quad \text{AND} \quad \frac{|\hat{\mu}_1 - \hat{\mu}_2| - \delta}{\text{SE}} < -T_{\alpha,n_1+n_2-2} \tag{5.7.1779}$$

Note that the two means are considered equivalent if, and only if, both null hypotheses are rejected! We must show that difference in the means is less than $+\delta$ and greater than $-\delta$ to show that the means are equivalent; it cannot be true in just one direction. It is also prudent to point out that this is different than a traditional two-sided hypothesis test. When conducting a two-sided test with a Type I probability of α, we use $\alpha/2$ to compare to the p-value on each side. In this situation we use the full value of α on both tests because they are both one-sided.

✍**Example:**

Suppose we are analysing the effectiveness of the door gunner in a helicopter. It is normal for the door gunner to use the M-249 but a unit wants to instead arm them with the M-4. The M-249 is a machine gun capable of a higher volume of fire, but it is heavier, harder to move, and more prone to jam. Can the M-4 provide equivalent combat power? We have the following data:

Weapon Type	**Target Damage Score**
M-249	180
M-249	143
M-4	65
M-4	112
M-4	139
M-4	112
M-4	125
M-4	78
M-4	138
M-4	84
M-249	117
M-249	169
M-249	111
M-249	114
M-249	166
M-4	134
M-249	131
M-4	69
M-249	93
M-249	177

The reader can see the weapon used and the damage score for each of the 20 trials. This example is small enough that we can go through the calculations manually. Three basic statistics are calculated and shown in the table below:

Weapon	**Sample size**	**Sample mean**	**Sample variance**
M-249	$n_1 = 10$	$\hat{\mu}_1 = 140.1$	$\hat{\sigma}_1^2 = 981.21$
M-4	$n_2 = 10$	$\hat{\mu}_2 = 105.6$	$\hat{\sigma}_2^2 = 849.6$

Using the values calculated in the table above we can calculate the test statistic and critical value. First for the upper end of the curve:

$$\text{SE} = \sqrt{\frac{\hat{\sigma}_1^2}{n_1} + \frac{\hat{\sigma}_2^2}{n_2}} = \sqrt{\frac{981.21}{10} + \frac{849.6}{10}} = \sqrt{183.0811} \cong 13.53$$

We reject H_0 if:

$$\frac{|\hat{\mu}_1 - \hat{\mu}_2| + \delta}{\text{SE}} > T_{\alpha, n_1+n_2-2}$$

Hence:

$$\frac{|140.1 - 105.6| + 20}{13.53} > T_{0.05,18}$$

That is (right TOST):

$$4.03 > 1.734 \xrightarrow{\text{yields}} \text{True}$$

The statement is true so we reject H_0 in the first one-sided test. Next, we conduct the second test (left TOST):

$$\frac{|\hat{\mu}_1-\hat{\mu}_2|-\delta}{\text{SE}}<-T_{\alpha,n_1+n_2-2}$$

Hence:

$$\frac{|140.1-105.6|-20}{13.53}<-T_{0.05,18}$$

That is:

$$1.07<-1.734\xrightarrow{\text{yields}}\text{False}$$

The statement is false and we fail to reject H_0 in the second one-side test. Therefore, we also fail to reject the overall null hypothesis that the M-4 is not equivalent to the M-249. This is not a surprising outcome because our initial difference in means was 34.5.

The same reasoning can be applied for other tests. This is why in the `R` software you can find also a function to compute the TOST for proportions!

Remark

Depending on the statistical software packages, the degrees of freedom may be calculated using the Welch correction. Some software packages return only one p-value and only one confidence interval (most of the time for reasons we can't explain they return that of the left TOST only). Some even return a completely wrong calculation of the p-value. In other words it is better to run a TOST on more than three statistical packages to be almost sure to get a converging conclusion...

5.7.13.3.2 Power of the one sample Z-test and T-test

Very generally, in the case of a bilateral test, the above relation will be written:

$$1-\beta=1-P\left(Y_{\mathcal{N}(\bar{X},1)}\leq\mu+Z_{1-\alpha/2}\right)=1-P\left(Y_{\mathcal{N}(0,1)}\leq\mu-\bar{X}+Z_{1-\alpha/2}\right)\quad(5.7.1780)$$

If the standard deviation of the mean (e.g. variance) is not unitary, we have:

$$1-\beta=1-P\left(Y_{\mathcal{N}(0,\sigma_{\bar{X}})}\leq\mu-\bar{X}+Z_{1-\alpha/2}\sigma_{\bar{X}}\right)\quad(5.7.1781)$$

Therefore we get:

$$1-\beta=1-P\left(Y_{\mathcal{N}(0,1)}\leq\frac{\mu-\bar{X}}{\sigma_{\bar{X}}}+Z_{1-\alpha/2}\right)=1-P\left(Y_{\mathcal{N}(0,1)}\leq\frac{\mu-\bar{X}}{\sigma/\sqrt{n}}+Z_{1-\alpha/2}\right)\quad(5.7.1782)$$

written in another way:

$$\begin{aligned}1-\beta&=1-P\left(Y_{\mathcal{N}(0,1)}\leq\frac{\mu-\bar{X}}{\sigma}\sqrt{n}+Z_{1-\alpha/2}\right)=1-P\left(Y_{\mathcal{N}(0,1)}\leq d_\sigma\sqrt{n}+Z_{1-\alpha/2}\right)\\&=P\left(Y_{\mathcal{N}(0,1)}\leq-Z_{1-\alpha/2}-d_\sigma\sqrt{n}\right)=P\left(Y_{\mathcal{N}(0,1)}\leq Z_{\alpha/2}-d_\sigma\sqrt{n}\right)\end{aligned}\quad(5.7.1783)$$

It is in this form that we find the power of a bilateral test of the average (power of a 1 sample Z-test):

$$1-\beta=P\left(Y_{\mathcal{N}(0,1)}\leq Z_{\alpha/2}-d_\sigma\sqrt{n}\right) \tag{5.7.1784}$$

where d_σ is sometimes named the "size effect" and therefore defined by:

$$d_\sigma=\frac{\mu-\bar{X}}{\sigma}=\frac{\delta}{\sigma} \tag{5.7.1785}$$

and δ is named the "difference"!

It goes without saying that if the true variance is not known, we must be replace the Normal law by the Student law as:

$$1-\beta=P\left(Y_{\mathcal{N}(0,1)}\leq T_{\alpha/2}-d_S\sqrt{n}\right) \tag{5.7.1786}$$

with:

$$d_S=\frac{\mu-\bar{X}}{S}=\frac{\delta}{S} \tag{5.7.1787}$$

Caution with a small recurring trap! The development above corresponds to a δ which is negative with respect to the first example! The relation is a little bit different in the case where δ is positive but it does not matter because the power of the test is the same in absolute value!

For the sample size it quite simple. We have by equating the quantiles:

$$Z_{1-\beta}=Z_{\alpha/2}-d_\sigma\sqrt{n} \tag{5.7.1788}$$

And therefore in bilateral:

$$\boxed{n=\left(\frac{Z_{\alpha/2}-Z_{1-\beta}}{d_\sigma}\right)^2} \tag{5.7.1789}$$

where we see that if the power of the test is imposed as being equal to 50%, with having therefore $Z_{1-\beta}$ that is 0 then we fall back (!) on the relation of the sample size for the Normal distribution proved earlier above:

$$n=\left(\frac{Z_{\alpha/2}}{d_\sigma\sqrt{n}}\right)^2 \tag{5.7.1790}$$

Note also that we sometimes find in the literature the prior-previous relation (the sample size n such that power of the test is at least $1-\beta$) as follows:

$$n=\frac{\sigma^2\left(Z_{1-\alpha/2}+Z_{1-\beta}\right)^2}{(\mu_0-\mu_A)^2} \tag{5.7.1791}$$

Obviously we can set other parameters to determine the value of the remaining variable. We could also, for example, look for the value of the power of the test by fixing the standard deviation, the sample size and the risk threshold, etc.

One reader offered us a very elegant way of finding the same result with much less developments... Indeed, you need only to see in the previous figure that we have:

$$Z_{\beta}\frac{\sigma}{\sqrt{n}}+\bar{X}=Z_{1-\alpha/2}\frac{\sigma}{\sqrt{n}}+\mu \tag{5.7.1792}$$

equality from which we draw immediately an equivalent relation to the two previous one (which obviously gives the same numerical result):

$$n=\left(\frac{\sigma\left(Z_{\beta}-Z_{1-\alpha/2}\right)}{(\mu-\bar{X})}\right)^2 \tag{5.7.1793}$$

In practice, the sample standard deviation will usually be used in the analysis (thus a T-test or interval will be calculated instead of a Z-test or interval). In that case, there is greater uncertainty in the estimate, which must be incorporated into the sample size estimate. For the case of testing the mean of a normal population, the relation will be:

$$n=\left(\frac{\hat{\sigma}\left(T_{\beta,n-1}-T_{1-\alpha/2,n-1}\right)}{(\mu-\bar{X})}\right)^2 \tag{5.7.1794}$$

Remark

The attentive reader will have perhaps noticed that we assumed in the previous developments that the standard deviation of the mean of the null hypothesis and that of the alternative one is implicitly assumed to be the same... In practice this is almost all the time so, this is why almost all statistical software require only one standard deviation to calculate the power of the 1-Sample Z Test. However, for some rare academic softwares, they ask the standard deviation of the two means. But then the above mathematical developments are obviously different.

A test power analysis may have several facets:

1. We know the level of the test, the sample size and effect size (implicitly the difference) and we seek to calculate its power. This allows us to see if our experimental device is properly calibrated.
2. We know the desired test power, the risk threshold level and effect size to detect. We seek then to calculate the sample size needed to mount an effective experimental design.
3. We know the desired test power, the risk threshold level and sample size and we seek to know the effect size we can hope to highlight.

Without exception, we consider as unnecessary to show a test if the expected power is less than 80%. This power corresponds to a 80% probability of not rejecting the null hypothesis wrongly or, what remains to the same: a 20% of Type II error.

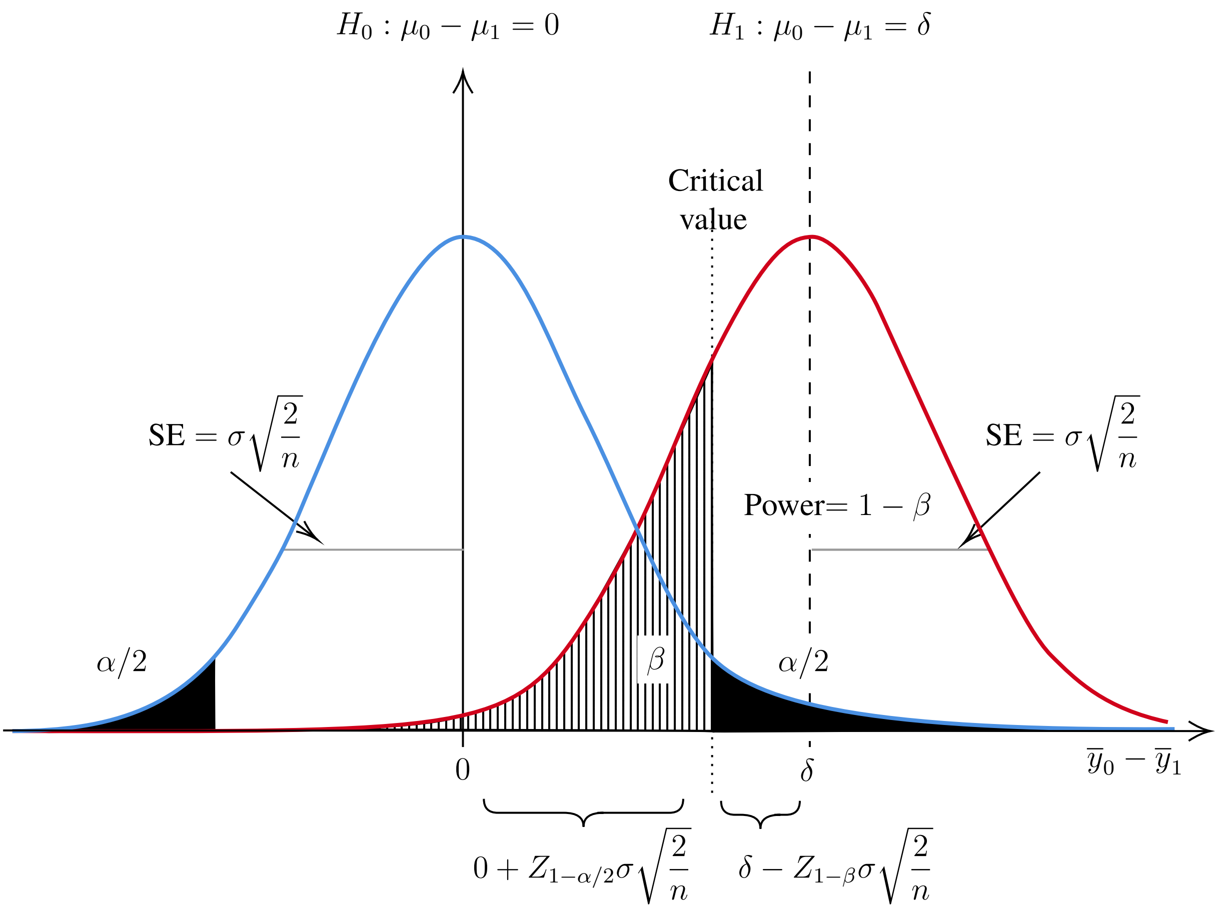
Obviously, it is possible to make the same reasoning (analytically when possible, otherwise numerically) with absolutely ALL the hypothesis tests that we have seen until now. So as there is a little more than a hundred hypothesis testing in the field of statistics as we have already mentioned... it is obvious that we're not going to have.... fun ... to make the same developments to determine the sample size, effect size and power for all these tests but only for the classics one. As long as we have computers at our disposal with the algorithms integrated by computer scientists, we do not need to redo any developments that would not bring much. Moreover, the majority of statistical softwares can calculate usually the power of only 5 to 10 common tests.

Remark

We will not deal with parametric statistical tests for the detection of outliers in this textbook as the Q-Dixon's test or Grubb's test and this just because they have too empirical origin and that they have no interest analytically speaking. By cons, if some readers insist, and that we have the time, we can put the details on these tests with detailed algorithms for calculating critical values using a simple spreadsheet and Monte Carlo technique with any distribution of their choice (but not only for data following a Normal law contrary to what is written in most books).

5.7.13.3.3 Power of the two sample Z-test and T-test

This figure below (taken from van Belle) illustrates some important basic concepts that will follow:



$H_0 : \mu_0 - \mu_1 = 0$
$H_1 : \mu_0 - \mu_1 = \delta$
Critical value
$\text{SE} = \sigma\sqrt{\frac{2}{n}}$
$\text{SE} = \sigma\sqrt{\frac{2}{n}}$
Power$= 1 - \beta$
$\alpha/2$
β
$\alpha/2$
0
δ
$\overline{y}_0 - \overline{y}_1$
$0 + Z_{1-\alpha/2}\sigma\sqrt{\frac{2}{n}}$
$\delta - Z_{1-\beta}\sigma\sqrt{\frac{2}{n}}$

Each curve represents the difference between two groups on some continuous measurement ($\Delta = y_0 - y_1$). The null hypothesis, that there is no difference between the two groups, is represented by the curve on the left ($\mu_\Delta = 0$). The alternative hypothesis, that there is some difference between the two groups, is represented by the curve on the right ($\mu_\Delta = \delta$). Each distribution is also characterized by its variance (σ^2) which is usually assumed to be the same (or similar enough...) for both distributions. The relationship between the standard error of the differences in means and the standard deviation[60]:

$$\text{SE}_\Delta = \sigma\sqrt{\frac{2}{n}} \tag{5.7.1795}$$

allows us to set up calculations for the sample size, n. The term $\sigma\sqrt{\frac{2}{n}}$ derives from the standard error for the difference between two means with equal variances.

The reader can also see the (conditional) probabilities about test results and true underlying differences that make up the classical components of sample size calculations:

- type I error or $\alpha = P(+$ result | - difference), i.e.. false positive
  - the traditional black-shaded $0.05/2$ tails on the null hypothesis
- type II error or $\beta = P($ result | + difference), i.e. false negative
  - the traditional hatched 0.2 left-handed tail on the alternative hypothesis
- power or $1 - \beta = P(+$ result $|$ + difference), i.e. true positive
  - the area to the right of β on the alternative hypothesis

Finally, you can also see that you can increase the power of a study without increasing the sample size by:

1. Measuring your outcome more precisely, which decreases the variance or "shrinks" the two curves towards their respective means and increases the area under the curve to the right of the critical value, or
2. Studying a greater effect size, in this case the difference between $\mu_\Delta = 0$ and $\mu_\Delta = \delta$, which separates the curves from each other and similarly increases the area under the curve to the right of the critical value

Returning to the figure above, the critical value is the point where the upper value of α on the null curve and the value for β on the alternative curve meet. This defines the point at which you accept or reject your null hypothesis, and sets up the sample size equation as:

$$0 + Z_{1-\alpha/2}\sigma\sqrt{\frac{2}{n}} = \delta - Z_{1-\beta}\sigma\sqrt{\frac{2}{n}} \tag{5.7.1796}$$

---

[60] This is based on: $\sqrt{\frac{\sigma^2}{n_1} + \frac{\sigma^2}{n_2}} = \sigma\sqrt{\frac{1}{n_1} + \frac{1}{n_2}} \cong \sigma\sqrt{\frac{2}{n}}$

Solving for n allows us to calculate sample sizes "sample size for difference of homoscedastic means":

$$\boxed{n=\frac{2\left(Z_{1-\alpha/2}+Z_{1-\beta}\right)^2}{\left(\frac{\mu_1-\mu_2}{\sigma}\right)^2}=\frac{2\left(Z_{1-\alpha/2}+Z_{1-\beta}\right)^2}{\left(\frac{\delta}{\sigma}\right)^2}}\tag{5.7.1797}$$

Substituting the usual values of 1.96 for α and 0.84 for β, and defining the denominator as the square of the standardized difference (Δ^2), yields the rule of thumb called "Lehr's equation" or the "Rule of 16" :

$$n=\frac{2(1.96+0.84)^2}{\Delta^2}=\frac{15.68}{\left(\frac{\delta}{\sigma}\right)^2}\cong\frac{16\sigma^2}{\delta^2}\tag{5.7.1798}$$

✍**Example:**

Say, for example, you want to demonstrate a 10 point difference in IQ between two groups, one of which is exposed to a potential toxin, the other of which is not. Using a mean population IQ of 100, and a standard deviation of 20 :

$$n=\frac{16}{(100-90/20)^2}=\frac{16}{(0.5)^2}=64$$

or a total sample size of 128.

We can re-arrange Lehr's equation to solve for the detectable standardized difference between two populations:

$$n=\frac{16}{(\Delta)^2}\Leftrightarrow\Delta=\frac{4}{\sqrt{n}}$$

For the unstandardised difference:

$$\delta=\frac{4\sigma}{\sqrt{n}}$$

So, for example, we were interested in knowing the difference in mean IQ we could detect with a sample size of 50. Applying the above relation we get about 12 IQ points.

In practice, the sample standard deviation will usually be used in the analysis (thus a T-test or interval will be calculated instead of a Z-test or interval). In that case, there is greater uncertainty in the estimate, which must be incorporated into the sample size estimate. For the case of testing the mean of a normal population, the formula is now:

$$\boxed{n=\frac{2\left(T_{1-\alpha/2,n-1}+Z_{1-\beta,n-1}\right)^2}{\left(\frac{\mu_1-\mu_2}{\hat{\sigma}}\right)^2}=\frac{2\left(T_{1-\alpha/2,n-1}+T_{1-\beta,n-1}\right)^2}{\left(\frac{\delta}{\hat{\sigma}}\right)^2}}\tag{5.7.1799}$$

5.7.13.3.4 Power of the one and two samples P-test

Same as with the confidence interval of the Normal distribution with known theoretical standard deviation (that is to say the entire population), we can determine the number of individuals (sample size) for a fixed test power for the 1 sample proportion test studied in detail earlier. For this, we use the same technique as for the power of the one sample Z-test. We write so at first:

$$Z_\beta\sqrt{\frac{\hat{p}\hat{q}}{n}}+\hat{p}=Z_{1-\alpha/2}\sqrt{\frac{pq}{n}}+p \tag{5.7.1800}$$

Hence we deduce:

$$\boxed{n=\left(\frac{Z_\beta\sqrt{\hat{p}\hat{q}}-Z_{1-\alpha/2}\sqrt{pq}}{p-\hat{p}}\right)^2} \tag{5.7.1801}$$

So if the power is 50% we fall back on:

$$n=\frac{Z_{1-\alpha/2}^2pq}{\delta^2} \tag{5.7.1802}$$

Report Definitions

Power is the probability of rejecting a false null hypothesis. It should be close to one.
N is the size of the sample drawn from the population. To conserve resources, it should be small.
Alpha is the probability of rejecting a true null hypothesis. It should be small.
Beta is the probability of accepting a false null hypothesis. It should be small.
P0 is the value of the population proportion under the null hypothesis.
P1 is the value of the population proportion under the alternative hypothesis.

Summary Statements

A sample size of 50 achieves 8% power to detect a difference (P1-P0) of 0.0500 using a two-sided binomial test. The target significance level is 0.0500. The actual significance level achieved by this test is 0.0328. These results assume that the population proportion under the null hypothesis is 0.5000.

Power Analysis of One Proportion

Chart Section

Figure 5.188: Power analysis table of one proportion test from PSS software

For the power of the test of the difference of two proportions (two sample proportion test), with the objective of determining the sample size, we have to put $n=n_1=n_2$. Therefore the developments we get during our study of the test of the difference of two proportions can be written:

$$Z=\dfrac{\hat{p}_1-\hat{p}_2}{\sqrt{\hat{p}(1-\hat{p})\left(\dfrac{1}{n_1}-\dfrac{1}{n_2}\right)}}=\dfrac{\hat{p}_1-\hat{p}_2}{\sqrt{\dfrac{2\hat{p}(1-\hat{p})}{n}}}=\dfrac{\hat{p}_1-\hat{p}_2}{\sqrt{\dfrac{2\hat{p}\hat{q}}{n}}} \qquad (5.7.1803)$$

with therefore:

$$\hat{p}=\dfrac{n_1\hat{p}_1+n_2\hat{p}_2}{n_1+n_2}=\dfrac{n(\hat{p}_1+\hat{p}_2)}{2n}=\dfrac{\hat{p}_1+\hat{p}_2}{2} \qquad (5.7.1804)$$

In the same way that we did for the Z-test and the one sample p-test, we have:

$$Z_\beta\sqrt{\mathrm{V}(\hat{p}_2-\hat{p}_1)}+(\hat{p}_2-\hat{p}_1)=Z_{1-\alpha/2}\sqrt{\dfrac{2\hat{p}\hat{q}}{n}}+\dfrac{\hat{p}_1+\hat{p}_2}{2} \qquad (5.7.1805)$$

Therefore:

$$Z_\beta\sqrt{\mathrm{V}(\hat{p}_2-\hat{p}_1)}+(\hat{p}_2-\hat{p}_1)=Z_{1-\alpha/2}\sqrt{\frac{2\hat{p}\hat{q}}{n}}+\hat{p} \qquad (5.7.1806)$$

So what it takes us to assume that the real difference between the two proportions is the average (which is debatable...).

But we also have (as the samples are independent and using the property of the variance):

$$Z_\beta\sqrt{\mathrm{V}(\hat{p}_2)+\mathrm{V}(\hat{p}_1)}+(\hat{p}_2-\hat{p}_1)=Z_{1-\alpha/2}\sqrt{\frac{2\hat{p}\hat{q}}{n}}+\hat{p} \qquad (5.7.1807)$$

Therefore:

$$Z_\beta\sqrt{\frac{\hat{p}_1\hat{q}_1}{n}+\frac{\hat{p}_2\hat{q}_2}{n}}+(\hat{p}_2-\hat{p}_1)=Z_{1-\alpha/2}\sqrt{\frac{2\hat{p}\hat{q}}{n}}+\hat{p} \qquad (5.7.1808)$$

That gives obviously:

$$Z_\beta\sqrt{\frac{\hat{p}_1\hat{q}_1+\hat{p}_2\hat{q}_2}{n}}+(\hat{p}_2-\hat{p}_1)=Z_{1-\alpha/2}\sqrt{\frac{2\hat{p}\hat{q}}{n}}+\hat{p} \qquad (5.7.1809)$$

We have then after rearrangement:

$$\boxed{n=\left(\frac{Z_\beta\sqrt{\hat{p}_1\hat{q}_1+\hat{p}_2\hat{q}_2}-Z_{1-\alpha/2}\sqrt{2\hat{p}\hat{q}}}{\hat{p}-(\hat{p}_2-\hat{p}_1)}\right)^2} \qquad (5.7.1810)$$

The `R` software has a function named `power.prop.test( )` that helps us play with the above relation.

Remark

You might find other relations in the literature for the sample size of the one sample or two sample proportions tests. But however be careful...!!! Sadly some textbooks calculates the n based on how to get a given confidence interval, and not on how to get a given power (hence the absence of Z_β the in the corresponding relations). So this has nothing to do with the sample size to get a given power but instead what is the sample size to do p-hacking.......

Now consider that the power is not given to find the sample size, but that we have the sample size and we want to computer the power!

As companion example consider that we are trying to test whether the sex ratio of some sampled individuals significantly differs from the expected sex ratio of 1 assuming we have $n = 64$, of which female=34 and male=30.

In order to find the power, we need to have a specific alternative in mind. Suppose that null hypothesis is $H_0 : p = 0.5$ vs. $H_1 : p > 0.5$, where $p = P(\text{Female})$. Also suppose we have $n = 64$ and you want the power of a test at level $\alpha = 0.05$ against the specific alternative $p = 0.6$.

For an exact binomial test, we need to first to find the critical value c such that $P(X \leq c \,|\, n = 64, p = 0.5)$ is maximized, but still below 0.95. With any statistical software or even spreadsheet software we can find that this value is $c = 40$ (cautious! many statistical softwares do a Normal approximation of the binomial law in such a power calculation...). Then the power of this test against the alternative value $p = 0.6$ is given by $P(X \leq 40 \,|\, n = 64, p = 0.6) = 0.3927$.

5.7.13.3.5 Power calculation based on simulations

In more complicated models it is not possible to determine an explicit expression for the power of a test and calculation of power based on simulations can be an attractive approach. Sometimes it may also just be easier to let the computer do the job by running simulations rather than to get bugged down in derivations of explicit expressions for power even though they may in fact be possible to derive.

Recall that power is the probability of getting a significant result when there is in fact a difference, thus in the long run it is the proportion of significant results to the total number of tests:

$$\text{power} = \frac{\text{no. } p\text{-values } < \alpha}{\text{no. tests}} \tag{5.7.1811}$$

We can let the computer generate random data from the model under the alternative hypothesis and then perform the significance test. We can even do that many many times and record the p-values allowing us to calculate the power via the relation above.

If the number of cases is already available, power calculations are not helpful. It is an attempt to interpret a result retrospectively via the power, which is not useful because no direct connection can be shown. Post-hoc power calculations should therefore be avoided. This has also been discussed in the literature for several years and a well-known article on the subject is [256].

Now that we have seen what are p-values, confidence intervals and power in the framework of null hypothesis statistical testing, the reader interested to take a look at a paper dedicated only to the topic of the most common misinterpretations of these three concepts can refer to: *Statistical tests, P values, confidence intervals, and power: a guide to misinterpretations* (see [216]).

5.7.13.4 A/B Tests

"A/B testing" (also named "bucket tests" or "split-run testing") is a randomized experiment with two variants, A and B. It includes application of statistical hypothesis testing or "two-sample hypothesis testing" as used in the field of statistics. A/B testing is a way to compare two versions of a single variable, typically by testing a subject's response to variant A against variant B, and determining which of the two variants is more effective.

Booming in business and a staple analysis in medical trials, the A/B tests assesses the effect of an intervention or treatment by comparing its success rate with that of a control condition. As the name implies, two versions (A and B) are compared, which are identical except for one variation that might affect a user's behaviour. Version A might be the currently used version (control), while version B is modified in some respect (treatment). For instance, on an e-commerce website the purchase funnel is typically a good candidate for A/B testing, as even marginal improvements in drop-off rates can represent a significant gain in sales. Significant improvements can sometimes be seen through testing elements like copy text, layouts, images and colors, but not always.

Remark

When running an A/B tests on something and regularly check ongoing experiments for significant results, you must be careful to not fall into the trap that statisticians call "repeated significance testing errors". Indeed, the significance calculation makes always critical assumption that we have that the sample size fixed in advance! If we wait and the sample size is too big, we fall again in the p-hacking case where the sample size is too big and then creates a false significant test.

Let us see three typical A/B tests by ascending order of mathematical complexity (the first one may be considered as a "frequentist test" and the two others as "bayesian tests").

5.7.13.4.1 Naive proportion approach

The most naive A/B test approach is completely based on the one-proportion p test" that is given for reminder (see page 872) by:

$$\hat{p}-Z_{\alpha/2}\sqrt{\frac{\hat{p}(1-\hat{p})}{n}}\leq p\leq \hat{p}+Z_{\alpha/2}\sqrt{\frac{\hat{p}(1-\hat{p})}{n}} \tag{5.7.1812}$$

but where the notation is traditionally changed as following:

$$\widehat{\text{CR}}-Z_{\alpha/2}\sqrt{\frac{\widehat{\text{CR}}(1-\widehat{\text{CR}})}{n}}\leq \text{CR}\leq \widehat{\text{CR}}+Z_{\alpha/2}\sqrt{\frac{\widehat{\text{CR}}(1-\widehat{\text{CR}})}{n}} \tag{5.7.1813}$$

where CR is the abbreviation of "conversion rate".

Practitioners of that naive test also define the "uplift" as being simply the relative increase in conversion rate between Group A and Group B. It is possible to have negative uplift if our Control group is more effective than the new Test group. Here is the expression:

$$\text{Uplift}=\frac{\text{Conversion rate Test group}}{\text{Conversion rate Control group}}-1 \tag{5.7.1814}$$

Obviously using the standard error measure of the one proportion p test and Z-value we can also compute the minimum and maximum expected uplift within a specific level of confidence if needed!

5.7.13.4.2 Fieller's test (ratio of two means)

The purpose of the "Fieller's test" is the calculation of a confidence interval for the ratio of two means. Its is an especially trendy test in the field of webdesign when two design or user interface of a same website (or the number of clicks) have to be compared. The Fieller's test is also commonly known under the name "A/B test for means".

Let us consider X and Y two random variables Normally distributed representing averages of samples of size n and m respectively and having same variance, such that:

$$\begin{aligned}X &= \mathcal{N}\left(\mu,\frac{\sigma^2}{n}\right)=\mathcal{N}(\mu,a\sigma^2)\\ Y &= \mathcal{N}\left(\nu,\frac{\sigma^2}{m}\right)=\mathcal{N}(\nu,b\sigma^2)\end{aligned} \tag{5.7.1815}$$

So this is a homoscedastic case and then in practice we take the global standard deviation.

In reality, however, we will have access only to the estimators:

$$X=\mathcal{N}\left(\hat{\mu},\frac{\hat{\sigma}^2}{n}\right)=\mathcal{N}(\hat{\mu},aS^2)Y \quad =\mathcal{N}\left(\hat{\nu},\frac{\hat{\sigma}^2}{m}\right)=\mathcal{N}(\hat{\nu},bS^2) \tag{5.7.1816}$$

What interests us is to build a confidence interval for the ratio:

$$\theta=\frac{\mu}{\nu} \tag{5.7.1817}$$

And this is the purpose of Fieller's test obviously!

The idea is then to compute and to group the two random variables into one:

$$X-\theta Y \tag{5.7.1818}$$

which by the null hypothesis will therefore follow a random variable of the type:

$$\mathcal{N}(0,(a+\theta^2 b)\sigma^2) \tag{5.7.1819}$$

We then have in extenso:

$$\frac{X-\theta Y}{\sigma\sqrt{a+\theta^2 b}}=\mathcal{N}(0,1)=Z \tag{5.7.1820}$$

If the standard deviation can only be estimated, we know that we then have:

$$\frac{X-\theta Y}{S\sqrt{a+\theta^2 b}}=T(m+n-2)=T(k) \tag{5.7.1821}$$

It follows, of course, that:

$$P\left(-T_{\alpha/2}(k)\leq\frac{X-\theta Y}{S\sqrt{a+\theta^2 b}}\leq T_{\alpha/2}(k)\right)=1-\alpha \tag{5.7.1822}$$

By symmetry of the Student's law we can therefore write that:

$$P\left(\frac{(X-\theta Y)^2}{S^2(a+\theta^2 b)}\right)=1-\alpha \tag{5.7.1823}$$

After rearrangement, we get:

$$P\left((Y^2-bS^2T^2_{\alpha/2}(k))\theta^2-2XY\theta+(X^2-aS^2T^2_{\alpha/2}(k))\leq 0\right)=1-\alpha \tag{5.7.1824}$$

There are now two interesting situations to consider depending on the sign of the coefficient θ^2 but let's put it aside for now concentrating only on the roots of the polynomial in the parenthesis. We then have (see section Calculus page 1383):

$$\theta_{1,2}=\frac{2XY\pm\sqrt{(-2XY)^2-4(Y^2-bS^2T^2_{\alpha/2}(k))(X^2-aS^2T^2_{\alpha/2}(k))}}{2(Y^2-bS^2S^2_{\alpha/2}(k))} \tag{5.7.1825}$$

This is simplified immediately into:

$$\theta_{1,2}=\frac{XY\pm\sqrt{(XY)^2-(Y^2-bS^2T^2_{\alpha/2}(k))(X^2-aS^2T^2_{\alpha/2}(k))}}{Y^2-bS^2S^2_{\alpha/2}(k)} \tag{5.7.1826}$$

The development in the root gives:

$$\theta_{1,2}=\frac{XY\pm\sqrt{aY^2S^2T_{\alpha/2}(k)+bX^2S^2T^2_{\alpha/2}(k)-abS^4T^4_{\alpha/2}(k)}}{Y^2-bS^2T^2_{\alpha/2}(k)} \tag{5.7.1827}$$

What can be rewritten in a form that will be useful to us:

$$\theta_{1,2}=\frac{\dfrac{X}{Y}\pm\dfrac{1}{Y}\sqrt{aS^2T_{\alpha/2}(k)+b\left(\dfrac{X}{Y}\right)^2S^2T^2_{\alpha/2}(k)-\dfrac{1}{Y^2}abS^4T^4_{\alpha/2}(k)}}{1-\dfrac{bS^2T^2_{\alpha/2}(k)}{Y^2}} \tag{5.7.1828}$$

Let us put:

$$g=\frac{bS^2T^2_{\alpha/2}(k)}{Y^2} \tag{5.7.1829}$$

Our roots can then be written:

$$\theta_{1,2}=\frac{\dfrac{X}{Y}\pm\sqrt{aS^2T_{\alpha/2}(k)+X^2g-gaS^2T^2_{\alpha/2}(k)}}{1-g} \tag{5.7.1830}$$

or:

$$\theta_{1,2}=\frac{\dfrac{X}{Y}\pm\dfrac{1}{Y}\sqrt{X^2g+aS^2T^2_{\alpha/2}(k)(1-g)}}{1-g} \tag{5.7.1831}$$

or otherwise:

$$\theta_{1,2}=\frac{\dfrac{X}{Y}\pm\dfrac{1}{Y}\sqrt{X^2g+a\dfrac{gY^2}{b}(1-g)}}{1-g} \tag{5.7.1832}$$

We do a last simplification:

$$\theta_{1,2}=\frac{\dfrac{X}{Y}\pm\sqrt{\left(\dfrac{X}{Y}\right)^2g+\dfrac{a}{b}g(1-g)}}{1-g} \tag{5.7.1833}$$

Who are therefore for recall the roots of:

$$P\left((Y^2-bS^2T^2_{\alpha/2}(k))\theta^2-2XY\theta+(X^2-aS^2T^2_{\alpha/2}(k))\leq 0\right)=1-\alpha \tag{5.7.1834}$$

The coefficient of θ^2 in the polynomial is $Y^2-bS^2T^2_{\alpha/2}(k)$. Therefore:

- If the latter is greater than zero, then the parabola (see section Analytical Geometric page 2776) is concave (seen from above) and the confidence interval is then between the two roots of the parabola (because the values there are negative according to the imposed inequality).
- If the coefficient of θ^2 in the polynomial is negative then the parabola is convex (seen from above) and the confidence interval is then outside the two roots of the parabola because the values there are negative according to the imposed inequality).
- If the coefficient of θ^2 has a near zero probability of being equal to zero we can ignore this scenario.

Obviously only the first case interests us because the second is difficult to interpret (the intervals would have the infinite bounds which is unrealistic and especially useless). So we must have:

$$Y^2-bS^2T^2_{\alpha/2}(k)>0 \tag{5.7.1835}$$

What can be written:

$$\frac{bS^2T^2_{\alpha/2}(k)}{Y^2}<1 \tag{5.7.1836}$$

Therefore:

$$g<1 \tag{5.7.1837}$$

✍**Example:**

Let us consider the case where we have:

$$\begin{aligned} X &= \mu_X = 160.3684 \\ m &= 19 \\ Y &= \mu_Y = 155 \\ n &= 19 \\ S &= 13.44278 \end{aligned} \tag{5.7.1838}$$

Therefore:

$$\begin{aligned} a &= \frac{1}{m} = \frac{1}{19} \\ b &= \frac{1}{n} = \frac{1}{19} \\ k &= m+n-2 = 36 \\ T^2_{\alpha/2}(k) &= T^2_{5\%/2}(36) = 1.688298 \end{aligned} \tag{5.7.1839}$$

We have:

$$\frac{X}{Y} = \frac{160.3684}{155} \cong 1.034635 \tag{5.7.1840}$$

and:

$$g = \frac{bS^2T^2_{\alpha/2}(k)}{Y^2} = 0.00112839 \tag{5.7.1841}$$

As well as (we give this calculation because some statistical software - `R` in particular - given them in the output while normally it is only useful for Student's t test of two independent homoscedastic samples):

$$\begin{aligned} \mathrm{V}_R &= \frac{(m-1)S_1^2+(n-1)S_2^2}{m+n-2} = 178.228 \\ T(36) &= \frac{(X-Y)-(\mu-\nu)}{\sqrt{\mathrm{V}_r\left(\dfrac{1}{m}+\dfrac{1}{n}\right)}} = \frac{X-Y}{\sqrt{\mathrm{V}_r\left(\dfrac{1}{m}+\dfrac{1}{n}\right)}} = 1.2397 \end{aligned} \tag{5.7.1842}$$

We then have the following interval between the two roots of the parabola:

$$\theta_{1,2} = \frac{\dfrac{X}{Y} \pm \sqrt{\left(\dfrac{X}{Y}\right)^2 g + \dfrac{a}{b}g(1-g)}}{1-g} = \{0.987, 1.084\} \tag{5.7.1843}$$

We can go a little further by considering the case where:

$$\frac{\text{cov}(X,Y)}{\sigma^2} = \rho \Leftrightarrow (X,Y) = \sigma^2\rho \tag{5.7.1844}$$

Either within the estimated framework:

$$\frac{\text{cov}(X,Y)}{\sigma^2} = S^2R \tag{5.7.1845}$$

This gives us the following distribution (assuming Normality) for the random variable grouping the first two according to $X - \theta Y$:

$$\mathcal{N}\left(0, aS^2 - 2\theta RS^2 + b\theta^2 S^2\right) \tag{5.7.1846}$$

We then have:

$$\frac{X - \theta Y}{S\sqrt{a - 2\theta R + b\theta^2}} = T(m + n - 2) = T(k) \tag{5.7.1847}$$

And therefore, as before, we can write:

$$P\left(\frac{(X - \theta Y)^2}{S^2(a - 2\theta R + b\theta^2)} \leq T^2_{\alpha/2}\right) = 1 - \alpha \tag{5.7.1848}$$

What we can rewrite in the following form:

$$P\left((X - \theta Y)^2 \leq T^2_{\alpha/2}(k)S^2(a - 2\theta R + b\theta^2)\right) = 1 - \alpha \tag{5.7.1849}$$

What developed gives:

$$P\left(X^2 - 2\theta XY + \theta^2 Y^2 \leq T_{\alpha/2}(k)S^2 a - 2\theta RT^2_{\alpha/2}(k)S^2 + b\theta^2 T_{\alpha/2}(k)S^2\right) = 1 - \alpha \tag{5.7.1850}$$

We group together the terms as earlier above:

$$P\left(\theta^2(Y^2 - bT^2_{\alpha/2}(k)S^2) - 2\theta(XY - RT^2_{\alpha/2}S^2) + (X^2 - T^2_{\alpha/2}S^2 a) \leq 0\right) \tag{5.7.1851}$$

We then have for roots after simplification of the numerical factors:

$$\theta_{1,2} = \frac{XY \pm \sqrt{(XY - RT^2_{\alpha/2}(k)S^2)^2 - (Y^2 - bT^2_{\alpha/2}(k)S^2)(X^2 - T^2_{\alpha/2}S^2 a)}}{Y^2 - bT^2_{\alpha/2}(k)S^2} \tag{5.7.1852}$$

After the simplification method seen above (pfff...) we finally get:

$$\theta_{1,2} = \frac{\dfrac{X}{Y} \pm \dfrac{1}{Y^2}ST^2_{\alpha/2}(k)\sqrt{-2RXY + RS^2T^2_{\alpha/2}(k) + bX^2 + a(Y^2 - bS^2T^2_{\alpha/2}(k))}}{1 - g} \tag{5.7.1853}$$

5.7.13.4.3 Bayesian A/B testing for binary outcomes

For a binary-outcome test (e.g. a test of conversion rates), the probability that B will beat A in the long run is given by[61]:

$$P(p_B > p_A) = \sum_{i=0}^{\alpha_B - 1} \frac{B(\alpha_A + i, \beta_B + \beta_A)}{(\beta_B + i)B(1 + i, \beta_B)B(\alpha_A, \beta_A)} \tag{5.7.1854}$$

where:

---

[61] The derivation and text mainly comes from https://www.evanmiller.org/bayesian-ab-testing.html.

- α_A is one plus the number of successes for A
- β_A is one plus the number of failures for A
- α_B is one plus the number of successes for B
- β_B is one plus the number of failures for B
- B is the beta function as seen on page 761 (keep in mind we must have $a>0,b>0$):

$$P_{a,b}(x)=\frac{x^{a-1}(1-x)^{b-1}}{B(a,b)}1_{]0,1[}=\frac{x^{a-1}(1-x)^{b-1}}{\int\limits_0^1 x^{a-1}(1-x)^{b-1}\mathrm{d}x}1_{]0,1[} \tag{5.7.1855}$$

Proof 5.48.4. The beta distribution is a convenient prior distribution for modelling a binomial parameter p (as we know that this is one of the rare distribution that has a domain of definition in $[0,1]$). Starting from a non-informative prior, the distribution of p after S successes and F failures is given by $B(S+1,F+1)$. For the remainder of the discussion let $\alpha=S+1$ and $\beta=F+1$, which are just the two parameters of the beta distribution for the belief.

Now suppose we have two experimental branches (A and B) and have a Bayesian belief for each one:

$$p_A=B(\alpha_A,\beta_A)\qquad p_B=B(\alpha_B,\beta_B) \tag{5.7.1856}$$

Using the probability density function of the beta distribution as prior for p, we can get the total probability that p_B is greater than p_A by integrating the joint distribution over all values for which p_B>p_A:

$$P(p_B>p_A)=\int\limits_0^1\int\limits_{p_A}^1\frac{p_A^{\alpha_A-1}(1-p_A)^{\beta_A-1}}{B(\alpha_A,\beta_A)}\frac{{p_B}^{\alpha_B-1}(1-p_B)^{\beta_B-1}}{B(\alpha_B,\beta_B)}\mathrm{d}p_B\mathrm{d}p_A \tag{5.7.1857}$$

sometimes named the "Euler's hypergeometric integral".

Evaluating the inner integral:

$$\begin{aligned}\int\limits_{p_A}^1\frac{{p_B}^{\alpha_B-1}(1-p_B)^{\beta_B-1}}{B(\alpha_B,\beta_B)}\mathrm{d}p_B&=\int\limits_{p_A}^1\frac{{p_B}^{\alpha_B-1}(1-p_B)^{\beta_B-1}}{\int\limits_0^1 x^{a-1}(1-x)^{b-1}\mathrm{d}x}\mathrm{d}p_B\\&=\frac{1}{\int\limits_0^1 x^{a-1}(1-x)^{b-1}\mathrm{d}x}\int\limits_{p_A}^1{p_B}^{\alpha_B-1}(1-p_B)^{\beta_B-1}\mathrm{d}p_B\\&=\frac{1}{B(\alpha_B,\beta_B)}\int\limits_{p_A}^1{p_B}^{\alpha_B-1}(1-p_B)^{\beta_B-1}\mathrm{d}p_B\end{aligned} \tag{5.7.1858}$$

the relation becomes:

$$P(p_B > p_A) = 1 - \int\limits_0^1 \frac{p_A^{\alpha_A - 1}(1-p_A)^{\beta_A - 1}}{B(\alpha_A, \beta_A)} I_{p_A}(\alpha_B, \beta_B) \mathrm{d}p_A \tag{5.7.1859}$$

Where I_x is the incomplete beta function (see section Statistics page 764). Using the identity $I_x(1,b) = 1-(1-x)b$, the recursive relationship:

$$I_x(a,b) = I_x(a-1,b) - \frac{x^{a-1}(1-x)^b}{(a-1)B(a-1,b)} \tag{5.7.1860}$$

and the fact that α and β are integers, we can express I_x as:

$$I_x(a,b) = 1-(1-x)^b - \sum_{j=1}^{a-1} \frac{x^{a-j}(1-x)^b}{(a-j)B(a-j,b)} \tag{5.7.1861}$$

Or equivalently:

$$I_x(a,b) = 1 - \sum_{i=0}^{a-1} \frac{x^i(1-x)^b}{(b+i)B(1+i,b)} \tag{5.7.1862}$$

Our probability integral can therefore be written:

$$\begin{aligned}
P(p_B > p_A) &= 1 - \int\limits_0^1 \frac{p_A^{\alpha_A - 1}(1-p_A)^{\beta_A - 1}}{B(\alpha_A, \beta_A)} I_{p_A}(\alpha_B, \beta_B) \mathrm{d}p_A \\
&= 1 - \int\limits_0^1 \frac{p_A^{\alpha_A - 1}(1-p_A)^{\beta_A - 1}}{B(\alpha_A, \beta_A)} \left(1 - \sum_{i=0}^{\alpha_B - 1} \frac{p_A^i (1-p_A)^{\beta_B}}{(\beta_B + i)B(1+i,\beta_B)}\right) \mathrm{d}p_A \\
&= 1 - 1 + \int\limits_0^1 \frac{p_A^{\alpha_A - 1}(1-p_A)^{\beta_A - 1}}{B(\alpha_A, \beta_A)} \sum_{i=0}^{\alpha_B - 1} \frac{p_A^i (1-p_A)^{\beta_B}}{(\beta_B + i)B(1+i,\beta_B)} \mathrm{d}p_A \\
&= \int_0^1 \sum_{i=0}^{\alpha_B - 1} \frac{p_A^{\alpha_A - 1 + i}(1-p_A)^{\beta_A + \beta_B - 1}}{(\beta_B + i)B(\alpha_A, \beta_A)B(1+i,\beta_B)} \mathrm{d}p_A \\
&= \sum_{i=0}^{\alpha_B - 1} \int\limits_0^1 \frac{p_A^{\alpha_A - 1 + i}(1-p_A)^{\beta_A + \beta_B - 1}}{(\beta_B + i)B(\alpha_A, \beta_A)B(1+i,\beta_B)} \mathrm{d}p_A \\
&= \sum_{i=0}^{\alpha_B - 1} \frac{B(\alpha_A + i, \beta_A + \beta_B)}{(\beta_B + i)B(\alpha_A, \beta_A)B(1+i,\beta_B)} \int\limits_0^1 \frac{p_A^{\alpha_A - 1 + i}(1-p_A)^{\beta_A + \beta_B - 1}}{B(\alpha_A + i, \beta_A + \beta_B)} \mathrm{d}p_A
\end{aligned} \tag{5.7.1863}$$

Finally:

$$\boxed{P(p_B > p_A) = \sum_{i=0}^{\alpha_B - 1} \frac{B(\alpha_A + i, \beta_A + \beta_B)}{(\beta_B + i)B(1+i,\beta_B)B(\alpha_A, \beta_A)}} \tag{5.7.1864}$$

■ Q.E.D.

The reader must know that even if there exist a closed formula, a the day we write these lines, most statistical software implement numerical methods (simulations) to calculate this probability!

Remarks

R1. If we want to assume that each value of p has the same probability, i.e. we have no out-of-data (prior) information that we would like to include in our model, then we can set $\alpha_A = \beta_A = \alpha_B = \beta_B$, that means a uniform distribution for all the values of p in $[0, 1]$ interval.

R2. The reader can refer to our `R` companion free e-book to see how to apply these equations easily on practical cases with a free open-source software and code!

5.7.13.4.4 Bayesian A/B testing for count datas

Analysing count data (for example, if you're comparing the number of sales per salesman, or number of sales week over week) requires a different relation. The probability that group 1 has a higher arrival rate than group 2 is given by:

$$P(\lambda_1 > \lambda_2) = \sum_{k=0}^{\alpha_1 - 1} \frac{(\beta_1+\beta_2)^{-(k+\alpha_2)}\beta_1^k \beta_2^{\alpha_2}}{(k+\alpha_2)B(k+1,\alpha_2)} \tag{5.7.1865}$$

A derivation and implementation follow; they both closely mirror the binary-outcome case.

Proof 5.48.5. Let λ_1 and λ_2 be the Poisson parameter for each group. With a gamma-distributed prior belief (see section Statistics page 767), the posterior beliefs are given by:

$$\lambda_1 = \Gamma(\alpha_1, \beta_1) \qquad \lambda_2 = \Gamma(\alpha_2, \beta_2) \tag{5.7.1866}$$

Using the probability density function of the gamma distribution, we can get the total probability that λ_1 is greater than λ_2 by integrating the joint distribution over all values for which $\lambda_1 > \lambda_2$:

$$P(\lambda_1 > \lambda_2) = \int\limits_0^{+\infty}\int\limits_{\lambda_2}^{+\infty} \Gamma(\alpha_1,\beta_1)\Gamma(\alpha_2,\beta_2)\mathrm{d}\lambda_1\mathrm{d}\lambda_2 = \int\limits_0^{+\infty}\int\limits_{\lambda_2}^{+\infty} \frac{\beta_1^{\alpha_1}\lambda_1^{\alpha_1-1}e^{-\beta_1\lambda_1}}{\Gamma(\alpha_1)}\frac{\beta_2^{\alpha_2}\lambda_2^{\alpha_2-1}e^{-\beta_2\lambda_2}}{\Gamma(\alpha_2)}\mathrm{d}\lambda_1\mathrm{d}\lambda_2 \tag{5.7.1867}$$

Evaluating the inner integral, the equation becomes:

$$\int\limits_0^{+\infty} Q(\alpha_1, \beta_1\lambda_2)\frac{\beta_2^{\alpha_2}\lambda_2^{\alpha_2-1}e^{-\beta_2\lambda_2}}{\Gamma(\alpha_2)}\mathrm{d}\lambda_2 \tag{5.7.1868}$$

Where Q is the upper incomplete regularized gamma function (see section Differential and Integral Calculus page 1578). Using the identity $Q(1, z) = e^{-z}$ and the recursive relationship:

$$Q(a+n, z) = Q(a, z) + z^a e^{-z}\sum_{k=0}^{n-1}\frac{z^k}{\Gamma(a+k+1)} \tag{5.7.1869}$$

we can express Q as (see section Differential and Integral Calculus page 1578):

$$Q(n,z)=e^{-z}\sum_{k=0}^{n-1}\frac{z^k}{\Gamma(k+1)} \tag{5.7.1870}$$

The probability integral can therefore be written (we used the integral already seen during our study of the Gamma function at page 1574):

$$\begin{aligned}P(\lambda_1>\lambda_2)&=\int\limits_0^{+\infty}e^{-\beta_1\lambda_2}\left(\sum_{k=0}^{\alpha_1-1}\frac{(\beta_1\lambda_2)^k}{\Gamma(k+1)}\right)\frac{\beta_2^{\alpha_2}\lambda_2^{\alpha_2-1}e^{-\beta_2\lambda_2}}{\Gamma(\alpha_2)}\mathrm{d}\lambda_2\\&=\sum_{k=0}^{\alpha_1-1}\int\limits_0^{+\infty}\frac{e^{-\beta_1\lambda_2}(\beta_1\lambda_2)^k}{\Gamma(k+1)}\frac{\beta_2^{\alpha_2}\lambda_2^{\alpha_2-1}e^{-\beta_2\lambda_2}}{\Gamma(\alpha_2)}\mathrm{d}\lambda_2\\&=\sum_{k=0}^{\alpha_1-1}\frac{\beta_1^k\beta_2^{\alpha_2}}{\Gamma(k+1)\Gamma(\alpha_2)}\int_0^{+\infty}e^{-(\beta_1+\beta_2)\lambda_2}\lambda_2^{k+\alpha_2-1}\mathrm{d}\lambda_2\\&=\sum_{k=0}^{\alpha_1-1}\frac{\beta_1^k\beta_2^{\alpha_2}}{\Gamma(k+1)\Gamma(\alpha_2)}\frac{\Gamma(k+\alpha_2)}{(\beta_1+\beta_2)^{(k+\alpha_2)}}\\&=\sum_{k=0}^{\alpha_1-1}\beta_1^k\beta_2^{\alpha_2}(\beta_1+\beta_2)^{-(k+\alpha_2)}\frac{\Gamma(k+\alpha_2)}{\Gamma(k+1)\Gamma(\alpha_2)}\frac{k+\alpha_2}{k+\alpha_2}\end{aligned} \tag{5.7.1871}$$

Using $\Gamma(z+1)=z\Gamma(z)$, we have:

$$P(\lambda_1>\lambda_2)=\sum_{k=0}^{\alpha_1-1}\beta_1^k\beta_2^{\alpha_2}(\beta_1+\beta_2)^{-(k+\alpha_2)}\frac{\Gamma(k+\alpha_2+1)}{\Gamma(k+1)\Gamma(\alpha_2)}\frac{1}{k+\alpha_2} \tag{5.7.1872}$$

Replacing the gamma functions with a beta function (see page 761), we have:

$$\boxed{P(\lambda_1>\lambda_2)=\sum_{k=0}^{\alpha_1-1}\frac{(\beta_1+\beta_2)^{-(k+\alpha_2)}\beta_1^k\beta_2^{\alpha_2}}{(k+\alpha_2)B(k+1,\alpha_2)}} \tag{5.7.1873}$$

■ Q.E.D.

Remark

Again, the reader can refer to our R companion free e-book to see how to apply these equations easily on practical cases with a free open-source software and code!

5.7.13.5 Analysis Of VAriance (ANOVA)

"Analysis Of VAriance" is a collection of statistical models used to analyse the differences among group means and their associated procedures (such as "variation" among and between groups), developed by statistician and evolutionary biologist Ronald Fisher. In the ANOVA setting, the observed variance in a particular variable is partitioned into components attributable to different sources of variation.

The main techniques of analysis of variances are the following one (some of them are detailed further below) in the order of most to less used one (and in increasing order of complexity):

- Two variable one-way fixed factor ANOVA (Student T-test)[62]
- One-way fixed factor ANOVA (n independent fixed variables)[63]
- Two-way fixed factor ANOVA with/without repetitions[64]
- Multifactor ANOVA with/without repetition
- Repeated Measures ANOVA (RM-ANOVA)[65]
- Block[66] (randomized) design (ANOVA in blocks)
- Latin square ANOVA
- Greaco-Latin square ANOVA
- Youden square ANOVA[67]
- Split-Plot ANOVA
- Split-Block ANOVA
- Strip-Plot ANOVA
- Split-Split-Plot ANOVA
- Analysis of Covariance (ANCOVA)
- Nested (Hierarchical) analysis of variance (HANOVA)
- Partially Nested ANOVA (PANOVA)
- Multivariate analysis of variance (MANOVA)
- Random effects ANOVA
- Mixed effects (with fixed and random factors) ANOVA
- Cross-Over ANOVA
- Robusts ANOVA (by permutations, M-estimators based)
- ...

and some of the ANOVA above are said "balanced" or "unbalanced", depending if the number of measurement are equal or not equal for each variable and therefore can be calculated with different types of sum of square errors in the unbalance case, named "Type I sum of squares",

---

[62] There is a nonparametric rank-transformed equivalent named Friedman test that we will see further below.

[63] There is a nonparametric rank-transformed equivalent named Kruskal-Wallis where the post-hoc will be typically the Mann-Whitney U test that we will all see further below.

[64] In facts for all ANOVA there exist a mathematical variant for repeated measurements.

[65] Repeated measures ANOVA is the equivalent of the one-way ANOVA, but for related, not independent groups, and is the extension of the dependent T-test. A repeated measures ANOVA is also referred to as a within-subjects ANOVA or ANOVA for correlated samples.

[66] There is a variant where blocked are considered as fixed or random... In facts the block is considered as an another factor. Then it's just a two-way ANOVA

[67] These are incomplete Latin squares, in which the number of columns is not equal to the number of rows.

"Type II sum of squares" or "Type III sum of squares". So we can say that there is at least between 20 and 60 types of different ANOVA[68] (including the special variations but without including the randomized/bootstrapped versions...)!

It must also be known that the terminology of ANOVA is largely from the statistical design of experiments (see section Industrial Engineering page 8780). The experimenter adjusts factors and measures responses in an attempt to determine an effect. Factors are assigned to experimental units by a combination of randomization[69] and blocking to ensure the validity of the results.

Remark

For the reader interested to have a deeper overview, however without too much mathematical details, at the opposite of the present book, we recommend the following actual worldwide reference for experts in ANOVA and Design of Experiments: *Design and Analysis of Experiments*[a] (authors: Hinkelmann, K. and Kempthorne, O.), approximately 730.- USD and 1,800 pages (see [249],[250] and [251]) and *Applied Linear Statistical Models* (see [324]).

[a] Three volume set!!!

The purpose of this section will mainly have for purpose to avoid the following type of telephone conversation between an ANOVA specialist (S) and a research scientist or engineer (R). R: « Hello, Mr. Stat, I wonder whether you have just a minute for a quick statistical question. » S: « Usually I do not do statistical consulting over the phone, but let me see if I can help you. What is the problem? » R: « We are developing new growth media for industrial producers for growing flower plants. We have three such media and we use them with four flower varieties. We have five replications for each combination of medium and flower. We have analysed the data as a 3×4 two-way classification with five observations per cell. But my graduate assistant has talked to one of your students and he is now confused about the validity of this analysis. I just want you to confirm that we have done the right thing. » S: « Well, I do not know.» R: «What do you mean, you do not know? You are the expert!? » S: « I really need to know more about how you performed the experiment. For example, how did you prepare the media that you used in the individual pots? I assume that you grow the flowers in pots in the greenhouse. » R: « Yes, that is right. My graduate assistant simply mixed each medium in a big container, which we then put in the individual pots. » S: « That may be a problem, because now you may not have any replication. » R: « What do you mean, we have no replication? I just told you that we have five replications. » S: « Yes, but ... I think it would be best if you would come to my office for me to explain this to you and to take a closer look at your experiment. » R: « But we have already submitted the paper for publication. » S: « Then why don't you come when you get the reviews back.» Silence. R: « Yes, thank you. I'll do that... »

This is, of course, just a fictitious conversation[70]. But many consulting statisticians have had similar conversations (most of the time the paper was already rejected). The aim of this section is to help engineers not only to better understand each other but also to obtain a better understanding of the intricacies of designing and analysing experiments.

---

[68] For more details see the Data Science mind map at page 6770.

[69] In the pharmaceutical field (mainly!), we use randomization to make the treated groups (if they are sufficiently large and comparable) and untreated groups comparable in terms of potential severity factors, which makes it possible to neutralize the differences due to the factors of severity, in order to isolate the effect of the treatment. It should be noted that randomization does not only neutralize known factors but also unknown severity factors!

[70] Another typical real example can be found on the following YouTube video: `https://vimeo.com/815286997`

5.7.13.5.1 ANOVA with one fixed factor

The objective of the analysis of variance (at the contrary to what its name might suggest...) is a statistical technique for comparing the means of two or more populations and that is very widely used in the pharmaceutical field or in the R&D labs or benches test[71]. This method, however, takes its name from that it use measures of variance to determine the statistical significance, or not, of the differences of measured averages on populations or samples.

More precisely, the real meaning is to know if the fact that the sample averages are (slightly) different can be assigned at random sampling or due to the fact that a variability factor actually generates significantly different samples (if we have the population size, we have obviously not such question!).

Remark

For more information about the vocabulary and application, the engineer and the researcher should refer to standard ISO 3534-3:1999.

For the analysis of variance named also "one factor ANOVA" (Analysis Of VAriance) or "one factor ANAVAR" (ANAlysis of VARiance), or "one-way ANOVA" or more rigorously "one fixed factor ANOVA with repetitions" or "ANOVA with one fixed categorical variable with repetition" or "complete random design" (CRD), we first recall, as we proved, that the Fisher-Snedecor law is given by the ratio of two independent random variables that follow a Chi-square law and divided by the degree of freedom such as:

$$\frac{U/k}{V/l}=F_{k,l}(x)=\frac{\Gamma\left(\dfrac{k+l}{2}\right)\left(\dfrac{k}{l}\right)^{\frac{k}{2}}}{\Gamma\left(\dfrac{k}{2}\right)\Gamma\left(\dfrac{l}{2}\right)}\frac{x^{\frac{k}{2}-1}}{\left(1+\dfrac{k}{l}x\right)^{\frac{k+l}{2}}} \tag{5.7.1874}$$

and we will now see its importance.

Remark

When a factor can have a very large number of levels we consider having chosen some given levels of the factor among a multitude of possible as a random selection. This is why we speak then in this latter case of "random factor" which is the subject of specific ANOVA models that we will study once those on fixed factors mastered (e.g. ANOVA mixing fixed and random factors are named "mixed ANOVA").

Let us consider a random sample of size n, say $X_1,X_2,\ldots,X_n$ sampled from the law $\mathcal{N}(\mu_X,\sigma_X)$ and a random sample of size m, say $Y_1,Y_2,\ldots,Y_m$ sampled from the law $\mathcal{N}(\mu_Y,\sigma_Y)$.

Consider now the maximum likelihood estimators of the standard deviation of the Normal law traditionally noted in the field of analysis of variance:

$$S_{*X}^2=\frac{1}{n}\sum_{i=1}^{n}(X_i-\mu_X)^2 \quad\text{and}\quad S_{*Y}^2=\frac{1}{n}\sum_{i=1}^{n}(Y_i-\mu_Y)^2 \tag{5.7.1875}$$

---

[71] In the case of "random factor" (concept that we will see later!) however we instead compare variances....!

The above statistics are those that we could use to estimate the variances if the average theoretical μ_X, μ_Y were known. So we can use a result proved above in our study of confidence intervals:

$$\chi^2(n) = \frac{nS^2_{*X}}{\sigma^2_X} \quad \text{and} \quad \chi^2(m) = \frac{mS^2_{*Y}}{\sigma^2_Y} \tag{5.7.1876}$$

As the X_i are independent of the Y_j (hypothesis that suppose the covariance to be zero, the converse being for reminder not always!), the random variables:

$$\frac{nS^2_{*X}}{\sigma^2_X} \quad \text{and} \quad \frac{mS^2_{*Y}}{\sigma^2_Y} \tag{5.7.1877}$$

are independent from each other.

Remark

There is an existing type of ANOVA for the case where the variables are not independent (we then speak about "covariate"). This is the "ANCOVA" which means "ANalysis of COvariance and VAriance" that uses a mix of linear regression (see section Numerical Methods page 6329) and ANOVA. The purpose of the ANCOVA is to statistically eliminate the indirect effect of the covariate. We will see much later how it works in details.

We can therefore apply the Fisher-Snedecor law with:

$$U = \frac{nS^2_{*X}}{\sigma^2_X};\ k = n \quad \text{and} \quad V = \frac{mS^2_{*Y}}{\sigma^2_Y};\ l = m \tag{5.7.1878}$$

Therefore we get:

$$\frac{U/k}{V/l} = \frac{\frac{nS^2_{*X}}{\sigma^2_X}/n}{\frac{mS^2_{*Y}}{\sigma^2_Y}/m} = \frac{\frac{S^2_{*X}}{\sigma^2_X}}{\frac{S^2_{*Y}}{\sigma^2_Y}} = \frac{S^2_{*X}\sigma^2_Y}{S^2_{*Y}\sigma^2_X} = F_{n,m}(x) \tag{5.7.1879}$$

Finally:

$$\frac{\sigma^2_X}{\sigma^2_Y} = \frac{1}{F_{n,m}(x)}\frac{S^2_{*X}}{S^2_{*Y}} \tag{5.7.1880}$$

This theorem allows us to deduce the confidence interval of the ratio of two variances when the theoretical mean is known. Since Fisher function is not symmetrical, the only possibility to make the inference is to use numerical calculation and then we will denote for a given confidence interval the test as follows:

$$\boxed{\frac{1}{F_{\alpha/2}(n,m)}\frac{S^2_{*X}}{S^2_{*Y}} \leqslant \frac{\sigma^2_X}{\sigma^2_Y} \leqslant \frac{1}{F_{1-\alpha/2}(n,m)}\frac{S^2_{*X}}{S^2_{*Y}}} \tag{5.7.1881}$$

In the case where the averages μ_X, μ_Y are unknown, we use the unbiased estimators of the variances noted traditionally in the field of analysis of variance:

$$S^2_X = \frac{1}{n-1}\sum_{i=1}^{n}(X_i - \bar{X})^2 \quad \text{and} \quad S^2_Y = \frac{1}{m-1}\sum_{j=1}^{m}(Y_j - \bar{Y})^2 \tag{5.7.1882}$$

To estimate the theoretical variances, we use the result proved above:

$$\frac{(n-1)S_X^2}{\sigma_X^2}=\chi^2(n-1) \quad \text{and} \quad \frac{(m-1)S_Y^2}{\sigma_Y^2}=\chi^2(m-1) \tag{5.7.1883}$$

As the X_i are independent of the Y_j (assumption!), the variables:

$$\frac{(n-1)S_X^2}{\sigma_X^2} \quad \text{and} \quad \frac{(m-1)S_Y^2}{\sigma_Y^2} \tag{5.7.1884}$$

are independent from each other. We can therefore apply the Fisher-Snedecor distribution:

$$U=\frac{(n-1)S_X^2}{\sigma_X^2};\; k=n-1 \quad \text{and} \quad V=\frac{(m-1)S_Y^2}{\sigma_Y^2};\; l=m-1 \tag{5.7.1885}$$

Therefore we get:

$$\frac{U/k}{V/l}=\frac{\frac{(n-1)S_X^2}{\sigma_X^2}/(n-1)}{\frac{(m-1)S_Y^2}{\sigma_Y^2}/(m-1)}=\frac{\frac{S_X^2}{\sigma_X^2}}{\frac{S_Y^2}{\sigma_Y^2}}=\frac{S_X^2\sigma_Y^2}{S_Y^2\sigma_X^2}=F_{n-1,m-1}(x) \tag{5.7.1886}$$

Finally:

$$\frac{\sigma_X^2}{\sigma_Y^2}=\frac{1}{F_{n-1,m-1}(x)}\frac{S_X^2}{S_Y^2} \tag{5.7.1887}$$

This theorem allows us to deduce the confidence interval of the ratio of two variances when the sample mean is known. Since Fisher function is not symmetrical, the only possibility to make the inference is to use numerical calculation and then we will denote for a given confidence interval the "Fisher F-test" as follows:

$$\boxed{\frac{1}{F_{\alpha/2}(n-1,m-1)}\frac{S_X^2}{S_Y^2}\leqslant\frac{\sigma_X^2}{\sigma_Y^2}\leqslant\frac{1}{F_{1-\alpha/2}(n-1,m-1)}\frac{S_X^2}{S_Y^2}} \tag{5.7.1888}$$

keeping in mind that its use implicitly requires constraints of Normality of the studied variables.

Rondal A. Fisher (11890-11962 according to holocene calendar) is, as Karl Pearson (11857-11936 according to holocene calendar), one of the main founders of the modern theory of statistics. Fisher studied at Cambridge, where he obtained in 11912 (holocene calendar) a degree in astronomy. It is by studying the theory of error in astronomical observations that Fisher became interested in statistics. Fisher is the inventor of the branch of statistics named "analysis of variance".

In the early 120th century (holocene calendar), Rondald A. Fisher therefore develops the very important methodology of experimental design (see section Industrial Engineering page 8780). To confirm the usefulness of a factor, he developed a test to ensure that the different samples are of different natures. This test is based on the analysis of variance (of the samples), and named also ANOVA but for "normalized analysis of variance".

Let us take k samples of n random values each. Each of the values being considered as an observation or measurement of something or on the basis of something (a different place or a different object... in short: a single factor of variability between samples!). We will have a total of N observations (measurements) given by:

$$N = kn \qquad (5.7.1889)$$

If each sample has an equal number of values n (sample size) such that $n_1 = n_2 = \ldots = n_k$ we then speak of "balanced plan" or "balanced design" with k levels (or k modalities).

Remark

If we have more factors of variability (e.g. each place compares himself to different laboratories), then we will talk about "multifactorial ANOVA". Therefore, if there are only two sources of variability, we talking about "two factor ANOVA" (see below for details on the various of two-factor ANOVA).

We will consider that each of the k samples is sampled (follows) a random variable following Normally distributed:

Factor 1			
Sample 1	Sample 2	Sample ...i	Sample k
x_{11} x_{21} $\ldots$ x_{n1}	x_{12} x_{22} $\ldots$ x_{n2}	$\ldots$ $\ldots$ x_{ij} $\ldots$	x_{1k} x_{2k} $\ldots$ x_{nk}
Average: $\bar{x}_1$	Average: $\bar{x}_2$	Average: $\bar{x}_i$	Average: $\bar{x}_k$

Table 5.53: **Typical "cross" table of a one factor ANOVA**

Therefore in a one-way analysis of variance (one-way ANOVA), a single factor (treatment) with several levels is considered.

In terms of testing, we test whether the mean of the k samples of size n are equal under the assumption that their variances are equal. What we write as under hypothesis notation as follows:

$$\begin{aligned} H_0 &: \quad \mu_1 = \mu_2 = \ldots = \mu_k = \mu \\ H_1 &: \quad \exists i, j \quad \mu_i \neq \mu_j \end{aligned} \qquad (5.7.1890)$$

In other words, the samples are representative of the same population (i.e. of a same statistical law). That is to say, the variations between the values of different samples are essentially due to probabilities. For this we study the variability of results in the samples and between samples.

Remark

The statistical model of the observations can also be written in the following very important form, named a "factor effects model" or even sometimes a "classificatory linear model":

$$\boxed{x_{ij} = \mu + \tau_i + \varepsilon_{ij}} \qquad (5.7.1891)$$

The parameter μ is the "overall mean", τ_i is the ith "treatment effect", and ε_{ij} is a "random error". It is assumed that ε_{ij}'s are i.i.d $\mathcal{N}(0, \sigma^2)$. This is a completely additive model (there is no interaction!). Under this form the hypotheses are then:

$$\begin{aligned} H_0 &: \quad \sigma_{\mu_i} = 0 \\ H_1 &: \quad \sigma_{\mu_i} > 0 \end{aligned} \tag{5.7.1892}$$

Notice that we have therefore:

$$\mu = \frac{1}{k}\sum_{i=1}^{k}\mu_i \qquad \text{and} \qquad \sum_{i=1}^{k}\tau_i = 0 \tag{5.7.1893}$$

It is exactly the same as we will see later as writing (formulation found in some publications or books):

$$\begin{aligned} H_0 &: \quad \sigma_{\mu} = 0 \\ H_1 &: \quad \sigma_{\mu} > 0 \end{aligned} \tag{5.7.1894}$$

So we will for the rest denote by i the index number of the sample (1 to k) and j the index of the observation (from 1 to n). Therefore x_{ij} will be the value of the j-th observation of the data sample number i (we chose to reverse the usual notation so be careful not to mislead afterwards ... we're sorry ... it was bad choice me made when we started to write this textbook!).

According to the above hypothesis, we have:

$$x_{ij} = \mathcal{N}(\mu_i, \sigma) \tag{5.7.1895}$$

We will denote by $\bar{x}_i$ the empirical/estimated (arithmetic) average of the sample i (often named "marginal average" and sometimes denoted also $\bar{x}_{i.}$):

$$\bar{x}_i = \frac{1}{n_i}\sum_{j=1}^{n_i} x_{ij} \quad \Rightarrow \quad \sum_{j=1}^{n_i} x_{ij} = n_i\bar{x}_i \tag{5.7.1896}$$

and $\bar{\bar{x}}$ (also sometimes denoted $\bar{x}_{..}$) the empirical/estimated (arithmetic) average of the N values (therefore the average of the $\bar{x}_i$) is then given by:

$$\bar{\bar{x}} = \frac{1}{N}\sum_{i=1}^{k}\sum_{j=1}^{n_i} x_{ij} = \frac{1}{N}\sum_{i=1}^{k}(n_i\bar{x}_i) \tag{5.7.1897}$$

Using the properties of the mean and variance already proved above we know that:

$$\bar{x}_i = \mathcal{N}\left(\mu_i, \frac{\sigma_i}{\sqrt{n_i}}\right) \quad \text{and} \quad \bar{\bar{x}} = \mathcal{N}\left(\mu, \frac{\sigma}{\sqrt{n}}\right) \tag{5.7.1898}$$

with μ which is the average of the true averages (expected means) μ_i:

$$\mu = \frac{1}{N}\sum_{i=1}^{k}\mu_i \tag{5.7.1899}$$

Remark

Writing the model as factor effect model:

$$x_{ij}=\mu+\tau_i+\varepsilon_{ij} \tag{5.7.1900}$$

we see that the maximum likelihood estimators of the model parameters are $\hat{\mu}=\bar{\bar{x}}$ and $\hat{\tau}_i=\bar{x}_i-\bar{\bar{x}}$. Hence:

$$\hat{x}_{ij}=\bar{\bar{x}}+(\bar{x}_i-\bar{\bar{x}})=\bar{x}_i \tag{5.7.1901}$$

Let us now introduce three important variances:

1. The "total variance" as being intuitively the estimated unbiased variance unbiased considering the set of N observations as a single sample:

   $$\mathrm{V}_T=\frac{\displaystyle\sum_{ij}(x_{ij}-\bar{\bar{x}})^2}{N-1} \tag{5.7.1902}$$

   where the numerator is named "sum of the squares of total differences".

2. The "variance between samples" (that is to say between the averages of the samples) is also intuitively the variance estimator of the averages of samples:

   $$\mathrm{V}_E=\frac{\displaystyle\sum_{i}(\bar{x}_i-\bar{\bar{x}})^2}{k-1} \tag{5.7.1903}$$

   where the numerator term is named "sum of the squared differences between samples".

   As we have proved that if all variables are identically distributed (same variance and same mean) and independent the variance of individuals is n times that of the average:

   $$\sigma_{\bar{X}}=\frac{\sigma}{\sqrt{n}} \quad\Leftrightarrow\quad \mathrm{V}(\bar{X})n=\mathrm{V}(X) \tag{5.7.1904}$$

   then the "variance of observations" (random variables in a sample) is given by:

   $$\mathrm{V}_A=n\mathrm{V}_E=\frac{n\displaystyle\sum_{i}(\bar{x}_i-\bar{\bar{x}})^2}{k-1} \tag{5.7.1905}$$

   We then have therefore above the hypothesis of equality of variances that is expressed in mathematical form for the developments that will follow.

3. The "residual variance" is the effect of the "uncontrolled factors". It is by definition the average of the sample variances (its like: standard error):

   $$\mathrm{V}_R=\frac{1}{k}\sum_i\frac{\displaystyle\sum_{j}(x_{ij}-\bar{x}_i)^2}{n-1}=\frac{\displaystyle\sum_{ij}(x_{ij}-\bar{x}_i)^2}{k(n-1)} \tag{5.7.1906}$$

   where the numerator term is named "sum of squared residuals errors" or even more often "residual errors".

Finally, these indicators are sometimes summarized as follows:

$$\begin{array}{lll} Q_T=\sum_{ij}(x_{ij}-\bar{\bar{x}})^2 & \mathrm{df}_T=N-1=kn-1 & \mathrm{V}_T=\dfrac{Q_T}{\mathrm{df}_T} \\ Q_A=n\sum_{i}(\bar{x}_i-\bar{\bar{x}})^2 & \mathrm{df}_A=k-1 & \mathrm{V}_A=\dfrac{Q_A}{\mathrm{df}_A} \\ Q_R=\sum_{ij}(x_{ij}-\bar{x}_i)^2 & \mathrm{df}_R=k(n-1) & \mathrm{V}_R=\dfrac{Q_R}{\mathrm{df}_R} \end{array} \tag{5.7.1907}$$

Note that if the samples do not have the same size (which is rare in practice), then we have:

$$\boxed{\begin{array}{lll} Q_T=\sum_{ij}(x_{ij}-\bar{\bar{x}})^2 & \mathrm{df}_T=N-1 & \mathrm{V}_T=\dfrac{Q_T}{\mathrm{df}_T} \\ Q_A=n\sum_{i}(\bar{x}_i-\bar{\bar{x}})^2 & \mathrm{df}_A=k-1 & \mathrm{V}_A=\dfrac{Q_A}{\mathrm{df}_A} \\ Q_R=\sum_{ij}(x_{ij}-\bar{x}_i)^2 & \mathrm{df}_R=\sum_{i}(n_i-1) & \mathrm{V}_R=\dfrac{Q_R}{\mathrm{df}_R} \end{array}} \tag{5.7.1908}$$

Remarks

R1. The term Q_T is often indicated in the industry by the acronym SST meaning in "Sum of Squares Total" or more rarely TSS for "Total Sum of Squares".

R2. The term Q_A is often indicated in the industry by the acronym SSB meaning in "Sum of Squares Between (samples)" or more rarely SSk for "Sum of Squares Between treatments" (hence sometimes denoted also: $\mathrm{SS}_{\mathrm{tr}}$).

R3. The term Q_R is often indicated in the industry by the acronym SSW meaning in "Sum of Squares Within (samples)" or more rarely SSE for "Sum of Squares due to Errors" (hence sometimes denoted also: SS_E).

Let us indicate that we often see in the literature (we will use a little further below this notation):

$$\begin{aligned} Q_R&=\sum_{ij}(x_{ij}-\bar{x}_i)^2=\frac{n_i-1}{n_i-1}\sum_{ij}(x_{ij}-\bar{x}_i)^2=\sum_{i=1}^{k}\sum_{j=1}^{n_i}(x_{ij}-\bar{x}_i)^2\\ &=\sum_{i=1}^{k}(n_i-1)\sum_{j=1}^{n_i}\frac{(x_{ij}-\bar{x}_i)^2}{n_i-1}=\sum_{i=1}^{k}(n_i-1)S_i^2 \end{aligned} \tag{5.7.1909}$$

so with the unbiased estimator of the variance of the observations:

$$S_i^2=\frac{1}{n_i-1}\sum_{j}^{n_i}(x_{ij}-\bar{x}_i)^2 \tag{5.7.1910}$$

Before going further, let us stop on the residual variance. We then have for samples that are not of the same size:

$$\boxed{\mathrm{V}_R=\frac{\displaystyle\sum_{ij}(x_{ij}-\bar{x}_i)^2}{\displaystyle\sum_i(n_i-1)}}\tag{5.7.1911}$$

This writing is often named "pooled variance". The square root of a pooled variance estimator is knows obviously as a "pooled standard deviation". We also see that if we assume all the mean $\bar{x}_i$ to be equal and also all samples sizes n_i we fall back on the standard error.

Let us now open a small important parenthesis... Let's take the case of two samples only:

$$\mathrm{V}_R=\frac{\displaystyle\sum_j(x_{1j}-\bar{x}_1)^2+\sum_j(x_{2j}-\bar{x}_2)^2}{(n_1-1)+(n_2-1)}=\frac{\displaystyle\sum_j(x_{1j}-\bar{x}_1)^2+\sum_j(x_{2j}-\bar{x}_2)^2}{n_1+n_2-2}\tag{5.7.1912}$$

Therefore by introducing the maximum likelihood estimator of the variance:

$$\mathrm{V}_R=\frac{(n_1-1)S_1^2+(n_2-1)S_2^2}{(n_1-1)+(n_2-1)}=\frac{(n_1-1)S_1^2+(n_2-1)S_2^2}{n_1+n_2-2}\tag{5.7.1913}$$

Remark

It is then quite easy to understand where the following relation comes from:

$$V_R=S_R^2=\frac{\displaystyle\sum_{i=1}^{p}\left((n_i-1)S_i^2\right)}{\left(\displaystyle\sum_{i=1}^{p}n_i\right)-p}\tag{5.7.1914}$$

also named the "variance of repeatability of p data series".

In laboratories experiments this also leads to the definition of "inter-series variance" (difference between mean values variance of the data series and the variance of repeatability divided by the number of measurements per series), where given p data series (i varies from 1 to p), each data series containing j values (j varies from 1 to n_i):

$$S_g^2=S_{\mu_i}^2-\frac{S_R^2}{n}=\frac{\dfrac{\displaystyle\sum_{i=1}^{p}\left(n_i(\mu_i-\mu_p)^2\right)}{p-1}-S_R^2}{n}\tag{5.7.1915}$$

In practice, if the variance of the means is smaller than the contribution of the variance of repeatability, S_R^2, the inter-series variance is declared equal to zero.

We can also observe that in the specific case where $n_1=n_2=n$:

$$\mathrm{V}_R=\frac{nS_1^2-S_1^2+nS_2^2-S_2^2}{2n-2}=\frac{n(S_1^2+S_2^2)-(S_1^2+S_2^2)}{2(n-1)}=\frac{(n-1)(S_1^2+S_2^2)}{2(n-1)}=\frac{S_1^2+S_2^2}{2}\tag{5.7.1916}$$

So:

$$S_1^2 \leqslant \mathrm{V}_R \leqslant S_2^2 \qquad (5.7.1917)$$

Now suppose we want to compare with a confidence interval the mean of two populations with different variance to know whether they are different or not.

We currently know two tests to check the averages. The Z-test and T-test. As in the industry (practice) it is rare that we have time to take large samples, let's focus on the second we had proved above:

$$\bar{X} - \frac{S}{\sqrt{n}} T_{\alpha/2}(n-1) \leq \mu \leq \bar{X} + \frac{S}{\sqrt{n}} T_{\alpha/2}(n-1) \qquad (5.7.1918)$$

And also recall that:

$$S_{\bar{X}} = \frac{S}{\sqrt{n}} \qquad (5.7.1919)$$

Now let us recall that we have proved that if we have two random variables of distribution:

$$\mathcal{N}(\mu_1, \sigma_1) \qquad \mathcal{N}(\mu_2, \sigma_2) \qquad (5.7.1920)$$

then the subtraction of the averages gives (property of stability of the average):

$$\mathcal{N}\left(\mu_1 - \mu_2, \sqrt{\sigma_1^2 + \sigma_2^2}\right) \qquad (5.7.1921)$$

So for the difference average of two random variables coming from two population samples we obtain directly:

$$\mathcal{N}\left(\bar{X}_2 - \bar{X}_1, \sqrt{S_{\bar{X}_1}^2 + S_{\bar{X}_2}^2}\right) = \mathcal{N}\left(\bar{X}_2 - \bar{X}_1, \sqrt{\frac{S_1^2}{n_1} + \frac{S_2^2}{n_2}}\right) \qquad (5.7.1922)$$

And now the idea is to take the approximation (under the assumption that the variances are equal):

$$\mathcal{N}\left(\bar{X}_2 - \bar{X}_1, \sqrt{\frac{S_1^2}{n_1} + \frac{S_2^2}{n_2}}\right) \cong \mathcal{N}\left(\bar{X}_2 - \bar{X}_1, \sqrt{\frac{\mathrm{V}_R}{n_1} + \frac{\mathrm{V}_R}{n_2}}\right) = \mathcal{N}\left(\bar{X}_2 - \bar{X}_1, \sqrt{\mathrm{V}_R\left(\frac{1}{n_1} + \frac{1}{n_2}\right)}\right) \qquad (5.7.1923)$$

This approximation is named "homoscedastic hypothesis".

We then have the following confidence interval (assuming that we know only an estimation of the variance) remembering that the subtraction or the sum of two independent random variables implies that their variances always add (so it is the same for degrees of freedom of the Student law as we have proved above due to the direct connection with the law of the chi-squared):

$$(\bar{X}_2 - \bar{X}_1) - \sqrt{\mathrm{V}_R\left(\frac{1}{n_1} + \frac{1}{n_2}\right)} T_{\alpha/2}(n-1) \leqslant \mu_2 - \mu_1 \leqslant (\bar{X}_2 - \bar{X}_1) + \sqrt{\mathrm{V}_R\left(\frac{1}{n_1} + \frac{1}{n_2}\right)} T_{\alpha/2}(n-1) \qquad (5.7.1924)$$

with:

$$n=n_1+n_2 \tag{5.7.1925}$$

As the idea in practice is often to test the equality of expected means (and therefore that their difference is zero) from the known estimators then:

$$(\bar{X}_2-\bar{X}_1)-\sqrt{\text{V}_R\left(\frac{1}{n_1}+\frac{1}{n_2}\right)}T_{\alpha/2}(n-2)\leqslant 0\leqslant(\bar{X}_2-\bar{X}_1)+\sqrt{\text{V}_R\left(\frac{1}{n_1}+\frac{1}{n_2}\right)}T_{\alpha/2}(n-2) \tag{5.7.1926}$$

In most softwares on the market, the result is given only from the fact that quantile T that we get is included in the $T_{\alpha/2}$ corresponding to the given confidence interval given by (for reminder):

$$T^{\text{calc}}(n-2)=\frac{(\bar{X}_2-\bar{X}_1)-(\mu_2-\mu_1)}{\sqrt{\text{V}_R\left(\frac{1}{n_1}+\frac{1}{n_2}\right)}} \tag{5.7.1927}$$

in the case of the homoscedastic hypothesis (equality of variances homogeneity of variances).

Remark

The latter relation is named "independent two-sample T-test", or "homoscedastic T-test" or "T-test of equality of 2 observations expectations with equal variances" or more simply but somewhat abusively "2-sample t-Test" with samples of different sizes and equal variances. Often in the literature, both theoretical means are equal when comparing. It follows that we then have:

$$T^{\text{calc}}(n-2)=\frac{\bar{X}_2-\bar{X}_1}{\sqrt{\text{V}_R\left(\frac{1}{n_1}+\frac{1}{n_2}\right)}}=\frac{\bar{X}_2-\bar{X}_1}{S_R\sqrt{\left(\frac{1}{n_1}+\frac{1}{n_2}\right)}} \tag{5.7.1928}$$

Otherwise, in the most general case of the assumption of heteroscedasticity (not equality of variances), we explicitly write (we'll come back on this later during our study of the Welch test...):

$$\boxed{T^{\text{calc}}(n-2)=\frac{(\bar{X}_2-\bar{X}_1)-(\mu_2-\mu_1)}{\sqrt{\frac{S_1^2}{n_1}+\frac{S_2^2}{n_2}}}} \tag{5.7.1929}$$

Therefore:

$$|T^{\text{calc}}(n-1)|\leqslant|T_{\alpha/2}(n-1)| \tag{5.7.1930}$$

Remark

The ante-previous relation is named "independent two-sample T-test", or "heteroscedasticity T-test" or even "test of equality of expected means: two observations with different variances". If the sizes of the samples are equal and that the variances are also equal and that we assume the two expected mean equal during the comparison, it follows that we then have:

$$T^{\text{calc}}(n-2)=\frac{\bar{X}_2-\bar{X}_1}{S_{1,2}\sqrt{\dfrac{2}{n}}} \tag{5.7.1931}$$

If we need to compare two means differentiated by the index i,j among a number k of multiple means of an ANOVA (as post-hoc test to identify which means are different as the ANOVA omnibus[72] test doesn't tell us anything about this!), the previous relation is then generalized to:

$$T^{\text{calc}}(n-k)=\frac{\bar{X}_i-\bar{X}_j}{\sqrt{\text{V}_R\left(\dfrac{1}{n_i}+\dfrac{1}{n_j}\right)}} \tag{5.7.1932}$$

and rewritten traditionally as following:

$$\text{LSD}=\bar{X}_i-\bar{X}_j=T^{\text{calc}}(n-k)\sqrt{\text{V}_R\left(\frac{1}{n_i}+\frac{1}{n_j}\right)} \tag{5.7.1933}$$

and is named the "least significant difference Fisher test" or simply abbreviated LSD[73]. Obviously the test consist to verify that $\bar{X}_i-\bar{X}_j>\text{LSD}$ at a given α threshold and repeat this procedure for all $k(k-1)/2$ comparisons.

Remark

Remember that we have derived the following two-sample Student T-test:

$$T^{\text{calc}}(n_1+n_2-2)=\frac{\bar{X}_{T1}-\bar{X}_2}{\sqrt{\text{V}_R\left(\dfrac{1}{n_1}+\dfrac{1}{n_2}\right)}} \tag{5.7.1934}$$

with the following pooled variance:

$$\text{V}_R=\frac{(n_1-1)S_1^2+(n_2-1)S_2^2}{n_1+n_2-2} \tag{5.7.1935}$$

In practice it may happens that practitioners use the trimmed mean μ_{T_α} of each sample as the means and the Winsorized sample (unbiased) variances $S_{n[\alpha]}$ as the variances (see section of Numerical Methods page 6560). The test is then named the "trimmed means T-test" (yes the name doesn't highlight the fact that the variances are Winsorized... who the hell knows why...????) and written as:

$$T^{\text{calc}}_{\text{T\&W}}(n_1+n_2-2)=\frac{\bar{X}_{T_\alpha 1}-\bar{X}_{T_\alpha 2}}{\sqrt{\text{V}_{R,W}\left(\dfrac{1}{n_1}+\dfrac{1}{n_2}\right)}} \tag{5.7.1936}$$

---

[72] "omnibus" derives from the Latin word "for all". In plain language, you can interpret an omnibus test or omnibus statistic like an "overall test" - it is testing a number of things at once.

[73] Post-hoc tests don't need ANOVA to be run first, except the LSD test (ANOVA is so-named "protector test" to it). Post-hoc by no means mean « post-ANOVA » (those who claim it, even authors of textbooks, have clearly no idea what the tests actually do!). Post hoc (or post factum) means « after the data is collected ».

with the following pooled variance:

$$\mathrm{V}_{R,W}=\frac{(n_1-1)S^2_{n[\alpha],1}+(n_2-1)S^2_{n[\alpha],2}}{n_1+n_2-2} \tag{5.7.1937}$$

This is typically a test from the family of "Robust Null Hypothesis Significance Testing" (RNHST).

This finished, we close now this parenthesis and return to our main topic... We were therefore at the following table if you remember:

$$\begin{aligned}
&Q_T=\sum_{ij}(x_{ij}-\bar{\bar{x}})^2 && \mathrm{df}_T=N-1=kn-1 && \mathrm{V}_T=\frac{Q_T}{\mathrm{df}_T}\\
&Q_A=n\sum_{i}(\bar{x}_i-\bar{\bar{x}})^2 && \mathrm{df}_A=k-1 && \mathrm{V}_A=\frac{Q_A}{\mathrm{df}_A}\\
&Q_R=\sum_{ij}(x_{ij}-\bar{x}_i)^2 && \mathrm{df}_R=k(n-1) && \mathrm{V}_R=\frac{Q_R}{\mathrm{df}_R}
\end{aligned} \tag{5.7.1938}$$

Where we have in the case of samples of the same size:

$$\mathrm{df}_T=\mathrm{df}_A+\mathrm{df}_R=k-1+k(n-1)=k-1+kn-k=kn-1 \tag{5.7.1939}$$

and also the total error that is the sum of the errors of the averages (between classes) and of the residual error (intra-class) and this that the samples are of the same size or not:

$$\boxed{Q_T=Q_A+Q_R} \tag{5.7.1940}$$

Remark

Remember that this sum of square total decomposition is also sometime written:

$$\text{SSTO}=\text{SSTR}+\text{SSE} \tag{5.7.1941}$$

where SSTR stands for "Sum of Square Treatment Residuals" (the equivalent of Q_A) and SSE for "Sum of Square Errors" (the equivalent of Q_R).

Indeed:

$$\begin{aligned}
Q_T&=\sum_{ij}(x_{ij}-\bar{\bar{x}})^2=\sum_i\sum_j\left((x_{ij}-\bar{x}_i)+(\bar{x}_i-\bar{\bar{x}})\right)^2\\
&=\sum_i\sum_j(x_{ij}-\bar{x}_i)^2+\sum_i\sum_j(\bar{x}_i-\bar{\bar{x}})^2+2\sum_i\sum_j(x_{ij}-\bar{x}_i)(\bar{x}_i-\bar{\bar{x}})
\end{aligned} \tag{5.7.1942}$$

But we have:

$$\sum_i\sum_j(x_{ij}-\bar{x}_i)(\bar{x}_i-\bar{\bar{x}})=\sum_i\left[(\bar{x}_i-\bar{\bar{x}})\sum_j(x_{ij}-\bar{x}_i)\right]=0 \tag{5.7.1943}$$

Because:

$$\sum_j(x_{ij}-\bar{x}_i)=0\quad\forall i \tag{5.7.1944}$$

Therefore:

$$Q_T=\sum_i\sum_j\left(x_{ij}-\bar{x}_i\right)^2+\sum_i\sum_j\left(\bar{x}_i-\bar{\bar{x}}\right)^2=Q_R+Q_A \tag{5.7.1945}$$

Now, under the strong assumption (which we will be absolutely required a little further below) that the true variances are linked such as:

$$\sigma_R^2=\sigma_A^2=\sigma_T^2=\sigma^2 \tag{5.7.1946}$$

and therefore that respective estimators are asymptotically equal ... which in practice is approximately true only when certain conditions are met (which is why it is absolutely necessary before making an ANOVA to run an a priori calculation of the power and the sample size of the ANOVA test) we have:

$$\frac{Q_R}{\sigma^2}=\frac{\displaystyle\sum_{ij}\left(x_{ij}-\bar{x}_i\right)^2}{\sigma^2}=\chi^2_{N-k} \tag{5.7.1947}$$

that follows immediately from the proof that we made during our study of statistical inference with the Chi-square law where we got (for refresh!):

$$\chi^2_{n-1}=\frac{(n-1)S^2}{\sigma^2}=\frac{(n-1)\left(\dfrac{1}{n-1}\displaystyle\sum_{i=1}^{n}(X_i-\bar{X})^2\right)}{\sigma^2}=\frac{\displaystyle\sum_{i=1}^{n}(X_i-\bar{X})^2}{\sigma^2} \tag{5.7.1948}$$

To determine the number of degrees of freedom of the Chi-square law of:

$$\frac{Q_A}{\sigma^2}=\frac{\displaystyle\sum_i n_i\left(\bar{x}_i-\bar{\bar{x}}\right)^2}{\sigma^2} \tag{5.7.1949}$$

we will use the fact that (by the same reasoning as for the ante-previous relation):

$$\frac{Q_T}{\sigma^2}=\frac{\displaystyle\sum_{ij}\left(x_{ij}-\bar{\bar{x}}\right)^2}{N-1}=\chi^2_{N-1} \tag{5.7.1950}$$

and since that $Q_T=Q_A+Q_R$, then we must have:

$$\frac{Q_T}{\sigma^2}=\frac{Q_A+Q_R}{\sigma^2}=\frac{Q_A}{\sigma^2}+\frac{Q_R}{\sigma^2}=\chi^2_?+\chi^2_{N-k}=\chi^2_{N-1} \tag{5.7.1951}$$

It follows by the linearity property of the Chi-Square law:

$$\frac{Q_A}{\sigma^2}=\frac{\displaystyle\sum_i n_i\left(\bar{x}_i-\bar{\bar{x}}\right)^2}{\sigma^2}=\chi^2_{k-1} \tag{5.7.1952}$$

So to summarize we have:

$$\boxed{\frac{Q_A}{\sigma^2}=\chi^2_{k-1}\quad\text{and}\quad\frac{Q_R}{\sigma^2}=\chi^2_{N-k}} \tag{5.7.1953}$$

Now comes the Fisher law in the assumption that the variances are equal (and measurement Normally distributed)! Because:

$$\frac{(k-1)S_A^2}{\sigma^2}=\chi^2_{k-1} \quad \text{and} \quad \frac{(N-k)S_R^2}{\sigma^2}=\chi^2_{N-k} \tag{5.7.1954}$$

What we want to do is to see if there is a difference between the variance of the averages (between classes) and the residual variance (intra-class). To compare two variances when the true averages are unknown we saw that the best was to use the Fisher test. But, we proved in our study of the Fisher law a little above that:

$$\frac{\sigma_X^2}{\sigma_Y^2}=\frac{1}{F_{n-1,m-1(x)}}\frac{S_X^2}{S_Y^2} \tag{5.7.1955}$$

where in our case study:

$$\frac{\sigma_A^2}{\sigma_R^2}=1 \Rightarrow F_{k-1,N-k}=\frac{S_A^2}{S_R^2}=\frac{\mathrm{V}_A}{\mathrm{V}_R}=\frac{\dfrac{\displaystyle\sum_i n_i(\bar{x}_i-\bar{\bar{x}})^2}{k-1}}{\dfrac{\displaystyle\sum_{ij}(x_{ij}-\bar{x}_i)^2}{N-k}}=\frac{\dfrac{Q_A}{k-1}}{\dfrac{Q_R}{N-k}} \tag{5.7.1956}$$

Since there are dozens of different types of ANOVA we have to understand very good this choice of the simplest ANOVA we are studying right now! Thus, if the averages are the same, the null hypothesis is then that variance ratio is equal to unity (under the above assumptions already mentioned far above). If F is too large at a given threshold, then we reject the null hypothesis of equality of means (because verbatim variances will be strongly different). So it seems here logic to compare the variances between groups (numerator) with that in the groups (denominator) but as we shall see this is not always the choice to be made (especially in hierarchical ANOVA)!

Given the assumption of the first equality of the above relation (the one that precedes the implication), we understand at the same time much better the great sensitivity of the ANOVA results to the non equality of true variances!

Let us also indicate that the previous relation:

$$\boxed{F_{k-1,N-k}=\frac{\dfrac{Q_A}{k-1}}{\dfrac{Q_R}{N-k}}=\frac{\dfrac{\text{SSB}}{k-1}}{\dfrac{\text{SSW}}{N-k}}} \tag{5.7.1957}$$

is often given in the literature as follows:

$$F_{k-1,N-k}=\frac{\text{MSk}}{\text{MSE}}=\frac{\text{variance between treatments}}{\text{variance within treatments}}=\frac{\text{signal}}{\text{noise}} \tag{5.7.1958}$$

where MSk is named "Mean Square for treatments" and MSE "Mean Square for Error". This ratio will therefore give us the value of the random variable F (whose support is for reminder bounded at zero). Regarding the choice of the test (right/left one-sided or bilateral), note that if the averages are really equal, then for all i:

$$(\bar{x}_i-\bar{\bar{x}})=0 \tag{5.7.1959}$$

So in this case:

$$F_{k-1,N-k}=\frac{\dfrac{\sum\limits_{i}n_i(\bar{x}_i-\bar{\bar{x}})^2}{k-1}}{\dfrac{\sum\limits_{ij}(x_{ij}-\bar{x}_i)^2}{N-k}}=\frac{\dfrac{\sum\limits_{i}n_i\cdot 0}{k-1}}{\dfrac{\sum\limits_{ij}(x_{ij}-\bar{x}_i)^2}{N-k}}=0 \tag{5.7.1960}$$

Which brings us of course to immediately adopt a right-sided test!

Otherwise, in general, the interpretation of this fraction is basically as following: This is the ratio (normalized to the number of degrees of freedom) of the sum of the error of the averages (between classes) and that of the residual error (intra-class) or in other words the ratio of the interclass variance by the residual variance. The ratio thus follows a Fisher distribution with two parameters given by the degrees of freedom of the respective classes.

Remark

If there are only two populations (samples), we must understand that then that use of the Student T-test is more than enough and is perfectly equivalent! In fact, the ANOVA is an indirect comparison of means, the Student T-test a direct comparison... so it is obvious to guess which one is better in this particular situation!

All calculations we have made until now are very often represented in softwares in a standard table form as represented below (this is for example how Microsoft® Excel® 11.8346 or Minitab 15.1.1 give the results):

Source	**Sum of squares (SSE)**	χ^2 **df**	**Mean squares**	F	**Critical** F
Inter-Class	$Q_A=\sum\limits_i n_i\left(\bar{x}_i-\bar{\bar{x}}\right)^2$	$k-1$	$\text{MSk}=\dfrac{Q_A}{k-1}$	$\dfrac{\text{MSk}}{\text{MSE}}$	$P(F>F_{k-1,N-k})$
Intra-Class	$Q_R=\sum\limits_{ij}(x_{ij}-\bar{x}_i)^2$	$N-k$	$\text{MSE}=\dfrac{Q_R}{N-k}$		
Total	$Q_T=\sum\limits_{ij}(x_{ij}-\bar{\bar{x}})^2$	$N-1$			

Table 5.54: **One-way fixed factor ANOVA table**

The null hypothesis will not be rejected if the value of:

$$F_{k-1,N-k}=\frac{\text{MSk}}{\text{MSE}} \tag{5.7.1961}$$

is smaller or equal to the quantile of the distribution F that corresponds to the cumulative probability to 1 subtracted from confidence level α and denoted by F_c.

The p-value in the ANOVA table and the multiple comparison results like Dunnett's test (see further below) and Tukey's test (see also further below page 1207) are based on different methodologies and can occasionally produce contradictory results. For example, it is possible that the ANOVA p-value can indicate that there are no differences between the means while the multiple comparisons output indicates that some means that are different. In this case, you can generally trust the multiple comparisons output.

It must be remembered that to use ANOVA, we must therefore assume that the samples come from different populations (unpaired data) and follow a Normal law (even if the ANOVA is relatively robust to non-normality). It is therefore necessary to check the normality of the distributions and the homoscedasticity (Levene test for example). Otherwise, nonparametric variants of the analysis of variance must be used (Kruskal-Wallis ANOVA or Friedman's ANOVA, for example among others that we will see later).

Remarks

R1. Notice that in practice, inter-class variance is often named "inter-laboratory variance" and the intra-class variance is verbatim often named "intra-laboratory variance".

R2. There are, in this early 121st century (holocene calendar) more than 50 existing tests or procedures comparison for the variance. The opinion varies among practitioners relatively to their relevance and the effectiveness of homogeneity of variance tests (HVT). Some argue that they are absolutely necessary to be applied before doing any ANOVA, others say that these tests are anyway of poor performance, the ANOVA being anyway more robust to homoscedasticity than the differences than can be detected by HVT, particularly in case of non-Normality. In fact, all these issues are related to the "Behrens-Fisher problem", which is that the comparison of means without assuming the equivariance. However among the fifty existing tests, several comparative studies have highlighted the following efficient tests that we will present further below: Bartlett's test, Levene and Brown-Forsythe.

R3. When certain levels of a factor are combined into one to be compared to a reference level statisticians then talk about creating "contrasts" (see just below).

The distribution of $\bar{x}_i$ is $\mathcal{N}(\mu_i,\sigma_\varepsilon^2/n)$. Therefore as we have already seen before we can write:

$$\bar{x}_i - T_{\alpha/2}(N-k)\frac{\sigma_\varepsilon}{\sqrt{n}} \leq \mu_i \leq \bar{x}_i + T_{\alpha/2}(N-k)\frac{\sigma_\varepsilon}{\sqrt{n}} \tag{5.7.1962}$$

Hence:

$$\bar{x}_i - T_{\alpha/2}(N-k)\frac{\text{MSE}}{\sqrt{n}} \leq \mu_i \leq \bar{x}_i + T_{\alpha/2}(N-k)\frac{\text{MSE}}{\sqrt{n}} \tag{5.7.1963}$$

A confidence interval for the difference of two means is then as usual:

$$(\bar{x}_i-\bar{x}_j) - T_{\alpha/2}(N-k)\sqrt{\frac{2\text{MSE}}{n}} \leq \mu_i-\mu_j \leq (\bar{x}_i-\bar{x}_j) + T_{\alpha/2}(N-k)\sqrt{\frac{2\text{MSE}}{n}} \tag{5.7.1964}$$

5.7.13.5.1.1 Welch Test

During our one-way fixed factor ANOVA study above, we had introduced the fact that it was possible to compare the average of two populations whose data followed a Normal distribution but of unequal variances using the heteroscedastic T-test Student:

$$T^{\text{calc}}(n-2)=\frac{(\bar{X}_2-\bar{X}_1)-(\mu_2-\mu_1)}{\sqrt{\dfrac{S_1^2}{n_1}+\dfrac{S_2^2}{n_2}}} \tag{5.7.1965}$$

with:

$$n=n_1+n_2 \tag{5.7.1966}$$

But in reality we had a little passed into silence ... (some will have perhaps noticed it) that we are not authorized to make this last addition of the degrees of freedom as soon as the variances are not equal! Indeed, let us go back to the source of the Student distribution:

$$T(n-1)=\frac{Z}{\dfrac{U}{n-1}} \tag{5.7.1967}$$

where for recall, the variable Z follows a reduced Normal centered law and the random variable U follows a χ^2 law with $n-1$ degrees of freedom. And remember that we have proved that:

$$\chi^2(n-1)=\frac{(n-1)S^2}{\sigma^2} \tag{5.7.1968}$$

But now, let us consider that this same random variable U is given by (we work as a reminder with the standard deviation of the mean!):

$$\begin{aligned}U&=\frac{S_1^2}{n_1}+\frac{S_2^2}{n_2}=\frac{\dfrac{\sigma_1^2}{n_1-1}\chi^2(n_1-1)}{n_1}+\frac{\dfrac{\sigma_2^2}{n_2-1}\chi^2(n_2-1)}{n_2}=\frac{\dfrac{\sigma_1^2}{f_1}\chi^2_{n_1-1}}{n_1}+\frac{\dfrac{\sigma_2^2}{f_2}\chi^2_{n_2-1}}{n_2}\\&=\frac{\sigma_1^2}{n_1f_1}\chi^2_{n_1-1}+\frac{\sigma_2^2}{n_2f_2}\chi^2_{n_2-1}=aX+bY\end{aligned} \tag{5.7.1969}$$

where X and Y are two independent random variables following χ^2 laws with respectively f_1 and f_2 degrees of freedom such that:

$$X=\chi^2(f_1)\qquad\text{and}\qquad Y=\chi^2(f_2) \tag{5.7.1970}$$

where we impose that a and b are positive because otherwise, as proved earlier above, aX and bY would not follow gamma laws.

Let us recall then that (see page 773):

$$\text{E}(X)=f_1\qquad\text{and}\qquad\text{V}(X)=2f_1 \tag{5.7.1971}$$

We then have:

$$aX=\gamma\left(\frac{f_1}{2},\frac{1}{2a}\right)\qquad\text{and}\qquad bY=\gamma\left(\frac{f_2}{2},\frac{1}{2b}\right) \tag{5.7.1972}$$

However $U=aX+bY$ does not follow a gamma law if $a\neq b$ (as we demonstrated during our study of the Gamma law at page 767). Assuming, however, that they are close enough, numerical simulations have shown that we can approximate the law of U by the following gamma law:

$$\gamma\left(\frac{f}{2},\frac{1}{2g}\right) \tag{5.7.1973}$$

which has therefore for expected mean and variance (see page 767):

$$\mu=\frac{\dfrac{f}{2}}{\dfrac{1}{2g}}=fg \qquad \sigma^2=\frac{\dfrac{f}{2}}{\left(\dfrac{1}{2g}\right)^2}=2fg^2 \tag{5.7.1974}$$

and we will determine the positive numbers f and g so that the expected means and the variances coincide with those of U.

We therefore have by the independence of the two random variables:

$$\mathrm{E}(U)=af_1+bf_2 \qquad \text{and} \qquad \mathrm{V}(U)=2(a^2f_1+b^2f_2) \tag{5.7.1975}$$

So that the expectation and the variance of our approximation correspond to that of U, we must have:

$$fg=af_1+bf_2 \qquad \text{and} \qquad 2fg^2=2(a^2f_1+b^2f_2) \tag{5.7.1976}$$

By dividing the second equation by the first the f disappears and we find:

$$g=\frac{a^2f_1+b^2f_2}{af_1+bf_2} \tag{5.7.1977}$$

Replacing in the first we find what it is customary to call the "Welch-Satterthwaite equation":

$$f=\frac{(af_1+bf_2)^2}{af_1+bf_2} \tag{5.7.1978}$$

Thus explicitly:

$$f=\frac{\left(\left(\dfrac{\sigma_1^2}{n_1f_1}\right)f_1+\left(\dfrac{\sigma_2^2}{n_2f_2}\right)f_2\right)^2}{\left(\dfrac{\sigma_1^2}{n_1f_1}\right)^2f_1+\left(\dfrac{\sigma_2^2}{n_2f_2}\right)^2f_2}=\frac{\left(\dfrac{\sigma_1^2}{n_1}+\dfrac{\sigma_2^2}{n_2}\right)^2}{\dfrac{(\sigma_1^2/n_1)^2}{f_1}+\dfrac{(\sigma_2^2/n_2)^2}{f_2}}=\frac{\left(\dfrac{\sigma_1^2}{n_1}+\dfrac{\sigma_2^2}{n_2}\right)^2}{\dfrac{(\sigma_1^2/n_1)^2}{n_1-1}+\dfrac{(\sigma_2^2/n_2)^2}{n_2-1}} \tag{5.7.1979}$$

As we do not know in practice the variances (and therefore the true standard deviations), we actually take:

$$\boxed{f=\frac{\left(\dfrac{S_1^2}{n_1}+\dfrac{S_2^2}{n_2}\right)^2}{\dfrac{(S_1^2/n_1)^2}{n_1-1}+\dfrac{(S_2^2/n_2)^2}{n_2-1}}} \tag{5.7.1980}$$

So the expression above rounded to the nearest integer is the number of degrees of freedom that must actually be taken for the Student heteroscedastic test:

$$T^{\text{calc}}([f])=\frac{(\bar{X}_2-\bar{X}_1)-(\mu_2-\mu_1)}{\sqrt{\dfrac{S_1^2}{n_1}+\dfrac{S_2^2}{n_2}}} \qquad (5.7.1981)$$

Finally, let us indicate that in the general case with n terms, the Welch-Satterthwaite equation is written (without proof):

$$f_n=\frac{\left(\displaystyle\sum_{i=1}^{n}\frac{S_i}{n_i}\right)^2}{\displaystyle\sum_{i=1}^{n}\frac{(S_i^2/n_i)^2}{n_i-1}} \qquad (5.7.1982)$$

Remark

For the special case $n=2$ the latter relation can often be found in the literature in the following form (...):

$$\nu=\frac{\left(\frac{s_1^2}{N_1}+\frac{s_2^2}{N_2}\right)^2}{\frac{s_1^4}{N_1^2\cdot\nu_1}+\frac{s_2^4}{N_2^2\cdot\nu_2}}=\frac{\left(\frac{s_1^2}{N_1}+\frac{s_2^2}{N_2}\right)^2}{\frac{s_1^4}{N_1^2\cdot(N_1-1)}+\frac{s_2^4}{N_2^2\cdot(N_2-1)}} \qquad (5.7.1983)$$

In the field of finance when using the CAPM model (see section Economy page 7740) or when using the ANCOVA (see section Statistics page ??) and not only that ... it is useful and important to compare the regression line slopes to find out if they are significantly different or not!

We have proved in the section of Numerical Methods (page 6348) that for a linear function whose parameters were estimated and which was expressed in the form:

$$\hat{Y}=Ax+B \qquad (5.7.1984)$$

and which exact unknown expression is:

$$Y=ax+b \qquad (5.7.1985)$$

we had:

$$A-T_{\alpha/2}(n-2)\sqrt{\frac{\frac{1}{n-2}\sum e_k^2}{n\mathbb{V}(x)}}\leq a\leq A+T_{\alpha/2}(n-2)\sqrt{\frac{\frac{1}{n-2}\sum e_k^2}{n\mathbb{V}(x)}} \qquad (5.7.1986)$$

and that if the real variance is unknown:

$$A-T_{\alpha/2}(n-2)\sqrt{\frac{\frac{1}{n-2}\sum e_k^2}{(n-1)\hat{\mathbb{V}}(x)}}\leq a\leq A+T_{\alpha/2}(n-2)\sqrt{\frac{\frac{1}{n-2}\sum e_k^2}{(n-1)\hat{\mathbb{V}}}(x)} \qquad (5.7.1987)$$

or sometimes also written:

$$A-T_{\alpha/2}(n-2)\sqrt{\frac{\text{SSE}}{n\text{V}(x)}}\leq a\leq A+T_{\alpha/2}(n-2)\sqrt{\frac{\text{SSE}}{n\text{V}(x)}} \tag{5.7.1988}$$

That has the same shape as the Student confidence interval test for the expected mean!

This being recalled, the objective now is to test if two slopes of two different regressions are equal (very important test for the study of the ANCOVA!), and then we write that the null hypothesis in the context of a hypothesis test obviously as following:

$$H_0:A_1=A_2\Leftrightarrow A_2-A_2=\Delta A=0 \tag{5.7.1989}$$

Since the confidence interval of a single slope of a regression is similar in all aspects to a confidence interval of the Student's mean, the difference of two slopes is then similar in all aspects to the Welch hypothesis test. We then have since we make the null hypothesis that the two true slopes have a null difference (i.e. $a_1=a_2$):

$$T^{\text{calc}}([f])=\frac{(A_2-A_1)-(a_2-a_1)}{\sqrt{\dfrac{\text{SSE}_1}{n_1\text{V}(x_1)}+\dfrac{\text{SSE}_2}{n_2\text{V}(x_2)}}}=\frac{A_2-A_1}{\sqrt{\dfrac{\text{SSE}_1}{n_1\text{V}(x_1)}+\dfrac{\text{SSE}_2}{n_2\text{V}(x_2)}}} \tag{5.7.1990}$$

with:

$$f\cong\frac{\left(\displaystyle\sum_{i=1}^{2}\frac{\dfrac{1}{n_i-2}\sum e_{i,k}^2}{n_i\text{V}(x_i)}\right)^2}{\displaystyle\sum_{i=1}^{2}\frac{\left(\dfrac{\dfrac{1}{n_i-2}\sum e_{i,k}^2}{n_i\text{V}(x_i)}\right)}{n_i-1}} \tag{5.7.1991}$$

Which is often written by tradition:

$$T^{\text{calc}}(f\cong n_1+n_2-4)\cong\frac{\hat{\beta}_2-\hat{\beta}_1}{S_{\hat{\beta}_1-\hat{\beta}_2}} \tag{5.7.1992}$$

Do not forget (very important case in the application of the ANCOVA) that if we work with the estimators, then $n_i\text{V}(x_i)$ become $(n_i-1)\hat{\text{V}}(x_i)$.

Remark

The variants of the T-test are: the Welch test that accounts for unequal group sizes and variance, the Yuen-Welch test that accounts for unequal variances and outliers, the permutation Welch/Yuen-Welch tests that accounts for non-normality and at the same time for unequal variances and outliers!

5.7.13.5.1.2 Contrasts

The F-test is rather unspecific. It basically gives us a "Yes/No" answer to the question: Is there any treatment effect at all? It does not tell us what specific treatment or treatment combination is special. Quite often, we have a more specific question than the aforementioned global null hypothesis. For example, we might want to compare a set of new treatments vs. a control treatment or we want to do pairwise comparisons between many (or all) treatments.

Many multiple comparison methods use the idea of what we name a "contrast". What is this? To introduce this concept let us consider a one-way fixed factor ANOVA where the null hypothesis H_0 was rejected but where actually we don't know what level of the variable cause the difference that brig us to reject the null hypothesis.

Consider for example that among the levels i, j, k, ... we suspect the levels i and k to differ. Therefore we would like to test the hypothesis:

$$\begin{gathered} H_0 : \mu_i = \mu_k \\ H_1 : \mu_i \neq \mu_k \end{gathered} \tag{5.7.1993}$$

or equivalently:

$$\begin{gathered} H_0 : \mu_i - \mu_k = 0 \\ H_1 : \mu_i - \mu_k \neq 0 \end{gathered} \tag{5.7.1994}$$

If we had suspected at the start of the experiment that the average of the two first level (considering an imaginary experiment with a factor having 5 fixed levels) did not differ from the average of the two highest levels, then the hypothesis would have been:

$$\begin{gathered} H_0 : \mu_1 + \mu_2 = \mu_3 + \mu_4 \\ H_1 : \mu_1 + \mu_2 \neq \mu_3 + \mu_4 \end{gathered} \tag{5.7.1995}$$

or:

$$\begin{gathered} H_0 : \mu_1 + \mu_2 - \mu_3 - \mu_4 = 0 \\ H_1 : \mu_1 + \mu_2 - \mu_3 - \mu_4 \neq 0 \end{gathered} \tag{5.7.1996}$$

In general a "contrast" is a linear combination of parameters of the form:

$$\boxed{C = \sum_{i=1}^{k} c_i \mu_i \quad \text{where} \quad \sum_i c_i = 0, c_i = \{\pm 1, 0\}} \tag{5.7.1997}$$

Remark

Two contrasts C_1, C_2 with coefficients $\{c_i\}$ and $\{d_i\}$, i.e.:

$$C_1 = \sum_{i=1}^{k} c_i \mu_i \qquad C_2 = \sum_{i=1}^{n} d_i \mu_i \tag{5.7.1998}$$

are said to be "orthogonal contrasts" if and only if $\sum c_i d_i = 0$.

For example, $C_1 = \mu - 2\mu_2 + \mu_3$ and $C_2 = \mu_1 - \mu_2$ are orthogonal contrast since $(1)(1) + (-2)(0) + (1)(-1) = 0$.

Both of the hypothesis above can then be expressed in terms of contrasts:

$$\boxed{\begin{aligned} H_0 &: \sum_i^k c_i\mu_i = 0 \\ H_1 &: \sum_i^k c_i\mu_i \neq 0 \end{aligned}} \tag{5.7.1999}$$

Therefore in the case of our previous example:

$$\begin{aligned} H_0 &: \mu_1 + \mu_2 - \mu_3 - \mu_4 = 0 \\ H_1 &: \mu_1 + \mu_2 - \mu_3 - \mu_4 \neq 0 \end{aligned} \tag{5.7.2000}$$

we have $c_1 = +1$, $c_2 = +1$, $c_3 = -1$, $c_4 = -1$, $c_5 = 0$.

Testing hypotheses involving contrasts can be done in three ways. We will introduce here only the one that gives the practitioner the possibility to build a confidence interval. This method uses a Student T-test. Indeed, let us write the contrast in terms of estimates:

$$\hat{C} = \sum_{i=1}^k c_i\bar{y}_{i.} \tag{5.7.2001}$$

as under the null hypothesis we should have (don't forget it!):

$$\hat{C} = \sum_{i=1}^k c_i\bar{y}_{i.} = 0 \tag{5.7.2002}$$

The variance of the sum can be written:

$$\text{V}(\hat{C}) = \text{V}\left(\sum_{i=1}^k c_i\bar{y}_i\right) = \sum_{i=1}^k c_i^2\text{V}(\bar{y}_i) \tag{5.7.2003}$$

If the equality of variance assumption is satisfied and the design is equilibrated we have:

$$\text{V}(\mu_i) = \frac{\sigma^2}{n} \tag{5.7.2004}$$

But with estimated we know that this is written:

$$\text{V}(\bar{y}_i) = \frac{S^2}{n} \tag{5.7.2005}$$

and therefore:

$$\text{V}(\hat{C}) = \sum_{i=1}^k c_i^2\text{V}(\bar{y}_i) = \sum_{i=1}^k c_i^2\frac{S^2}{n} = \frac{S^2}{n}\sum_{i=1}^k c_i \tag{5.7.2006}$$

Hence:

$$\frac{C-\mu}{\sigma_C}=\frac{C}{\sqrt{\text{V}(C)}} \tag{5.7.2007}$$

should follow a centered Normal law under the above assumptions:

$$\frac{C}{\sqrt{\text{V}(C)}}=\mathcal{N}(0,1) \tag{5.7.2008}$$

But as we work with estimators we know that we have instead:

$$T(N-k)=\frac{\hat{C}}{\sqrt{\text{V}(\hat{C})}}=\frac{\displaystyle\sum_{i=1}^{k}c_i\bar{y}_i}{\sqrt{\dfrac{S^2}{n}\displaystyle\sum_{i=1}^{k}c_i}} \tag{5.7.2009}$$

That is sometimes denoted in the field of analysis of variance:

$$T(N-k)=\frac{\displaystyle\sum_{i=1}^{k}c_i\bar{y}_i}{\sqrt{\dfrac{\text{MSE}}{n}\displaystyle\sum_{i=1}^{k}c_i}} \tag{5.7.2010}$$

Therefore the $100\cdot(1-\alpha)$ percent confidence interval on the contrast $\sum_{i=1}^{k}c_i\mu_i$ is:

$$\boxed{\sum_{i=1}^{k}c_i\bar{y}_i-T_{\alpha/2}(N-k)\sqrt{\frac{S^2}{n}\sum_{i=1}^{k}c_i}\leq\sum_{i=1}^{k}c_i\mu_i\leq\sum_{i=1}^{k}c_i\bar{y}_i+T_{\alpha/2}(N-k)\sqrt{\frac{S^2}{n}\sum_{i=1}^{k}c_i}} \tag{5.7.2011}$$

Clearly if this confidence interval includes zero, we would be unable to reject the null hypothesis.

Remark

Keep in mind that if you want to test for example in the framework of an ANOVA that $H_0:\ \mu_2=(\mu_1+\mu_3)/2$, it is therefore equivalent to write and test the following contrast $\sum c_i\mu_i=\mu_1-2\mu_2+\mu_3=\bar{y}_1-2\bar{y}_2+\bar{y}_3$.

5.7.13.5.2 ANOVA with two fixed factors without repetitions

We will now see the concept of interaction that is essential to understand what is behind the fixed two-factor ANOVA, also named "ANOVA with two fixed categorical variables" or "two-way ANOVA" or "randomized complete block design[74]", without and especially later with (!) repetitions. Indeed, it is only with two-factor ANOVA with repetitions - by mathematical construction - that can be statistically (under given assumptions) consider objectively if two or more factors interact significantly together.

We must therefore, before moving to the pure mathematical part, introduce some concepts!

Definitions (#5.7.149):

D1. We say that there is "no interaction" when the average of responses by a factor based on its level varies by the same amount and with the same sign as the average of the responses of another factor depending on its levels. Then we say that: the response interaction curves in the diagram are parallel.

> Remark
>
> The parallelism of response curves is normal in the situation of no interaction because it means that whatever the level of one or the other factors, the variation (if there is any) of the response will always be the same amplitude. What is characteristic of independence (at least locally).

D2. We say that two factors are "in interaction" when the average responses by a factor depending on its levels do not change by the same magnitude and / or not with the same sign as the average of the responses of another factor according to their levels. Then we say that: the response curves in the interactions diagram are not parallel.

> Remark
>
> The absence of interaction is a very strong assumption and a rarely observed. Often we have interactions or strong interactions.

To understand the concept, we will use small examples have no repeated measures to such we will have a simple qualitative idea of the phenomenon, but by no means a scientific approach of the concept of interaction (that will be study later in details).

For every small example below we visualize the situations by means of two types of representations: a graph illustrating the main effects on the one hand and a pattern of the interactions on the other hand.

---

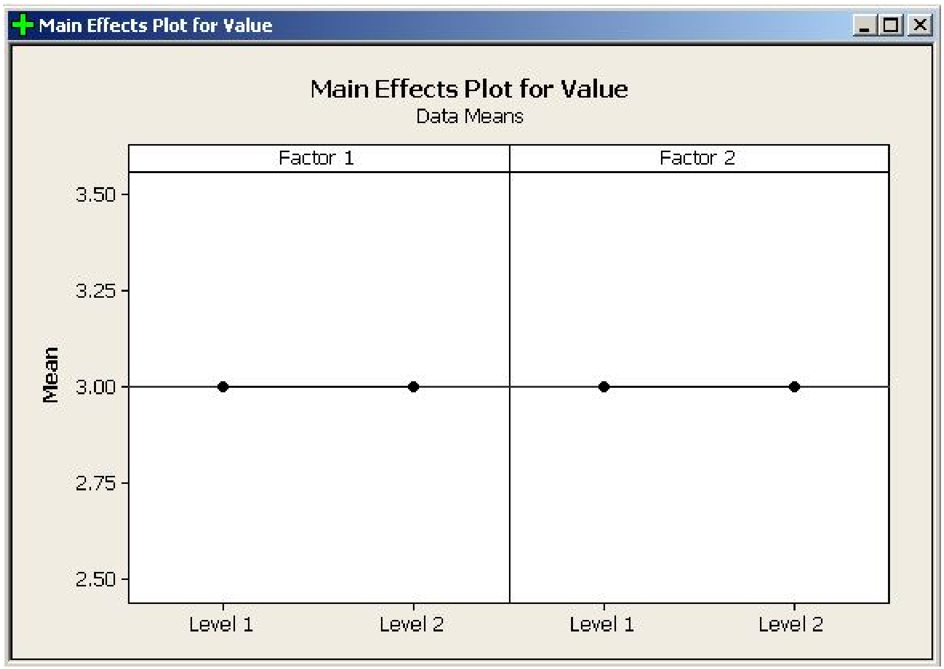
[74] As already mentioned, a "block" can be considered as a factor and hence the mathematical treatment is exactly the same!

Consider the following small table with two factors at two levels ("explanatory variables") including four cells ("variable of interest"):

	Factor 2	
Factor 1	Level 1	Level 2
Level 1	3	3
Level 2	3	3

Table 5.55: **First example of 2-factor ANOVA without repetition**

We will get as result with software such as Minitab:



Main Effects Plot for Value
Main Effects Plot for Value
Data Means
Factor 1
Factor 2
3.50
3.25
3.00
2.75
2.50
Mean
Level 1
Level 2
Level 1
Level 2

Figure 5.189: **Main effects plot without interactions in Minitab 15**

We see well that no factor has a major effect on anything. What is relatively obvious given the content of the previous table...

The diagram of interactions (often named "profiler" in the industry) gives:

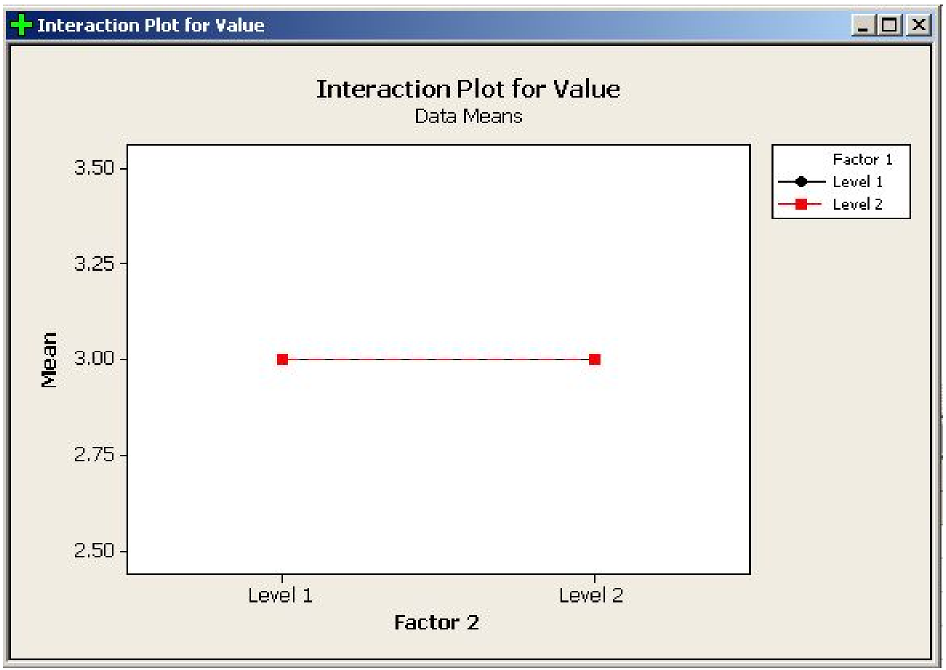


Figure 5.190: **Interactions plot without interactions in Minitab 15**

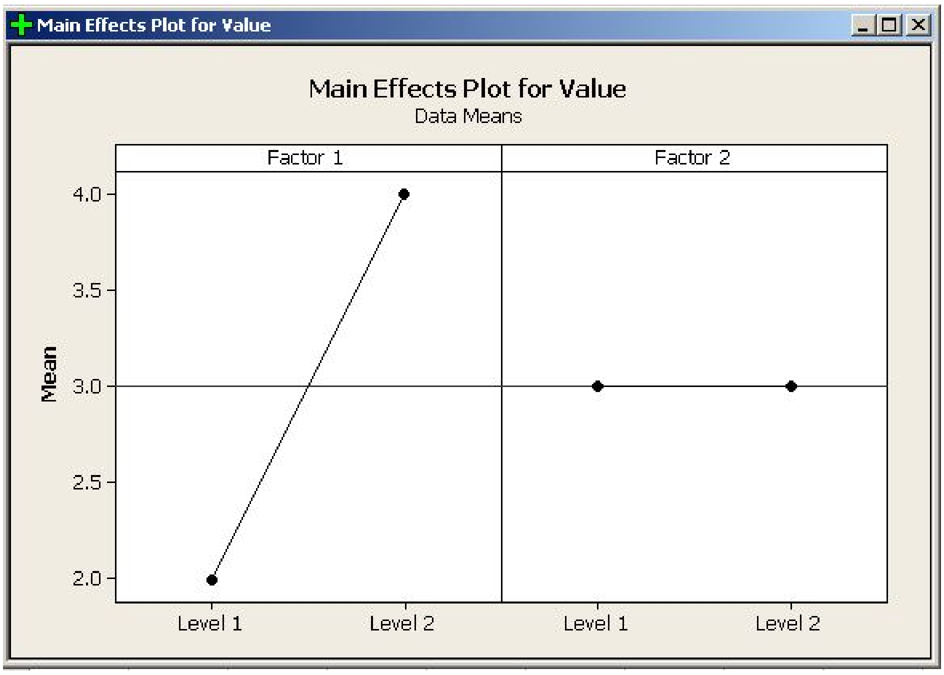
where we can see that the factors do not interact between them (or neutralize themselves it depends...). Then we say that there is "(a priori) no effect or no interaction (locally)". In fact in some experiments the absence of interaction is a very strong assumption and therefore very rare. This is why we must pay attention to the chosen words when interpreting interaction plots (because do not to go through pure calculations is dangerous for this step or simply not scientific!).

Now consider the following table:

	Factor 2	
Factor 1	Level 1	Level 2
Level 1	2	2
Level 2	4	4

Table 5.56: **Second example of 2-factor ANOVA without repetition**

It seems obvious that the factor one through considered with its levels seems to have an influence on the answer. But let us see the different representations:



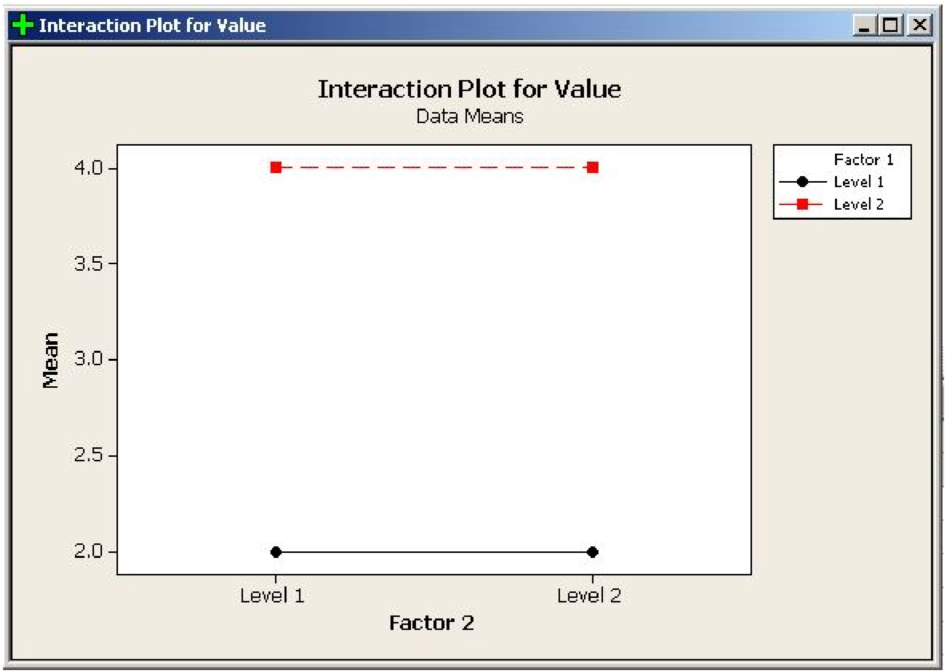


Figure 5.191: **Main effects and interactions plot with interactions in Minitab 15**

Let us comment the first graph as proposed by a reader:

This includes two parts: the left one analyses the effects of Factor 1 through its two levels; that of the right do the same for the Factor 2.

Have a closer look to the left part:

We see two points connected by a line segment. Here the first point, the one for the level 11, is located in the ordinate 2 while the second point, that for level 2, is located in the ordinate 4. Now remember that each point represents an average. And the ordinate of the first point is located at the average of $(2+2)/2=2$.

Having said that and hoping this helped to a better understanding, let us continue...

It is quite clear in the chart above that only the level of Factor 1 influences the answer, while Factor 2 has no effect on the answer. Then we say that: there is a main effect (locally) of the Factor 1.

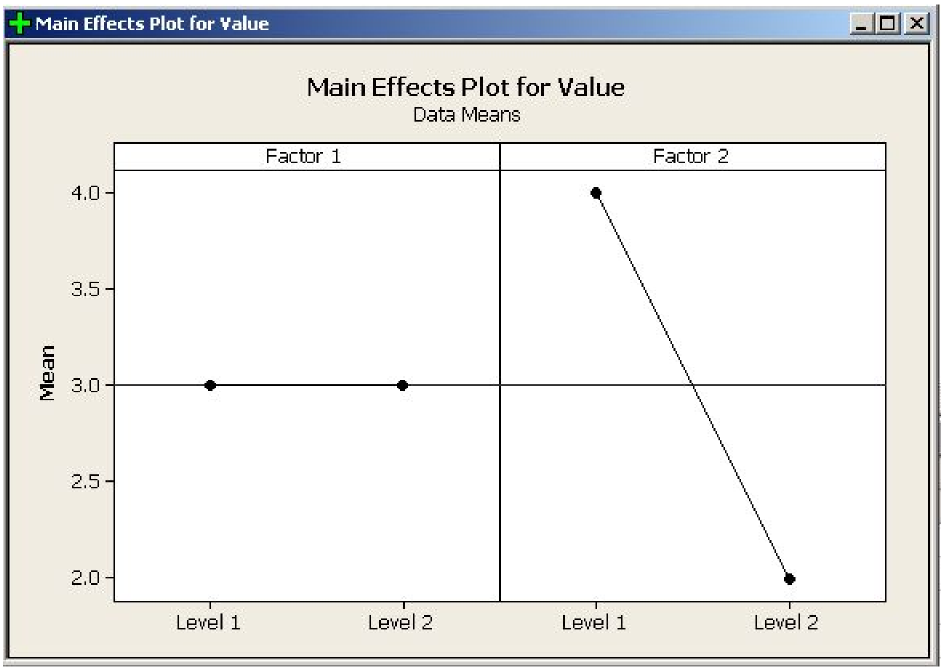
On the diagram of interactions, we have the same information but in a different form. We see that regardless of the level of Factor 2, the answers are horizontal and thus that it does not influence the results. We are then in a situation where "(a priori) the main effect is (locally) Factor 1 and there is an absence of interactions between factors".

Now consider the following table:

	Factor 2	
Factor 1	Level 1	Level 2
Level 1	4	2
Level 2	4	2

Table 5.57: **Third example of 2-factor ANOVA without repetition**

This time we can observe that the Factor 2 has an influence but not the Factor 1. But let us also see this with our two types of representations:



Main Effects Plot for Value
Main Effects Plot for Value
Data Means
Factor 1
Factor 2
Mean
4.0
3.5
3.0
2.5
2.0
Level 1
Level 2
Level 1
Level 2

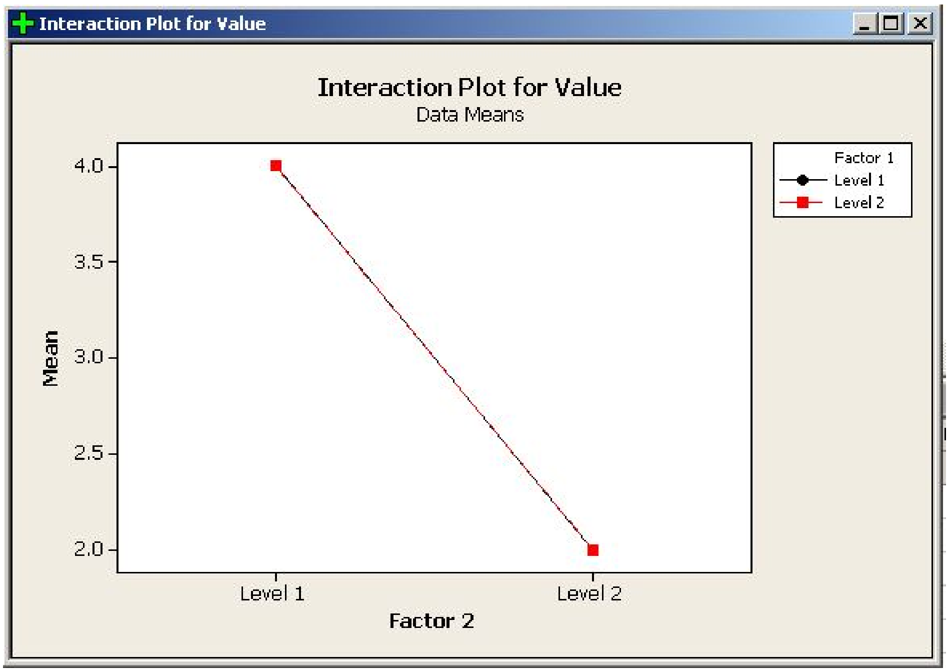


Figure 5.192: **Main effects and interactions plot with interactions in Minitab 15**

We see well on the top diagram that the Factor 1 has no influence. On the bottom diagram it is less obvious but the superposition of the two lines indicates that the Factor 1 has no influence. Then we say that there is: "(a priori) main effect (locally) of Factor 2 and absence of interactions between factors".

Now consider the following table:

	Factor 2	
Factor 1	Level 1	Level 2
Level 1	3	1
Level 2	5	3

Table 5.58: **Fourth example of 2-factor ANOVA without repetition**

We see that both factors have an influence on the answer. We can clearly see it on the both diagrams below:

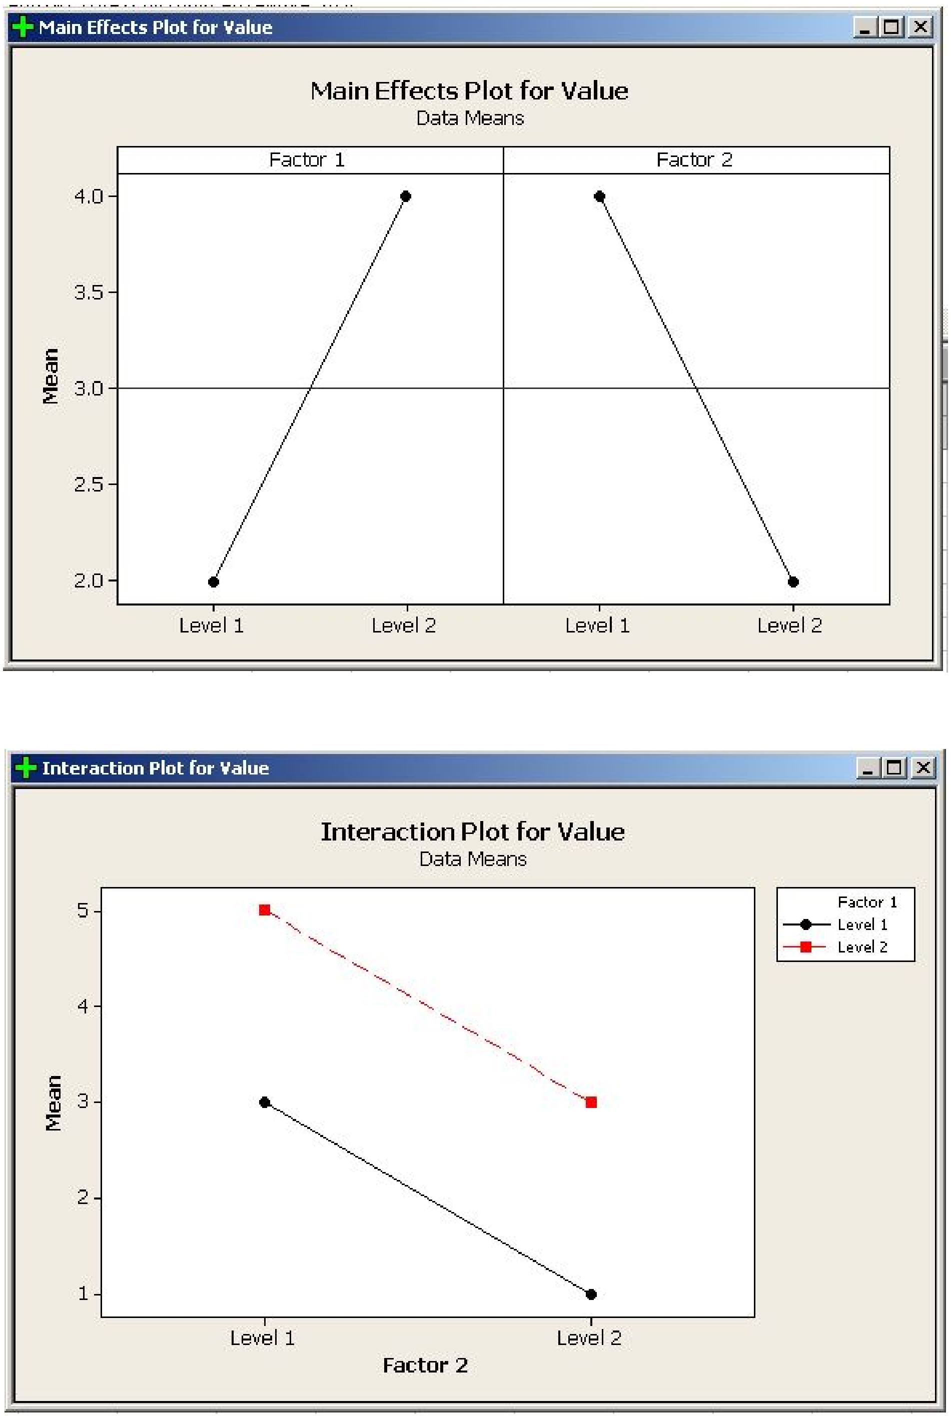

Figure 5.193: **Main effects and interactions plot with interactions in Minitab 15**

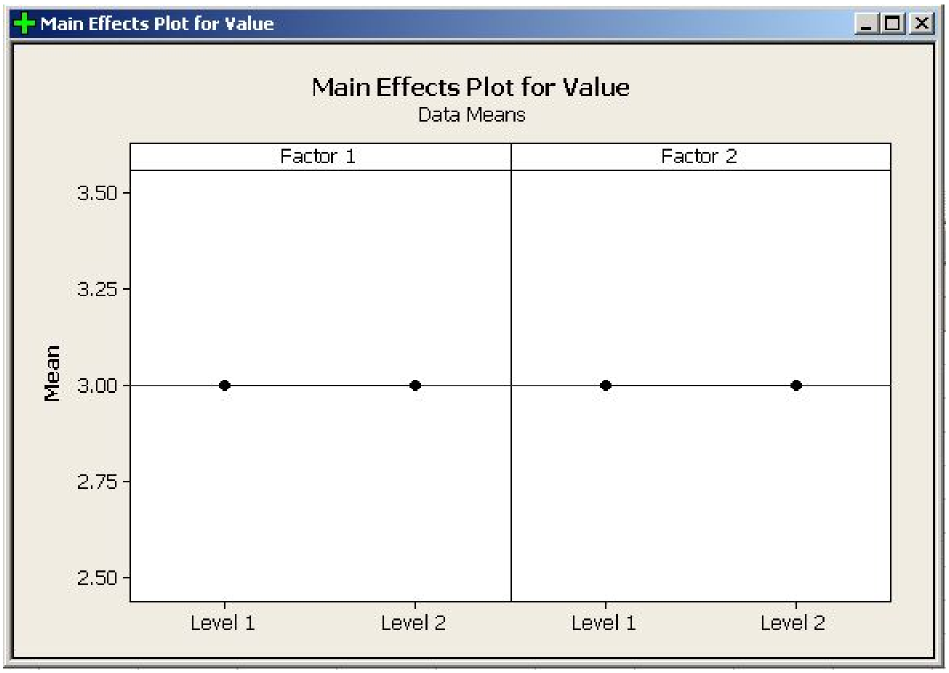
We can see very well on the top diagram that the Factor 1 has an influence on the answer and that we have the same conclusion for the Factor 2 (and furthermore to in the same magnitude regardless of the direction!). On the bottom diagram it is less obvious, but the same conclusion is valid. We then say that: "(a priori) both factors are (locally) significant and without interactions".

Now consider the following table:

	Factor 2	
Factor 1	Level 1	Level 2
Level 1	2	4
Level 2	4	2

Table 5.59: **Fifth example of 2-factor ANOVA without repetition**

which in this form is not always obvious to interpret. But with the diagrams we immediately have a more relevant information:



Main Effects Plot for Value

Level 1
Level 2
Factor 2
Factor 1
Level 1
Level 2

Figure 5.194: **Main effects and interactions plot ("disordonal interaction") with interactions in Minitab 15**

We see well on the top diagram that none of the factors has an effect in average on the answer a priori (same diagram as at the very beginning of this series of examples with the same mean!). The bottom diagram gives us additional information by cons (!!!): The factors have a cross-influence and as this cross-influence is of the same magnitude, the effects cancel out. Then we say that: "(a priori) the two factors are (locally) in interaction in F1 * F2".

Caution! It may happen that a "statistical interaction" like the one above may not mean what you thing! In regression, when you predict Y from two variables (say, X and Z), they are therefore said to "interact" when the predictiveness of one variable depends on the other. For example, perhaps X predicts Y strongly when Z is high but terribly otherwise. In this case, you might say that X and Z interact to predict Y. We could think of one predictor (e.g., Z) like a light switch that turns the other variable on or off. For X to predict Y, you also need the right combination of X and Z. Very important! And for this reason, analysts and data scientists often explore this by including product terms in their regressions:

$$Y = X + Z + X * Z$$

If $X * Z$ explains unique variance in Y, this is a sign that Z and X interact. We can re-arrange terms to tell the story of this interaction, but this is how we commonly test it. So.... $X * Z$ is strong and significant. However... (!!!) you can also get the same effect in other cases. Eek! Why? Imagine that X has a quadratic relationship to Y, say:

$$Y = X + X^2$$

This is just a special case of interaction. So, in this case, X "moderates itself" and that makes sense: if the relationship between X and Y is non-linear, it's stronger at some levels of X but weaker at others. The relationship between X and Y depends.... on X! Well, if other variables correlate with X (e.g., Z), guess what? They may act the same way because they are picking up on that quadratic relationship. So, if you run the usual "test for interaction":

$$Y = X + Z + X * Z$$

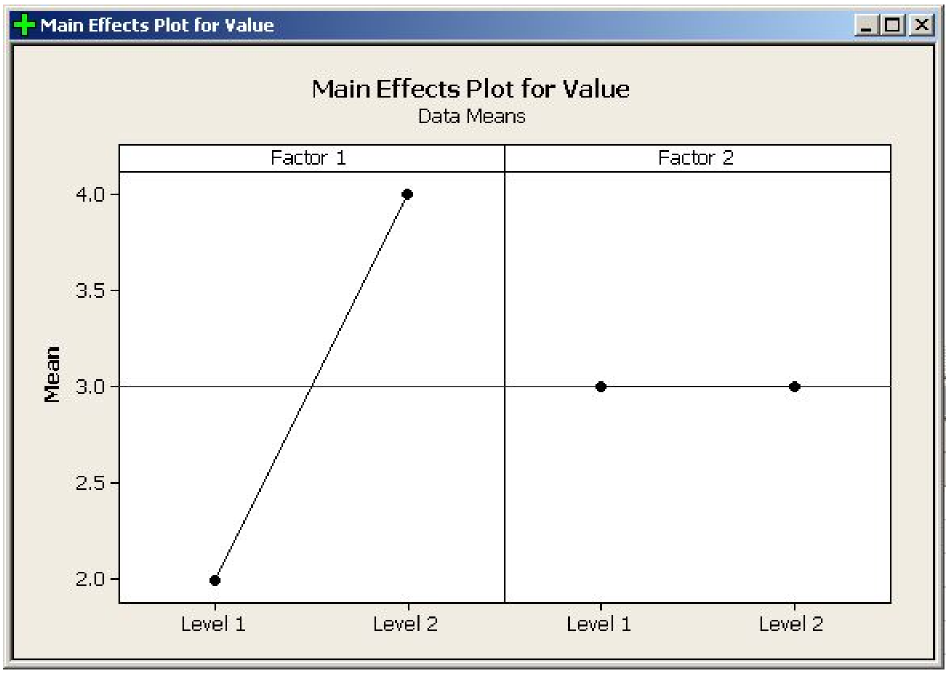
Your term may come up significant because it is tapping into the quadratic relationship X has with itself, which you haven't controlled for! So be sceptical of interactions, particularly when there is non-linearity present! Examine the linearity of relationships between your predictors (single one at a time) and your outcome if you do plan to test for interactions!

Now consider the following table:

	Factor 2	
Factor 1	Level 1	Level 2
Level 1	1	3
Level 2	5	3

Table 5.60: **Sixth example of 2-factor ANOVA without repetition**

which in this form is not also always obvious to interpret. But with the diagrams we immediately have a more relevant information:



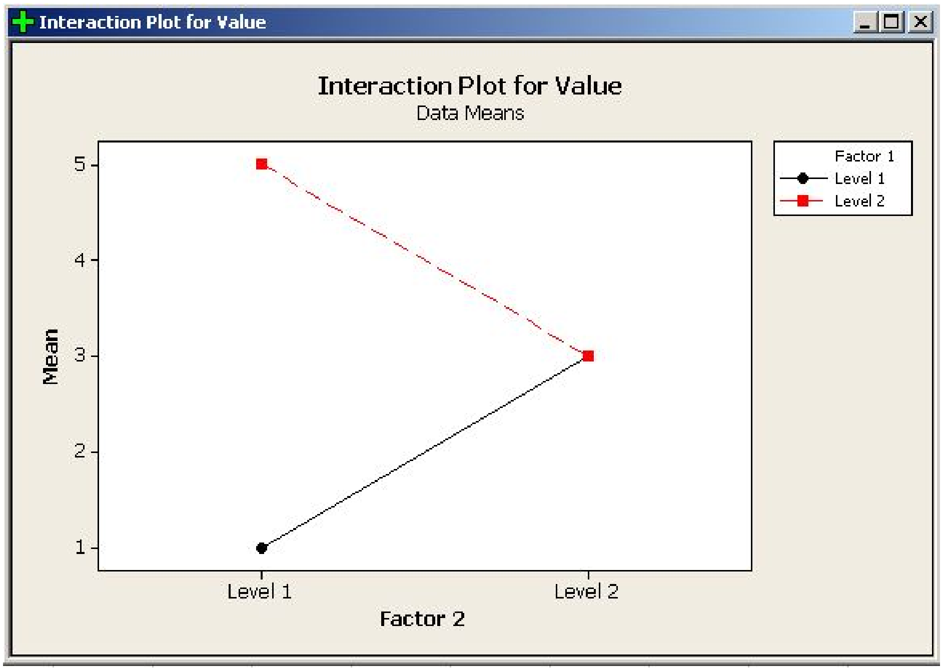


Figure 5.195: **Main effects and interactions plot with interactions in Minitab 15**

We observe well on the top diagram that the Factor 1 appears to have an influence and the factor 2 no (in average!). The bottom interactions diagram gives us, too, once again, additional information (!!!): It is that the factors are interacting. We say then that we have "(a priori) two factors (locally) in interaction F1 * F2 where the influence of Factor 1 is significant".

Now consider the following table:

	Factor 2	
Factor 1	Level 1	Level 2
Level 1	3	3
Level 2	5	1

Table 5.61: **Seventh example of 2-factor ANOVA without repetition**

We see that both factors influence the answer. We see that well on the both diagrams below:

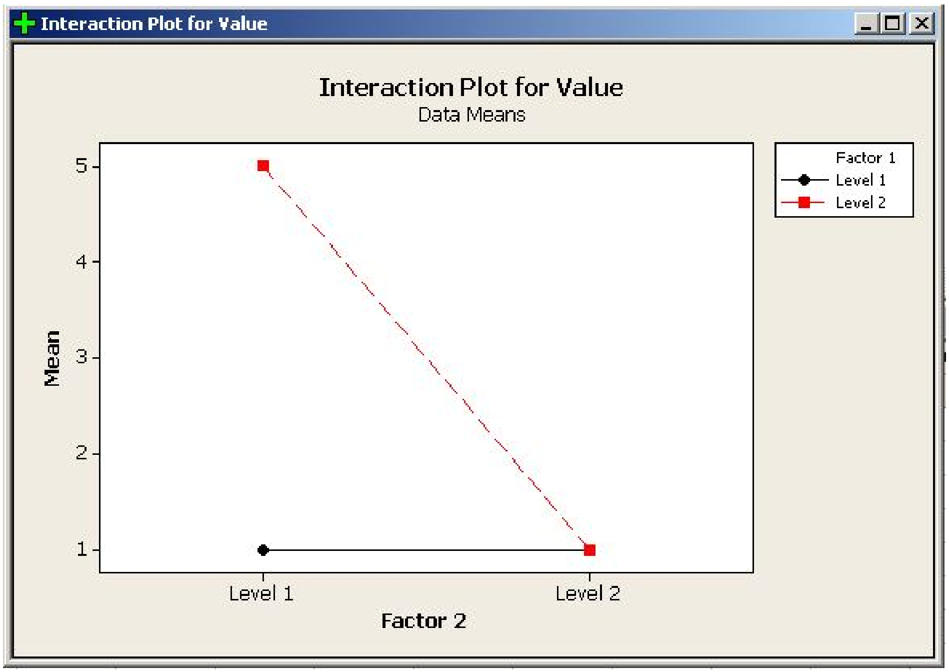

Figure 5.197: **Main effects and interactions plot with interactions in Minitab 15**

Here we say we have: "(a priori) the two factors (locally) interacting F1 * F2 where the influence of both factors is significant".

Remarks

R1. A belief (commonly spread) of people who have a lack experience in laboratories is to think that for an interaction to be significant it is necessary that the both factors that compose it are also significant.

R2. If an interaction is significant, the main effects are objectively rarely interpretable!

After all these diagrams and tables, let us turn back to the mathematical part:

We saw earlier how to perform a one-way fixed factor analysis of variance. To recap, this consists to a test for equality of means for k independent samples of n random variables each (in the case where all samples have the same number of measures: a balanced ANOVA). Each sample is regarded as an experiment on a different subject then considered therefore as an independent variable factor!!!

However it happens in the reality that we do for each sample vary a second parameter, then considered a second variable factor but independent of the first one. We speak then of course analysis of variance with two factors. In addition, we will consider in the first instance to simplify the calculations that the random variables are independent! Therefore a factor has no influence over the other has we already mention it !!! In other words there is no interaction between factors. We speak then of a "two-factor ANOVA without interactions".

To determine the formulation of the test to be performed, remember that for the analysis of variance with factor, we decomposed the total variance in the sum of the variance of average (inter-class) and of the residual variance (intraclass) such that:

$$Q_T = Q_A + Q_R \tag{5.7.2012}$$

explicitly we compare the samples $i=1\ldots k$:

$$\begin{aligned}Q_T&=\sum_{ij}(x_{ij}-\bar{\bar{x}})^2=\sum_i\sum_j(x_{ij}-\bar{\bar{x}})^2=\sum_i\sum_j((x_{ij}-\bar{x}_i)+(\bar{x}_i-\bar{\bar{x}}))^2\\&=\sum_i\sum_j(x_{ij}-\bar{x}_i)^2+\sum_i\sum_j(\bar{x}_i-\bar{\bar{x}})^2+2\sum_i\sum_j(x_{ij}-\bar{x}_i)(\bar{x}_i-\bar{\bar{x}})\end{aligned}\tag{5.7.2013}$$

which had given us in the end:

$$Q_T=\sum_i\sum_j(x_{ij}-\bar{x}_i)^2+\sum_i\sum_j(\bar{x}_i-\bar{\bar{x}})^2=Q_R+Q_A\tag{5.7.2014}$$

For the ANOVA with two fixed factors we will start form the table below:

	Factor A				
Factor B	Sample 1	Sample 2	Sample ...j	Sample r	
Sample 1	x_{11}	x_{12}	$\ldots$	x_{1r}	Average $\bar{x}_1$
Sample 2	x_{21}	x_{22}	$\ldots$	x_{2r}	Average $\bar{x}_2$
Sample i	$\ldots$	$\ldots$	x_{ij}	$\ldots$	Average $\bar{x}_i$
Sample k	x_{n1}	x_{n2}	$\ldots$	x_{kr}	Average $\bar{x}_k$
	Average: $\bar{x}_1$	Average: $\bar{x}_2$	Average: $\bar{x}_j$	Average: $\bar{x}_r$	$\bar{\bar{x}}$

Table 5.63: **Typical cross structure for the analysis of variance of 2 fixed factors without repetitions**

for which in a laboratory the factor kept fixed while the other is varied will be named the "block factor" and the other will be named the "treatment factor" and in practice it will be ensured that the latter does not always change out in the same order in the purpose to eliminate possible inertia effects when switching from one treatment to another (the Americans refer to two-factor controlled ANOVAs without interactions under the terms: "randomized block design" (GRBD)).

To continue the whole trick is to break down the total variance by comparing the average of the rows (observations) indexed this time with $i=1\ldots k$ and of columns (samples) indexed with $j=1\ldots r$ relatively to the total average such as:

$$\begin{aligned}Q_T&=\sum_{ij}(x_{ij}-\bar{\bar{x}})^2=\sum_{ij}(x_{ij}-\bar{\bar{x}})^2=\sum_i\sum_j\left[(\bar{x}_i-\bar{\bar{x}})+(\bar{x}_j-\bar{\bar{x}})+(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})\right]^2\\&=\sum_{ij}[((\bar{x}_i-\bar{\bar{x}})+(\bar{x}_j-\bar{\bar{x}}))^2+2\left((\bar{x}_i-\bar{\bar{x}})+(\bar{x}_j-\bar{\bar{x}})\right)(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})\\&+(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})^2]\\&=\sum_{ij}[(\bar{x}_i-\bar{\bar{x}})^2+2(\bar{x}_i-\bar{\bar{x}})(\bar{x}_j-\bar{\bar{x}})+(\bar{x}_j-\bar{\bar{x}})^2+2((\bar{x}_i-\bar{\bar{x}})+(\bar{x}_j-\bar{\bar{x}}))(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})\\&+(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})^2]\end{aligned}\tag{5.7.2015}$$

But we have in a first time:

$$\sum_{ij}2(\bar{x}_i-\bar{\bar{x}})(\bar{x}_j-\bar{\bar{x}})=2\underbrace{\sum_i(\bar{x}_i-\bar{\bar{x}})}_{=0}\underbrace{\sum_j(\bar{x}_j-\bar{\bar{x}})}_{=0}=0\tag{5.7.2016}$$

So it remains:

$$\begin{aligned}Q_T = &\sum_{ij}[(\bar{x}_i-\bar{\bar{x}})^2+(\bar{x}_j-\bar{\bar{x}})^2+2((\bar{x}_i-\bar{\bar{x}})+(\bar{x}_j-\bar{\bar{x}}))(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})\\ &+(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})^2]\end{aligned}\tag{5.7.2017}$$

But we also have:

$$\begin{aligned}&\sum_{ij}2((\bar{x}_i-\bar{\bar{x}})+(\bar{x}_j-\bar{\bar{x}}))(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})\\ &=2\sum_{ij}((\bar{x}_i-\bar{\bar{x}})+(\bar{x}_j-\bar{\bar{x}}))(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})\\ &=2\sum_{ij}(\bar{x}_i-\bar{\bar{x}})(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})+2\sum_{ij}(\bar{x}_j-\bar{\bar{x}})(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})\end{aligned}\tag{5.7.2018}$$

For the rest, let us indicate first that relatively to our above table, we have:

$$\begin{aligned}\bar{\bar{x}}&=\frac{1}{rk}\sum_{ij}x_{ij}\\ \bar{x}_i&=\frac{1}{r}\sum_i x_i\\ \bar{x}_j&=\frac{1}{k}\sum_j x_j\end{aligned}\tag{5.7.2019}$$

It follows then that:

$$\begin{aligned}&\sum_{ij}(\bar{x}_i-\bar{\bar{x}})(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})=\sum_i(\bar{x}_i-\bar{\bar{x}})\left(\sum_j x_{ij}-\sum_j\bar{x}_i-\sum_j\bar{x}_j+\sum_j\bar{\bar{x}}\right)\\ &=\sum_i(\bar{x}_i-\bar{\bar{x}})\left(r\bar{x}_i-\bar{x}_i\sum_j 1-\sum_j\frac{1}{k}\sum_i x_{ij}+\bar{\bar{x}}\sum_j 1\right)\\ &=\sum_i(\bar{x}_i-\bar{\bar{x}})\left(r\bar{x}_i-\bar{x}_i r-\frac{1}{k}\sum_{ij}x_{ij}+\bar{\bar{x}}r\right)=\sum_i(\bar{x}_i-\bar{\bar{x}})(-r\bar{\bar{x}}+\bar{\bar{x}}r)\\ &=\sum_i(\bar{x}_i-\bar{\bar{x}})\cdot 0=0\end{aligned}\tag{5.7.2020}$$

and then it comes immediately that we have likewise:

$$\sum_{ij}(\bar{x}_j-\bar{\bar{x}})(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})=0\tag{5.7.2021}$$

So it remains in the end:

$$\begin{aligned}Q_T&=\sum_{ij}[(\bar{x}_i-\bar{\bar{x}})^2+(\bar{x}_j-\bar{\bar{x}})^2+(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})^2]\\ &=\sum_{ij}(\bar{x}_i-\bar{\bar{x}})^2+\sum_{ij}(\bar{x}_j-\bar{\bar{x}})^2+\sum_{ij}(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})^2\\ &=k\sum_j(\bar{x}_k-\bar{\bar{x}})^2+r\sum_i(\bar{x}_i-\bar{\bar{x}})^2+\sum_{ij}(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})^2\end{aligned}\tag{5.7.2022}$$

what we will denote in this textbook in the following condensed form:

$$\boxed{Q_T = Q_A + Q_B + Q_R} \tag{5.7.2023}$$

where Q_A, Q_B are obviously associated with the main effects (comparison of marginal means with the total average).

Therefore compared to the one-way fixed factor ANOVA we have an additional term for the total variance!

In order it is clear that the first sum of the differences from the first column factor:

$$\sum_{ij} (\bar{x}_i - \bar{\bar{x}}) \tag{5.7.2024}$$

will have just as for the one-way fixed factor ANOVA $k-1$ degrees of freedom. That is to say, under the same assumptions as the one-way fixed factor ANOVA:

$$\frac{\sum\limits_{ij} (\bar{x}_i - \bar{\bar{x}})}{\sigma^2} = \chi^2_{k-1} \tag{5.7.2025}$$

The second sum of the differences from the second factor (line factor):

$$\sum_{ij} (\bar{x}_j - \bar{\bar{x}}) \tag{5.7.2026}$$

is new but we prove in a perfectly identical way to the first one it will have $k-1$ degrees of freedom. That is to say, under the same assumptions as the one-way fixed factor ANOVA:

$$\frac{\sum\limits_{ij} (\bar{x}_j - \bar{\bar{x}})}{\sigma^2} = \chi^2_{r-1} \tag{5.7.2027}$$

For the third sum that follows mandatory also a chi-square law (since the total variance follows a chi-square law and that the first two terms of the sum also!):

$$\sum_{ij} (x_{ij} - \bar{x}_i - \bar{x}_j + \bar{\bar{x}})^2 \tag{5.7.2028}$$

it's a little bit trickier ... but there's a trick in the physicist way of life...! We know from our study of the one-way fixed factor ANOVA that the sum of the degrees of freedom of each term must equal the total number of degrees of freedom. In other words, we must have for the two-way fixed factor ANOVA:

$$\text{df}_T = N - 1 = kr - 1 = (k-1) + (r-1) + ??? \tag{5.7.2029}$$

So obviously what is missing is equal to:

$$??? = kr - 1 - [(k-1) + (r-1)] = kr - 1 - k + 1 - r + 1 = kr - k - r + 1 = (k-1)(r-1) \tag{5.7.2030}$$

Therefore:

$$\frac{\sum\limits_{ij}(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})^2}{\sigma^2}=\chi^2_{(k-1)(r-1)} \tag{5.7.2031}$$

We then have the following table:

$$\boxed{\begin{array}{lll}
Q_T=\sum\limits_{ij}(x_{ij}-\bar{\bar{x}})^2 & \mathrm{df}_T=N-1=kr-1 & \mathrm{V}_T=\dfrac{Q_T}{\mathrm{df}_T}\\
Q_A=k\sum\limits_{j}(\bar{x}_j-\bar{\bar{x}})^2 & \mathrm{df}_A=r-1 & \mathrm{V}_A=\dfrac{Q_A}{\mathrm{df}_A}\\
Q_B=r\sum\limits_{i}(\bar{x}_i-\bar{\bar{x}})^2 & \mathrm{df}_B=k-1 & \mathrm{V}_B=\dfrac{Q_B}{\mathrm{df}_B}\\
Q_R=\sum\limits_{ij}(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})^2 & \mathrm{df}_R=(k-1)(r-1) & \mathrm{V}_R=\dfrac{Q_R}{\mathrm{df}_R}
\end{array}} \tag{5.7.2032}$$

Finally, the rest is exactly the same as for the one-way fixed factor ANOVA just that we have two tests to do this time that are:

$$F_{k-1,(k-1)(r-1)}=\frac{\dfrac{Q_A}{k-1}}{\dfrac{Q_R}{(k-1)(r-1)}}\quad\text{and}\quad F_{r-1,(k-1)(r-1)}=\frac{\dfrac{Q_B}{r-1}}{\dfrac{Q_R}{(k-1)(r-1)}} \tag{5.7.2033}$$

The choice above seems intuitively practical...

All calculations we have made above are often represented in software in a standard form of a table whose form and content is presented below (this is how Minitab 15.1.1 and Microsoft® Excel® 11.8346 present it for example):

Sum of squares (SSE)	χ^2 **df**	**Mean squares**	F	**Critical** F
$Q_A=k\sum\limits_j(\bar{x}_j-\bar{\bar{x}})^2$	$k-1$	$\text{MSk}A=\dfrac{Q_A}{k-1}$	$\dfrac{\text{MSk}A}{\text{MSE}}$	$P(F>F_{k-1,(k-1)(r-1)})$
$Q_B=r\sum\limits_i(\bar{x}_i-\bar{\bar{x}})^2$	$r-1$	$\text{MSk}B=\dfrac{Q_B}{r-1}$	$\dfrac{\text{MSk}B}{\text{MSE}}$	$P(F>F_{r-1,(k-1)(r-1)})$
$Q_R=\sum_{ij}(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})^2$	$(k-1)(r-1)$	$\text{MSE}=\dfrac{Q_R}{(k-1)(n-1)}$		
$Q_T=\sum\limits_{ij}(x_{ij}-\bar{\bar{x}})^2$	$N-1$	$\text{MST}=\dfrac{Q_T}{N-1}$		

Table 5.64: Two-way fixed factor ANOVA table without repetitions

and the condition of acceptance of the null hypothesis of equality of means for each factor is the same as for the one-way fixed factor ANOVA (see the server of exercises for a detailed practical example with Microsoft® Excel® 11.8346).

So we have two Fisher tests to know whether if factor A (respectively B) have a significant influence on the measures or not.

Obviously, in the above developments, factors A and B are interchangeable in the developments by symmetry!

Remark

The corresponding factor effect model is (notice that the model is assumed to be purely additive, that is without interactions!):

$$\boxed{x_{ijk} = \mu + \tau_i + \beta_j + \varepsilon_{ij}} \tag{5.7.2034}$$

with $i = 1 \ldots a$, $j = 1 \ldots b$ where μ is the overall mean, τ_i is the effect of the ith of treatment A, β_j is the effect of the jth level of treatment B (main effects) and ε_{ij} is the habitual random error following $\mathcal{N}(0, \sigma_\varepsilon^2)$.

The assumptions on the effect terms are $\sum_{i=1}^{a} \tau_i = 0$, $\sum_{j=1}^{b} \beta_j = 0$.

The hypothesis of interest are $H_0: \; \tau_i = 0$ and $H_0: \; \beta_j = 0$.

We see that the maximum likelihood estimators of the model parameters are $\hat{\mu} = \bar{\bar{x}}$ and $\hat{\tau}_i = \bar{x}_i - \bar{\bar{x}}$ and $\hat{\beta}_j = \bar{x}_j - \bar{\bar{x}}$. Hence:

$$\hat{x_{ij}} = \bar{\bar{x}} + (\bar{x}_i - \bar{\bar{x}}) + (\bar{x}_j - \bar{\bar{x}}) = \bar{x}_i + \bar{x}_j - \bar{\bar{x}} \tag{5.7.2035}$$

5.7.13.5.3 ANOVA with two fixed factors with repetitions

So far we have examined ANOVA on experiments with one or two fixed factors (one or two categorical variables not sampled from a populations). In the case of two factors, we considered that for each combination of factors we only had one measure (cell). But it can happen (and this is better!) that have several measures for one combination of factors! We name this type of study of "experimental design with repeated measures" and the results will be processed with an analysis of variance for repeated measures (RM-ANOVA) with two fixed factors and interactions! This is an extremely important tool as it allows validation studies by several independent laboratories (or employees) and is also associated with many other statistical tools such as the study of reproducibility and repeatability (R&R Study) to name only the best known cases in the industrial field.

You must understand that it is mandatory in the field of statistics to involve interactions between factors systematically when we are dealing with an experience having repeated measures. This for the simple reason that the mathematical interaction term only appears in this situation!

Thus, it may be intuitive (even before the proof) that a two fixed factor ANOVA with repeated measures contains one double interaction, and two main effects. A three fixed factor ANOVA with repeated measures will have one triple interaction, three double interactions and 3 main effects. And so on...

Before we start, we will consider the following measurement table (this kind of table typically belongs to the family of "multi-dimensional crossed-table with subtotals"):

	Factor A				
Factor B	Sample 1	Sample 2	Sample ...j	Sample r	AVERAGE
Sample 1	x_{111}	x_{112}	...	x_{11r}	
Replication 2	x_{211}	x_{212}	...	x_{21r}	
Replication m	...	...	...	...	
Replication n	x_{n11}	x_{n12}	...	x_{n1r}	
Average Sample 1	$\bar{x}_{11}$	$\bar{x}_{12}$	...	$\bar{x}_{13}$	$\bar{x}_{1.}$
Sample 2	x_{121}	x_{122}	...	x_{12r}	
Replication 2	x_{221}	x_{222}	...	x_{22r}	
Replication m	...	...	...	...	
Replication n	x_{n21}	x_{n22}	...	x_{n2r}	
Average Sample 2	$\bar{x}_{21}$	$\bar{x}_{22}$	...	$\bar{x}_{2r}$	$\bar{x}_{2.}$
Sample i	...	...	x_{1ij}	...	
Replication 2	...	...	...	...	
Replication m	...	...	...	...	
Replication n	...	...	x_{nij}	x_{nir}	
Average Sample i	...	...	$\bar{x}_{ij}$	...	$\bar{x}_{i.}$
Sample k	x_{2k1}	x_{2k2}	...	x_{2kr}	
Replication 2	x_{21}	x_{22}	...	x_{2r}	
Replication m	...	...	...	...	
Replication n	x_{nk1}	x_{nk2}	...	x_{nkr}	
Average Sample k	$\bar{x}_{k1}$	$\bar{x}_{k2}$	...	$\bar{x}_{kr}$	$\bar{x}_{k.}$
AVERAGE	$\bar{x}_{.1}$	$\bar{x}_{.2}$	$\bar{x}_{.j}$	$\bar{x}_{.r}$	$\bar{\bar{x}}_{..}$

Table 5.65: **Typical cross structure for the analysis of variance of 2 fixed factors with repetitions**

with the usual properties of the mean (for reminder):

$$\begin{aligned}\bar{x}_{i.} &= \frac{1}{r}\sum_{j=1}^{r}\bar{x}_{ij} = \frac{1}{rn}\sum_{m=1}^{n}\sum_{j=1}^{r}x_{mij}\\ \bar{x}_{.j} &= \frac{1}{k}\sum_{i=1}^{k}\bar{x}_{ij} = \frac{1}{kn}\sum_{m=1}^{n}\sum_{k=1}^{k}x_{mij}\\ \bar{x}_{..} &= \frac{1}{r}\sum_{j=1}^{r}\bar{x}_{.j} = \frac{1}{k}\sum_{i=1}^{k}\bar{x}_{ij} = \frac{1}{krn}\sum_{m=1}^{n}\sum_{k=1}\sum_{j=1}^{r}x_{mij}\end{aligned} \tag{5.7.2036}$$

And remember that the two fixed factor ANOVA without replications (and therefore without possibility to analyse mathematically the interactions), all the trick was to break down the total variance by comparing the average of the lines indexed with $i = 1 \ldots k$ and of columns indexed with $j = 1 \ldots r$ compared with the total average.

The idea will now be just about the same except that we will compare the mean of the lines indexed with $i = 1 \ldots k$ and columns indexed with $j = 1 \ldots r$ not only in comparison to the total average but also that of each row and of each column.

For this purpose with start from what we got for the two fixed factor ANOVA without replication:

$$Q_T = \sum_{ij}(x_{ij}-\bar{\bar{x}})^2 = \sum_{ij}(x_i-\bar{\bar{x}})^2 + \sum_{ij}(x_j-\bar{\bar{x}})^2 + \sum_{ij}(x_{ij}-\bar{x}_i-\bar{x}_j+\bar{\bar{x}})^2 \tag{5.7.2037}$$

but whose notation will just be adapted to the context:

$$Q_T = \sum_{ij}(x_{ij}-\bar{\bar{x}}_{..})^2 = r\sum_{i}(x_{i.}-\bar{\bar{x}}_{..})^2 + k\sum_{j}(x_{.j}-\bar{\bar{x}}_{..})^2 + \sum_{ij}(x_{ij}-\bar{x}_{i.}-\bar{x}_{.j}+\bar{\bar{x}}_{..})^2 \tag{5.7.2038}$$

Obviously, with this notation the two fixed factor ANOVA without replication becomes:

$$\begin{aligned}Q_T &= \sum_{ij}(x_{ij}-\bar{\bar{x}})^2 &&\rightarrow\quad Q_T = \sum_{ij}(x_{ij}-\bar{\bar{x}}_{..})^2\\ Q_A &= r\sum_{i}(x_i-\bar{\bar{x}})^2 &&\rightarrow\quad Q_A = r\sum_{i}(x_{i.}-\bar{\bar{x}}_{..})^2\\ Q_B &= k\sum_{i}(x_j-\bar{\bar{x}})^2 &&\rightarrow\quad Q_B = k\sum_{j}(x_{.j}-\bar{\bar{x}}_{..})^2\end{aligned} \tag{5.7.2039}$$

But in the present case, we must add a term for the replication and adapt the notation for the measurements. So, without repeating all the developments (it is a bit cheeky but...) we get directly:

$$Q_T = \sum_{mij}(x_{mij}-\bar{\bar{x}}_{..})^2 = nr\sum_{i}(x_{i.}-\bar{\bar{x}}_{..})^2 + nk\sum_{j}(x_{.j}-\bar{\bar{x}}_{..})^2 + \sum_{ijm}(x_{mij}-\bar{x}_{i.}-\bar{x}_{.j}+\bar{\bar{x}}_{..})^2 \tag{5.7.2040}$$

where in order, m is the replication of the sample i of the factor A and of sample j of factor B.

It comes then obviously the interclass variances for factors A and B that are immediate:

$$\begin{aligned}Q_A &= nr\sum_i \left(x_{i.}-\bar{\bar{x}}_{..}\right)^2\\ Q_B &= nk\sum_j \left(x_{.j}-\bar{\bar{x}}_{..}\right)^2\end{aligned}\tag{5.7.2041}$$

where Q_A, Q_B are obviously again associated with main effects (comparisons of marginal averages with the total average).

Now let's play a little by introducing in the sum, in positive and negative in the last term:

$$\sum_{ijm}\left(x_{mij}-\bar{x}_{i.}-\bar{x}_{.j}+\bar{\bar{x}}_{..}\right)^2\tag{5.7.2042}$$

the average of replications:

$$\bar{x}_{ij}\tag{5.7.2043}$$

that we will find in fine in the total sum of squares:

$$\begin{aligned}&\sum_{mij}\left(x_{mij}-\bar{x}_{i.}-\bar{x}_{.j}+\bar{\bar{x}}_{..}\right)^2=\sum_{mij}\left(x_{mij}-\bar{x}_{i.}-\bar{x}_{.j}+\bar{\bar{x}}_{..}+\bar{x}_{ij}-\bar{x}_{ij}\right)^2\\ &=\sum_{mij}\left(\left(\bar{x}_{ij}-x_{i.}-x_{.j}+\bar{\bar{x}}\right)+\left(x_{mij}-\bar{x}_{ij}\right)\right)^2=\sum_{mij}\left(\bar{x}_{ij}-x_{i.}-x_{.j}+\bar{\bar{x}}\right)^2\\ &+2\sum_{mij}\left(\bar{x}_{ij}-x_{i.}-x_{.j}+\bar{\bar{x}}\right)\left(x_{mij}-\bar{x}_{ij}\right)+\sum_{mij}\left(x_{mij}-\bar{x}_{ij}\right)^2\\ &=n\sum_{ij}\left(\bar{x}_{ij}-x_{i.}-x_{.j}+\bar{\bar{x}}\right)^2+2\sum_{mij}\left(\bar{x}_{ij}-x_{i.}-x_{.j}+\bar{\bar{x}}\right)\left(x_{mij}-\bar{x}_{ij}\right)+\sum_{mij}\left(x_{mij}-\bar{x}_{ij}\right)^2\end{aligned}\tag{5.7.2044}$$

Of course, we recognize rather quickly the intra-classes variance (often also named "residual error" or simply in the particular case of the two fixed factor ANOVA with repetitions "repeatability error"):

$$Q_R=\sum_{mij}\left(x_{mij}-\bar{x}_{ij}\right)^2\tag{5.7.2045}$$

and the term we can interpret (by comparison with the two factor ANOVA without repetitions) as the variance of interaction:

$$Q_{A\times B}=Q_{A,B}=n\sum_{ij}\left(\bar{x}_{ij}-x_{i.}-x_{.j}+\bar{\bar{x}}\right)^2=n\sum_{ij}\left(\bar{x}_{ij}-\bar{\bar{x}}\right)\tag{5.7.2046}$$

If the ANOVA is balanced the term:

$$2\sum_{mij}\left(\bar{x}_{ij}-x_{i.}-x_{.j}+\bar{\bar{x}}_{..}\right)\left(x_{mij}-\bar{x}_{ij}\right)\tag{5.7.2047}$$

must vanish. Let us check this:

$$\begin{aligned}\sum_{mij}\left(\bar{x}_{ij}-x_{i.}-x_{.j}+\bar{\bar{x}}\right)\left(x_{mij}-\bar{x}_{ij}\right)&=\sum_{mij}\left(x_{mij}-\bar{x}_{ij}\right)\left(\bar{x}_{ij}-x_{i.}-x_{.j}+\bar{\bar{x}}\right)\\ &=\sum_i\sum_j\sum_m\left(x_{mij}-\bar{x}_{ij}\right)\left(\bar{x}_{ij}-x_{i.}-x_{.j}+\bar{\bar{x}}\right)\end{aligned}\tag{5.7.2048}$$

and therefore for i and j fixed it comes:

$$(\bar{x}_{ij} - x_{i.} - x_{.j} + \bar{\bar{x}}) \underbrace{\sum_m (x_{mij} - \bar{x}_{ij})}_{=0} = 0 \tag{5.7.2049}$$

And therefore the summation over all i and j will be zero also by extension. Those who have a doubt about the cancellation of the two terms of the development above, may be able to reassure themselves by making a numerical application (enjoy!...).

Then finally:

$$\begin{aligned} Q_T &= \sum_{mij} (x_{mij} - \bar{\bar{x}}_{..})^2 \\ &= \underbrace{nk\sum_j (x_{.j} - \bar{\bar{x}}_{..})^2}_{Q_A} + \underbrace{nr\sum_i (x_{i.} - \bar{\bar{x}}_{..})^2}_{Q_B} + \underbrace{n\sum_{ij} (x_{mij} - \bar{x}_{i.} - \bar{x}_{.j} + \bar{\bar{x}}_{..})^2}_{Q_{A\times B}} + \underbrace{\sum_{mij} (x_{mij} - \bar{\bar{x}}_{ij})^2}_{Q_R} \end{aligned} \tag{5.7.2050}$$

where for reminder, n is therefore the number of replications, r the number of samples of factor A and k and the number of samples of factor B (the latter two parameters are often mixed by those who make calculations by hand). Result is sometimes denoted as following in the literature:

$$\begin{aligned} Q_T &= \sum_{mij} (x_{mij} - \bar{x}_{...})^2 \\ &= nk\sum_j (x_{.j} - \bar{x}_{...})^2 + nr\sum_i (x_{i.} - \bar{x}_{...})^2 + n\sum_{ij} (x_{mij} - \bar{x}_{i.} - \bar{x}_{.j} + \bar{x}_{...})^2 + \sum_{mij} (x_{mij} - \bar{\bar{x}}_{ij})^2 \end{aligned} \tag{5.7.2051}$$

So in comparison to the two fixed factor ANOVA without replication, we have an additional term for the total variance.

In the order it is clear that the first sum of the differences from the first factor column:

$$\sum_j (x_{.j} - \bar{\bar{x}}_{..})^2 \tag{5.7.2052}$$

will have just like for one-way fixed factor ANOVA and two-way fixed factor ANOVA without repetition $k-1$ degrees of freedom. That is to say, under the same assumptions of these latter ANOVA, we have:

$$\frac{\displaystyle\sum_j (x_{.j} - \bar{\bar{x}}_{..})^2}{\sigma^2} = \chi^2_{k-1} \tag{5.7.2053}$$

The second sum of the differences relatively to the second factor line:

$$\sum_i (x_{i.} - \bar{\bar{x}}_{..})^2 \tag{5.7.2054}$$

will have under the same assumptions the property:

$$\frac{\sum\limits_{i}(x_{i.}-\bar{\bar{x}}_{..})^2}{\sigma^2}=\chi^2_{r-1} \tag{5.7.2055}$$

Thanks to the reasoning performed with two fixed actor ANOVA without repetition, we know that for the interaction term:

$$\sum_{ij}(x_{mij}-\bar{x}_{i.}-\bar{x}_{.j}+\bar{\bar{x}}_{..})^2 \tag{5.7.2056}$$

We have:

$$\frac{\sum\limits_{ij}(x_{mij}-\bar{x}_{i.}-\bar{x}_{.j}+\bar{\bar{x}}_{..})^2}{\sigma^2}=\chi^2_{(k-1)(r-1)} \tag{5.7.2057}$$

It remains to determine the number of degrees of freedom of the last term:

$$\sum_{mij}(x_{mij}-\bar{\bar{x}}_{ij})^2 \tag{5.7.2058}$$

To do this, we proceed in the same way as for the two fixed factor ANOVA without repetitions. We know from our study of the one-way fixed factor ANOVA that the sum of the degrees of freedom of each term must be equal tot the total number of degrees of freedom. In other words, we must have for the two fixed factors ANOVA:

$$\mathrm{df}_T=N-1=nkr-1=(k-1)+(r-1)+(k-1)(r-1)+??? \tag{5.7.2059}$$

So what is missing is obvious:

$$\begin{aligned}???&=nkr-1-[(k-1)+(r-1)+(k-1)(r-1)]\\&=nkr-1-k+1-r+1-(kr-k-r+1)\\&=nkr-1-k+1-r+1-kr+k+r-1\\&=nkr-kr=N-kr=kr(n-1)\end{aligned} \tag{5.7.2060}$$

Therefore:

$$\frac{\sum\limits_{mij}(x_{mij}-\bar{x}_{ij})^2}{\sigma^2}=\chi^2_{N-kr} \tag{5.7.2061}$$

We have then the following table:

$$\boxed{\begin{array}{lll}
Q_T=\sum\limits_{mij}(x_{mij}-\bar{\bar{x}}_{..})^2 & \mathrm{df}_T=N-1=nkr-1 & \mathrm{V}_T=\dfrac{Q_T}{\mathrm{df}_T}\\
Q_A=nk\sum\limits_{j}(\bar{x}_{.j}-\bar{\bar{x}}_{..})^2 & \mathrm{df}_A=k-1 & \mathrm{V}_A=\dfrac{Q_A}{\mathrm{df}_A}\\
Q_B=nr\sum\limits_{i}(\bar{x}_{i.}-\bar{\bar{x}}_{..})^2 & \mathrm{df}_B=r-1 & \mathrm{V}_B=\dfrac{Q_B}{\mathrm{df}_B}\\
Q_{A\times B}=n\sum\limits_{ij}(\bar{x}_{ij}-\bar{x}_{i.}-\bar{x}_{.j}+\bar{\bar{x}}_{..})^2 & \mathrm{df}_{A\times B}=(k-1)(r-1) & \mathrm{V}_{A\times B}=\dfrac{Q_{A\times B}}{\mathrm{df}_{A\times B}}\\
Q_R=\sum\limits_{mij}(x_{mij}-\bar{\bar{x}}_{..})^2 & \mathrm{df}_R=N-kr & \mathrm{V}_R=\dfrac{Q_R}{\mathrm{df}_R}
\end{array}} \tag{5.7.2062}$$

Finally, the rest is exactly the same as for the two-way fixed factor ANOVA without replication with the difference that now we just have three tests this time:

$$F_{k-1,N-kr}=\dfrac{\dfrac{Q_A}{k-1}}{\dfrac{Q_R}{N-kr}}\qquad F_{r-1,N-kr}=\dfrac{\dfrac{Q_B}{r-1}}{\dfrac{Q_R}{N-kr}}\qquad F_{(k-1)(r-1),N-kr}=\dfrac{\dfrac{Q_{A\times B}}{(k-1)(r-1)}}{\dfrac{Q_R}{N-kr}} \tag{5.7.2063}$$

Again the choice of the ratios is relatively intuitive!

All calculations we have made above are often represented in software in a standard form of a table whose form and content is presented below (this is how Minitab 15.1.1 and Microsoft® Excel® 11.8346 present it for example):

Sum of squares (SSE)	χ^2 **df**	**Mean squares**	F	**Critical** F
$Q_A=nk\sum_j(\bar{x}_{.j}-\bar{\bar{x}}_{..})^2$	$k-1$	$\text{MSk}A=\dfrac{Q_A}{k-1}$	$\dfrac{\text{MSk}A}{\text{MSE}}$	$P(F>F_{k-1,Nk-r})$
$Q_B=nr\sum_i(\bar{x}_{i.}-\bar{\bar{x}}_{..})^2$	$r-1$	$\text{MSk}B=\dfrac{Q_B}{r-1}$	$\dfrac{\text{MSk}B}{\text{MSE}}$	$P(F>F_{r-1,N-kr})$
$Q_{A\times B}=\sum_{mij}(\bar{x}_{mij}-\bar{x}_{i.}-\bar{x}_{.j}+\bar{\bar{x}}_{..})^2$	$(k-1)(r-1)$	$\text{MSk}AB=\dfrac{Q_{A\times B}}{(k-1)(n-1)}$	$\dfrac{\text{Msk}AB}{\text{MSE}}$	$P(F>F_{(k-1)(n-1),N-kr})$
$Q_R=\sum_{mij}(\bar{x}_{mij}-\bar{x}_{ij})^2$	$N-kr$	$\text{MSE}=\dfrac{Q_R}{N-kr}$		
$Q_T=\sum_{mij}(x_{mij}-\bar{\bar{x}}_{..})^2$	$N-1$	$\text{MST}=\dfrac{Q_T}{N-1}$		

Table 5.66: **Two-way fixed factor ANOVA table with repetitions**

and the null hypothesis of equality of means for each factor is the same as for one-way fixed factor ANOVA (see the exercise server for a detailed practical example with Microsoft® Excel® 11.8346).

So we have three Fisher tests to know whether for each if factor A, respectively B or interaction AB have a significant influence on the measures or not.

Obviously, in the above developments, factors A and B are interchangeable by symmetry!

Remark

The corresponding factor effect model is (notice that the model is not purely additive!):

$$\boxed{x_{ijk}=\mu+\tau_i+\beta_j+(\tau\beta)_{ij}+\varepsilon_{ijk}} \tag{5.7.2064}$$

with $i=1\ldots a$, $j=1\ldots b$, $k=1\ldots n$ where μ is the overall mean, τ_i is the effect of the ith of treatment A, β_j is the effect of the jth level of treatment B (main effects), $(\tau\beta)_{ij}$ is the effect of the interaction between τ_i and β_j, and ε_{ijk} is the habitual random error following $\mathcal{N}(0,\sigma_\varepsilon^2)$.

The assumptions on the effect terms are $\sum_{i=1}^a\tau_i=0$, $\sum_{j=1}^b\beta_j=0$, $\sum_{i=1}^a(\tau\beta)_{ij}=0$ for $j=1\ldots b$ and $\sum_{j=1}^b(\tau\beta)_{ij}=0$ for $i=1\ldots a$.

The hypothesis of interest are $H_0:\ \tau_i=0$, $H_0:\ \beta_j=0$ or $H_0:\ (\tau\beta)_{ij}=0$.

5.7.13.5.4 Multifactor ANOVA with Repeated Measures

The "multifactor categorical variables ANOVA with repeated measures" is simply the name by which specialists refer to the following fixed-factors ANOVA:

- three factors (fixed) ANOVA with or without repetition
- four factors (fixed) ANOVA with or without repetition
- five factors (fixed) ANOVA with or without repetition
- etc.

Obviously, the ANOVA with one and two fixed factors are also part of the family of multifactor ANOVA. Also be aware that most statistical software manages up to ANOVA with 15 fixed factors fixed factors (categorical variables) on the assumption condition that the plan is balanced (i.e. for each level of each factor, there is the same number of measurements). A spreadsheet software (like Microsoft® Excel® for example) by default is able to deal with ANOVA having a maximum of two fixed factors.

Okay now the reader may be disappointed (well I am also disappointed to have only one life...) because honestly I do not want to redo all the developments seen above for the one-way and two-way fixed factors ANOVA for 3, 4 and up to 15 factors because it would take more than 100 A4 pages to do in a pedagogical and clear form plus it is always based on the same mechanical development. Sadly the generalized theory of ANOVA well being much shorter, it is indigestible for my taste.

Remark

The practitioner (and the reader) must avoid at any cost to do the confusion between "Multifactor" / factorial ANOVA that refer to cases where we have more than one factor (i.e., categorical explanatory variable) and "Multivariate" ANOVA that is also named MANOVA (note the initial M) that refers to cases where we have multiple dependent / response variables (we will study that latter further below page 1091).

5.7.13.5.4.1 Interlude on CRD, RBD, RCBD, IBD, GRBD...

So far we have seen some very common ANOVA. But it is time to discuss the way to do the experiments before going further. But before it would be useful to first make a recall between two main type of experiments in science!

quote 5.7:1052.#50

> *To call in the statistician after the experiment is done may be no more than asking him to perform a post-mortem examination: he may be able to say what the experiment died of...*
>
> Ronald Fisher

Definition (#5.7.150): The "observational study" is defined as follows:

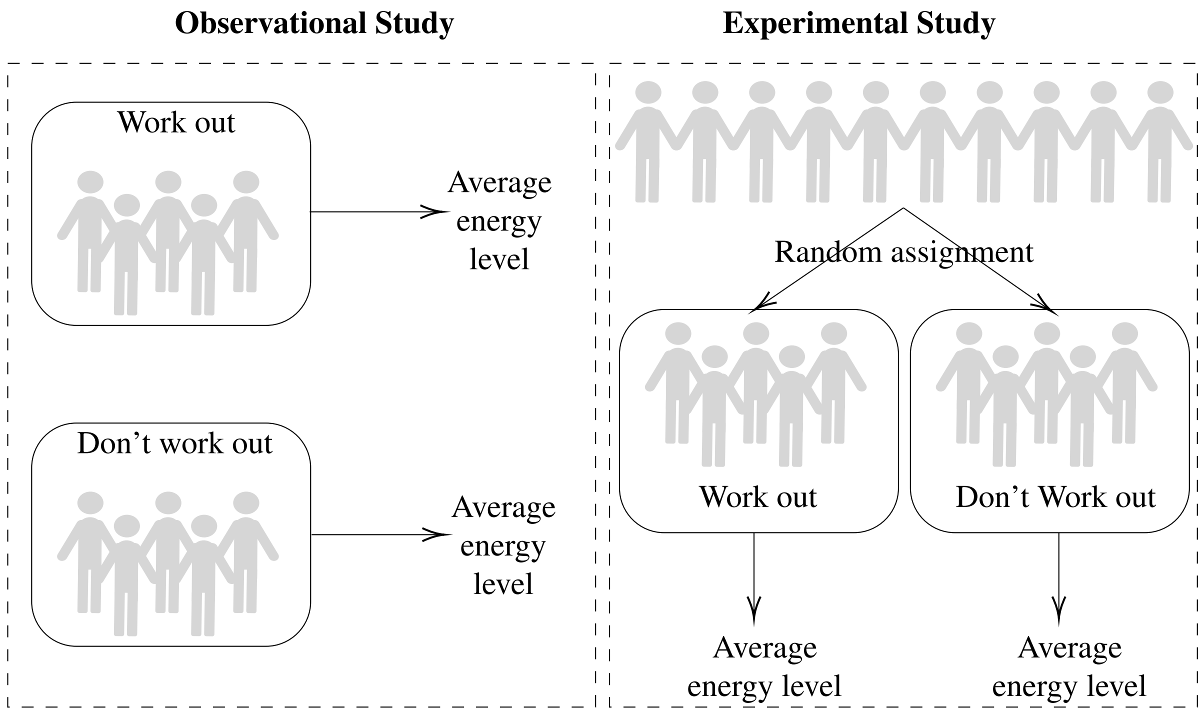
- Collect data in a way that does not directly interfere with how the data arise, i.e. merely "observe"
- Based on an observational study, we can only establish an **association**, in other words "**correlation**", between the explanatory and response variables
- If an observational study uses data from the past, it is named "retrospective study", whereas if data are collected throughout the study, it is named a "prospective study".

Definition (#5.7.151): The "experiment study" is defined as follows:

- Randomly assign subjects to various treatments
- Can establish **causal** connections between the explanatory and response variables!

As companion example, consider we want to evaluate the relationship between regularly working out and energy level. We can design the study as an observational study or an experiment.

- In an observational study, we sample two types of people from the population, those who choose to work out regularly and those who don't. Then, we find the average energy level for the two groups of people and compare.
- In an experiment, we sample a group of people from the population, and we randomly assign these people into two groups: those who will regularly work out throughout the course of study, and those who will not. The difference is that the decision of whether to work out or not is not left up to the subjects as in the observational study, but is instead imposed by researcher. At the end, we compare the energy level of the two groups.



Observational Study
Experimental Study

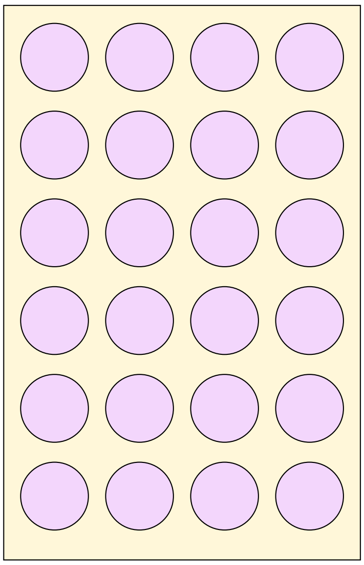
Average energy level
Don't work out
Average energy level
Random assignment
Work out
Don't Work out
Average energy level
Average energy level

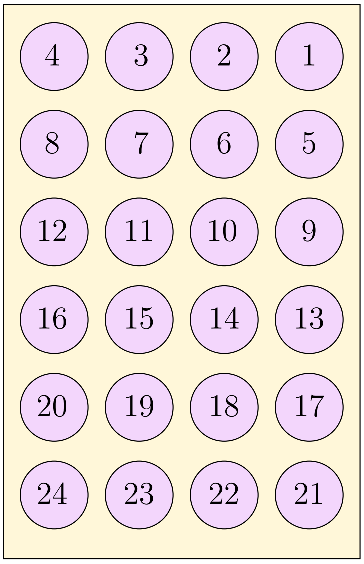
Figure 5.198: **Experimental vs Observational studies**

Based on the observational study, even if we find a difference between the energy levels of these two groups of people, we really can't attribute this difference solely to working out because there may be other variables that we didn't control for in this study that contribute to the observed difference. For example, people who are in better shape might be more likely to regularly work out and also have higher energy levels. However, in the experiment such variables that might also contribute to the outcome are likely equally represented in the two groups due to random assignment. Therefore, if we find a difference between the two averages, we can indeed make (likely) a causal statement attributing this difference to working out.

In practice, starting from the following experimental setup (one experimental unit, 24 observational units):



that we number as following:



we differentiate the following configurations[75] from the more common to the most rare or advanced type of design (also named "random control trials" (RCT) or "random control designs" (RCD)):

- "Complete randomized design" (CRD):

  One-Way ANOVA (but not only) are typically associated to CRD as the idea behind is to make measurement on experimental units that are randomized for each level of the factor, to avoid a possible bias (confounding). A typical corresponding configuration will be:

  Fertilizer 1 : Blue
  Fertilizer 2 : Red
  Fertilizer 3 : Black
  No Fertilizer: White (control)

  The corresponding linear model is simple, beginning with a grand mean μ, and an "offset" term α_i for each of the a treatment groups:

$$y_{ij} = \mu + \alpha_i + \varepsilon_{ij} \qquad i = 1 \ldots a \quad j = 1..n_i \tag{5.7.2065}$$

---

[75] Without taking into account that for each, there is a version for balanced and unbalanced designs and also a version for missing values

- "Randomized block design[76]" (RBD):

  When a factor is kept fixed, while we will vary the others, it will be named the "blocking factor[77]" and the others will be named "treatment factors" (some authors designate the two fixed factor ANOVA without interactions by the name "randomized block design").

  In the figure below, we see some blocks (corresponding typically to hard-to-change factors as days, observers, lands, etc.):

  Fertilizer 1 : Blue
  Fertilizer 2 : Red
  Fertilizer 3 : Black
  No Fertilizer: White (control)

  The corresponding linear model is simple as with just have a CRD applied to each block b:

$$y_{ijk}=\mu+\alpha_i+\beta_j+\varepsilon_{ijk} \qquad i=1\ldots a \quad j=1..b \quad k=1\ldots n_{ij} \tag{5.7.2066}$$

  In practice we will ensure that the randomization in the blocks is not always performed in the same order to eliminate potential inertia when changing from one treatment to the other effects (the reader can see in the previous figure that two blocks `I` and `V` have the same randomization). This lead us to the next type of design.

- "Randomized complete block design" (RCBD):

  The randomized complete block design (RCBD) also uses a restricted randomization scheme in the purpose to reduce the errors which account for differences among observation within each treatment. Within every block (e.g., location), the treatments are randomized to the experimental units (e.g., plots of land). This creates difference among the blocks and makes observation within a block more similar.

  The design is named "complete" because we see the complete set of treatments within every block and there is no identically randomized blocks (we will later also learn about incomplete block designs where this is not the case anymore). Note that blocking already exists at the time of randomization (and not only at the time of the analysis).

---

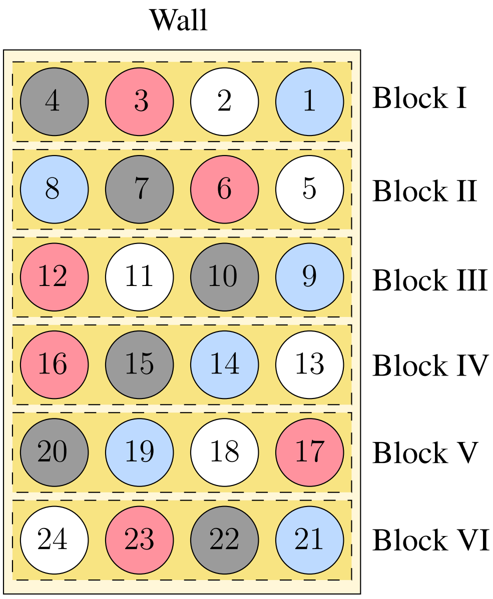
[76] That design and all others that follow belong to a family of designs named sometimes "crossover designs" or "crossover control trials"

[77] More formally a block is a matched group of individual who are similar or identical on a nuisance variable.

The analysis of a randomized complete block design is straightforward. We treat the block factor as "another" factor in our model[78] and then it is just a two-way ANOVA.

Because in the previous RBD the blocks I and V had identical randomization, we have now in RCBD configuration:

Fertilizer 1 : Blue
Fertilizer 2 : Red
Fertilizer 3 : Black
No Fertilizer: White (control)



So if you are able to maintain the condition homogeneous/constant throughout your experiment then CRD is just fine for lab experiment (lab experiments are usually conducted under the controlled conditions therefore the CRD test is usually used). But if you have resources like time, space and funds and you are confident enough to neutralize the variation (error) using suitable bollocking technique then go for the RCBD to reduce the experimental error.

- "Incomplete block design" (IBD):

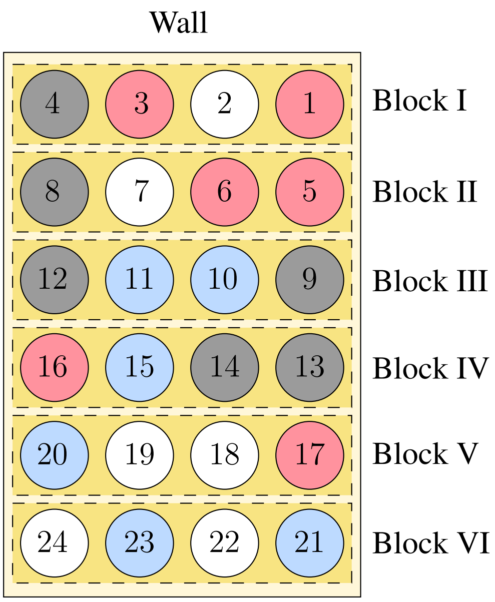
  Some experiments may consist of a large number of treatments and it may not be feasible to run all the treatments in all the blocks. Designs where only some of the treatments appear in every block are known as incomplete block designs.

  Here is an example where we can see that in some blocks, some treatments never appear:

---

[78] We can also block on more than one factor. A special case is the so-named Latin Square Design

Fertilizer 1 : Blue
Fertilizer 2 : Red
Fertilizer 3 : Black
No Fertilizer: White (control)



Wall
4 3 2 1
Block I

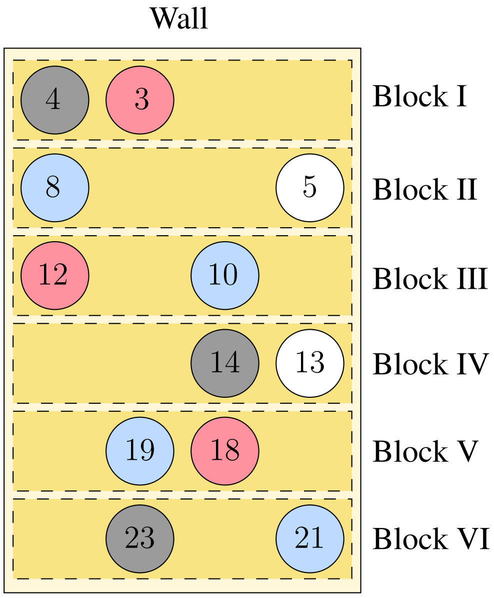
12 11 10 9
Block III
16 15 14 13
Block IV
20 19 18 17
Block V
24 23 22 21
Block VI

- "Balanced incomplete block design" (BIBD):

  In such a configuration, each block is selected in a balanced manner so that any pair of treatments occur together the same number of times as any other pairs.

  Considering the four treatments of our previous example, there are $\binom{4}{2} = 6$ ways of choosing three out of four:

Fertilizer 1 : Blue
Fertilizer 2 : Red
Fertilizer 3 : Black
No Fertilizer: White (control)



Wall
4 3
Block I
8 5
Block II
12 10
Block III
14 13
Block IV
19 18
Block V
23 21
Block VI

- "General randomized block design" (GRBD):

  Like a randomized complete block design (RCBD), a GRBD is randomized. Within each block, treatments are randomly assigned to experimental units: this randomization is also independent between blocks. In a (classic) RCBD, however, there is no replication of treatments within blocks. This replication allows the estimation and testing of an interaction term in the associated linear model.

- And others like PBIB (partial balanced incomplete design), CPBIB (cyclic balanced incomplete design), GCPIB (general cyclic balanced incomplete design), etc.

Pure random assignment guarantees quite well that the treatment and control groups will have identical characteristics on average, but in any particular random allocation, the two groups will differ along some dimensions! Methods used to pursue greater balance include stratification, pair-wise matching, and re-randomization. Sadly some researchers are not controlling for the method of randomization in their analysis and this leads to tests with incorrect sample size, and can result in lower power than if a pure random draw was used.

One way to control balance is just to do what we name a "randomization test". A randomization test is in reality a family of tests that we have already study before like:

- A series of Student T-test (see page 865) of two groups to compare the means of the treatment and control group variable by variable (at least the known one...) and check that the conclusion of the study remains the same or not.
- A series of Student paired T-test (see page 867) of two groups to compare the means of the treatment and control group knowing that they are correlated and do this variable by variable (at least the known one...) and check that the conclusion of the study remains the same or not.
- A series of Median test (see page 885) of two groups to compare the medians of the treatment and control group variable by variable (at least the known one...) and check that the conclusion of the study remains the same or not.
- A series of factorial ANOVA with or without repeated measures (see page 1001) to compare the averages of the treatment and control group by set of variables (at least the known one...) and check that the conclusion of the study remains the same or not (i.e. remember that's equivalent do to a regression of the type $y = a + b \cdot \text{Treat.} + \varepsilon$ and test whether $b = 0$).
- ...

Then we do this for 20 variables (still the known one...), find one or two are significant at a given threshold and then say «*This is about what we may expected by chance, so it seems randomization has succeeded quite well in generating balance*». But what if we find 3 or 4 differences out of 20 to be significant? Or what if none are individually significant, but the differences are all in the same direction?

An alternative, or complementary approach is to test for joint orthogonality. To do this, take a set of X variables $(x_1, x_2, \ldots, x_{20})$ and we run the following:

$$\text{Treat.} = a + b_1x_1 + b_2x_2 + b_3x_3 + \ldots + b_{20}x_{20} + \varepsilon$$

And then we test the joint hypothesis $b_1 = b_2 = b_3 = \ldots = b_{20} = 0$. And we will see later in the section of Numerical Methods that this can be run as a linear regression, with an F-test (see page 6335); or as a probit (see page 6453), with a χ^2-test.

If we have multiple treatment groups we can then run a multinomial logit (see page 6477) or any other preferred specification and test for joint orthogonality within this framework!

5.7.13.5.4.2 Interlude on Type I, Type II, Type III ANOVAs

The purpose of this interlude is to clarify the meaning of the different types of sums of squares (and the underlying "philosophies") found in most statistical software in the context of variance (ANOVA). For this, we will place ourselves in ANOVA with two fixed factors.

Indeed, when data is unbalanced, there are different ways to calculate the sums of squares for ANOVA. There are at least 3 approaches, commonly named Type I sums of squares, Type II sums of squares and type III sums of squares (also named "Yates's weighted squares of means"). These names seem to have been introduced into the statistics world from the SAS package but are since decades pretty widespread. Which type to use has led to an ongoing controversy. However, it essentially comes down to testing different hypotheses about the data.

To introduce these three types, let us consider a fixed two-factor analysis model of variance in which:

- The first factor that we will denote by F_1, has J levels ($J \geq 2$) that will be indexed with the letter j
- The second factor that we will denote by F_2, has K levels ($K \geq 2$) that will be indexed with the letter k
- At the intersection of the level j of F_1 and the level k of F_2, we realize n_{jk} observations ($n_{jk} \geq 1$) of a random variable y (and we assume this time that the experimental design is not necessarily balanced)
- Each observation is denoted y_{ijk} (with $i = 1 \ldots n_{jk}$ and $j = 1 \ldots J$ and $k = 1 \ldots K$)
- We put:
  - $n_{j+} = \sum_{k=1}^{K} n_{jk}$ as the marginal sample size of the level j of F_1
  - $n_{+k} = \sum_{j=1}^{J} n_{jk}$ as the marginal sample size of the level k of F_2
  - $n = \sum_{j=1}^{J}\sum_{k=1}^{K} n_{jk}$ as the total number of measurements

Let us introduce the different empirical partial averages of observations y_{ijk}:

$$\begin{aligned}
\bar{y}_{.jk} &= \frac{1}{n_{jk}}\sum_{i=1}^{n_{jk}} y_{ijk}\\
\bar{y}_{.j.} &= \frac{1}{n_{j+}}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}} y_{ijk}\\
\bar{y}_{..k} &= \frac{1}{n_{+k}}\sum_{j=1}^{J}\sum_{i=1}^{n_{jk}} y_{ijk}\\
\bar{y}_{...} &= \frac{1}{n}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}} y_{ijk}
\end{aligned} \tag{5.7.2067}$$

Now let us consider the total sum of squares of the model, quantity with as we know $n-1$ degrees of freedom:

$$\text{TSS}=\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{...})^2 \tag{5.7.2068}$$

We will first explicit again the decomposition of the quantity TSS. For this purpose, let us first notice the following equality:

$$y_{ijk}-\bar{y}_{...}=(y_{ijk}-\bar{y}_{.jk})+(\bar{y}_{.j.}-\bar{y}_{...})+(\bar{y}_{..k}-\bar{y}_{...})+(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...}) \tag{5.7.2069}$$

As:

$$\begin{aligned}(a+b+c+d)^2&=a^2+2ab+2ac+2ad+b^2+2bc+2bd+c^2+2cd+d^2\\&=a^2+b^2+c^2+d^2+\sum_{l}^{6}\text{DP}_l(abc)\end{aligned} \tag{5.7.2070}$$

where DP means "double product (terms)". So with our problem we have:

$$(y_{ijk}-\bar{y}_{...})^2=(y_{ijk}-\bar{y}_{.jk})^2+(\bar{y}_{.j.}-\bar{y}_{...})^2+(\bar{y}_{..k}-\bar{y}_{...})^2+(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})^2+\sum_{l}^{6}\text{DP}_l(ijk) \tag{5.7.2071}$$

By triple summation, we get:

$$\begin{aligned}\text{SST}=\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{...})^2&=\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{.jk})^2+\sum_{j=1}^{J}n_{j+}(\bar{y}_{.j.}-\bar{y}_{...})^2+\sum_{k=1}^{K}n_{+k}(\bar{y}_{..k}-\bar{y}_{...})^2\\&+\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})^2+\sum_{l}^{6}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}\text{DP}_l(ijk)\end{aligned} \tag{5.7.2072}$$

To detail the double products DP_l, let us first recall that if the quantities x_{jk} are reals independent of i, we can write:

$$\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}x_{jk}(y_{ijk}-\bar{y}_{.jk})=\sum_{j=1}^{J}\sum_{k=1}^{K}x_{jk}\left[\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{.jk})\right] \tag{5.7.2073}$$

But we also know that:

$$\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{.jk})=0 \tag{5.7.2074}$$

Therefore:

$$\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}x_{jk}(y_{ijk}-\bar{y}_{.jk})=\sum_{j=1}^{J}\sum_{k=1}^{K}x_{jk}\left[\underbrace{\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{.jk})}_{=0}\right]=0 \tag{5.7.2075}$$

It follows that the sums of the first three double products (those in which the quantity $(y_{ijk}-y_{jk})$ is in factor) are zero (i.e. $2ab$, $2ac$, $2ad$). By cons, the other three (i.e. $2bc$, $2bd$, $2cd$) are, in general, not zero. The fourth ($2bc$) is written:

$$\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}\text{DP}_4(ijk)=2\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.j.}-\bar{y}_{...})(\bar{y}_{..k}-\bar{y}_{...}) \qquad (5.7.2076)$$

double product that we will denote SDP_1. The sums of the last two double products ($2bd$ and $2cd$ hence $2d(b+c)$) will be grouped in the following expression:

$$\begin{aligned}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(\text{DP}_5(ijk)+\text{DP}_6(ijk))&=2\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})\left((\bar{y}_{.j.}-\bar{y}_{...})+(\bar{y}_{..k}-\bar{y}_{...})\right)\\&=2\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})(\bar{y}_{.j.}+\bar{y}_{..k}-2\bar{y}_{...})\end{aligned} \qquad (5.7.2077)$$

sum of double product that we will denote SDP_2.

Let's now explicit the square sums by introducing the following quantities (we know the degrees of freedom thanks to our study of the two way fixed factor ANOVA for recall!):

- Sum of squares due to the factor F_1 (quantity at $J-1$ degrees of freedom):

$$\text{SS}F_1=\sum_{j=1}^{J}n_{j+}(\bar{y}_{.j.}-\bar{y}_{...})^2 \qquad (5.7.2078)$$

- Sum of squares due to the factor F_2 (quantity at $K-1$ degrees of freedom):

$$\text{SS}F_2=\sum_{k=1}^{K}n_{+k}(\bar{y}_{..k}-\bar{y}_{...})^2 \qquad (5.7.2079)$$

- Sum of squares due to the interactions of the factors (quantity at $(J-1)(K-1)$ degrees of freedom):

$$\text{SS}F_{1*2}=\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})^2 \qquad (5.7.2080)$$

- Sum of squares due to errors (or residual, quantity at $n-JK$ degrees of freedom):

$$\text{SSE}=\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{ijk}}(y_{ijk}-\bar{y}_{.jk})^2 \qquad (5.7.2081)$$

We can finally rewrite the total sum of squares in the form:

$$\text{SST}=\text{SS}F_1+\text{SS}F_2+\text{SS}F_{1*2}+\text{SSE}+\text{SDP}_1+\text{SDP}_2 \qquad (5.7.2082)$$

But most often written:

$$\text{SST}=\text{SS}F_A+\text{SS}F_B+\text{SS}F_{A*B}+\text{SSE}+\text{SDP}_A+\text{SDP}_B \tag{5.7.2083}$$

Or explicitly:

$$\boxed{\begin{aligned}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{...})^2=&\sum_{j=1}^{J}n_{j+}(\bar{y}_{.j.}-\bar{y}_{...})^2+\sum_{k=1}^{K}n_{+k}(\bar{y}_{..k}-\bar{y}_{...})^2\\&+\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})^2\\&+\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{ijk}}(y_{ijk}-\bar{y}_{.jk})^2+2\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.j.}-\bar{y}_{...})(\bar{y}_{..k}-\bar{y}_{...})\\&+2\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})(\bar{y}_{.j.}+\bar{y}_{..k}-2\bar{y}_{...})\end{aligned}} \tag{5.7.2084}$$

We already know, from our derivation of the sum of squares of the balanced two way fixed factor ANOVA that in the balanced case:

$$\text{SDP}_A=\text{SDP}_B=0 \tag{5.7.2085}$$

The decomposition of SST is then of obvious interpretation. On the other hand, this is not the case with unbalanced plans ANOVA for which these two quantities are in general non-zero.

When the quantities SDP_A and SDP_B are non-zero, it is not possible to assign them to a single source of variation (F_A, F_B or $F_A\times F_B$). This explains the difficulties encountered in specifying the sources of variation in a model relating to an unbalanced plan. For this reason, other reasoning is used to specify these sources, which explains the existence of several types of sums of squares, according to the chosen philosophy.

Remark

Remember that obviously the three type of sum of squares that we will see now are always equal, and especially equal to zero as we already know!

Let us now represent the full model by $\text{SS}(A,B,AB)$, i.e.:

$$\begin{aligned}\text{SS}(A,B,AB)=&\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{...})^2=\sum_{j=1}^{J}n_{j+}(\bar{y}_{.j.}-\bar{y}_{...})^2+\sum_{k=1}^{K}n_{+k}(\bar{y}_{..k}-\bar{y}_{...})^2\\&+\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})^2\\&+\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{ijk}}(y_{ijk}-\bar{y}_{.jk})^2+2\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.j.}-\bar{y}_{...})(\bar{y}_{..k}-\bar{y}_{...})\\&+2\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})(\bar{y}_{.j.}+\bar{y}_{..k}-2\bar{y}_{...})\end{aligned} \tag{5.7.2086}$$

Other models are represented similarly:

$$\begin{aligned}\text{SS}(A,B)&=\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{...})^2=\sum_{j=1}^{J}n_{j+}(\bar{y}_{.j.}-\bar{y}_{...})^2+\sum_{k=1}^{K}n_{+k}(\bar{y}_{..k}-\bar{y}_{...})^2\\&+\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{ijk}}(y_{ijk}-\bar{y}_{.jk})^2+2\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.j.}-\bar{y}_{...})(\bar{y}_{..k}-\bar{y}_{...})\\&+2\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})(\bar{y}_{.j.}+\bar{y}_{..k}-2\bar{y}_{...})\end{aligned}\tag{5.7.2087}$$

indicates the model with no interaction. The next one:

$$\begin{aligned}\text{SS}(B,AB)&=\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{...})^2=\sum_{k=1}^{K}n_{+k}(\bar{y}_{..k}-\bar{y}_{...})^2\\&+\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})^2\\&+\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{ijk}}(y_{ijk}-\bar{y}_{.jk})^2+2\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.j.}-\bar{y}_{...})(\bar{y}_{..k}-\bar{y}_{...})\\&+2\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})(\bar{y}_{.j.}+\bar{y}_{..k}-2\bar{y}_{...})\end{aligned}\tag{5.7.2088}$$

indicates the model that does not account for main effects from factor A. We also have:

$$\begin{aligned}\text{SS}(A)&=\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(y_{ijk}-\bar{y}_{...})^2=\sum_{j=1}^{J}n_{j+}(\bar{y}_{.j.}-\bar{y}_{...})^2\\&+\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{ijk}}(y_{ijk}-\bar{y}_{.jk})^2+2\sum_{j=1}^{J}\sum_{k=1}^{K}n_{jk}(\bar{y}_{.j.}-\bar{y}_{...})(\bar{y}_{..k}-\bar{y}_{...})\\&+2\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{i=1}^{n_{jk}}(\bar{y}_{.jk}-\bar{y}_{.j.}-\bar{y}_{..k}+\bar{y}_{...})(\bar{y}_{.j.}+\bar{y}_{..k}-2\bar{y}_{...})\end{aligned}\tag{5.7.2089}$$

and so on.

The influence of particular factors (including interactions) can be tested by examining the differences between models. For example, to determine the presence of an interaction effect, an F-test of the models $\text{SS}(A,B,AB)$ and the no-interaction model $\text{SS}(A,B)$ would be carried out. It is handy to define incremental sums of squares to represent these differences. Let:

$$\begin{aligned}\text{SS}(AB|A,B)&=\text{SS}(A,B,AB)-\text{SS}(A,B)\\\text{SS}(A|B,AB)&=\text{SS}(A,B,AB)-\text{SS}(B,AB)\\\text{SS}(A|B)&=\text{SS}(A,B)-\text{SS}(B)\\\text{SS}(B|A)&=\text{SS}(A,B)-\text{SS}(A)\end{aligned}\tag{5.7.2090}$$

The notation shows the incremental differences in sums of squares, for example $\text{SS}(AB|A,B)$ represents the sum of squares for interaction after the main effects has been removed, and $\text{SS}(A|B)$ is the sum of squares for the A main effect after the B main effect have been removed and ignoring interactions. The different types of sums of squares then arise depending on the stage of model reduction at which they are carried out. In particular:

- The "Type I ANOVA" also named "sequential sum of squares" is computed using $\text{SS}(A)$ for factor A. $\text{SS}(B|A)$ for factor B. $\text{SS}(AB|B,A)$ for interaction AB. This tests the main effect of factor A, followed by the main effect of factor B after the main effect of A, followed by the interaction effect AB after the main effects. Because of the sequential nature and the fact that the two main factors are tested in a particular order, this type of sums of squares will give different results for unbalanced data depending on which main effect is considered first[79]. This is why type I sums of squares, in unbalanced designs, is reserved to models in which there is a natural order between the factors. Notice that for type I, the individual effect SS sum to the total effect SS as:

$$\begin{aligned}\text{SS}(A)+\text{SS}(B|A)+\text{SS}(AB|B,A)&=\text{SS}(A)+[\text{SS}(A,B)-\text{SS}(A)]+[\text{SS}(A,B,AB)-\text{SS}(A,B)]\\&=\text{SS}(A,B,AB)=\text{SST}\end{aligned}\tag{5.7.2091}$$

  Hence the type I ANOVA is term-order-sensitive. Forget about it and your study is doomed! But it handles interactions, follows the principle of marginality and quite simple. This is the default in the `R` statistical software.

- The "Type II ANOVA"is calculated using $\text{SS}(A|B)$ for factor A and $\text{SS}(B|A)$ for factor B. This type tests for each main effect after the other main effect. Note that no significant interaction is assumed (in other words, we should test for interaction first ($\text{SS}(AB|A,B)$) and only if AB is not significant, we continue with the analysis for main effects). If there is indeed no interaction, then type II is statistically more powerful than type III (see below). Notice the important property that type II is order independent at the opposite of the other types. Notice that for type II, it is obvious that the individual effect SS does not sum to the total effect SS at the opposite of Type I. Indeed:

$$\begin{aligned}\text{SS}(A|B)+\text{SS}(B|A)&=[\text{SS}(A,B)-\text{SS}(B)]+[\text{SS}(A,B)-\text{SS}(A)]\\&=2\text{SS}(A,B)-\text{SS}(A)-\text{SS}(B)\\&=\text{SS}(A)+\text{SS}(B)\neq\text{SST}\end{aligned}\tag{5.7.2092}$$

  Hence the type II ANOVA is order-insensitive but doesn't support interactions.

- The "Type III ANOVA" also named "marginal sum of squares" is calculated using $\text{SS}(A|B,AB)$ for factor A. $\text{SS}(B|A,AB)$ for factor B. This type tests for the presence of a main effect after the other main effect and interaction. This approach is therefore valid in the presence of significant interactions. However, it is often not interesting to interpret a main effect if interactions are present (generally speaking, if a significant interaction is present, the main effects should not be further analysed). If the interactions are not significant, type II gives a more powerful test. Notice also that as for type II, it is obvious that the individual effect SS does not sum to the total effect SS:

---

[79] However in the case of balanced designs, the result will be the same and we fall back on the classical two-way fixed factor ANOVA

$$\begin{aligned}\text{SS}(A|B,AB)+\text{SS}(B|A,AB) &= [\text{SS}(A,B,AB)-\text{SS}(B,AB)]+[\text{SS}(A,B,AB)-\text{SS}(A,AB)]\\ &= 2\text{SS}(A,B,AB)-\text{SS}(B,AB)-\text{SS}(A,AB)\\ &= 2\text{SS}(A,B,AB)-[\text{SS}(B)+\text{SS}(AB)]-[\text{SS}(A)+\text{SS}(AB)]\\ &= \text{SS}(A)+\text{SS}(B)\neq \text{SST}\end{aligned} \tag{5.7.2093}$$

Hence the type III ANOVA is order-insensitive and most flexible, but can mislead you no less in presence of disordinal interactions (and sometimes the ordinal too). This is the default in the SAS™ statistical software.

Remarks

R1. When data is balanced, the factors are orthogonal, and types I, II and III all give the same results!

R2. In the beginning of the 121st century (holocene calendar), the softwares SAS and SPSS use SS type III as their default, while functions that ship with base `R` use type I by default. This can lead to different results when analysing the same data with different statistics packages.

In summary, the hypothesis of interest is usually about the significance of one factor while controlling for the level of the other factors. This equates to using type II or III SS. In general, if there is no significant interaction effect, then type II is more powerful, and follows the principle of marginality. If interaction is present, then type II is inappropriate while type III can still be used, but results need to be interpreted with caution (in the presence of interactions, main effects are rarely interpretable).

The subject is quite controversial since decades. This is why, when possible, it would be better to avoid unbalanced experiments!

5.7.13.5.5 Hierarchical (Nested) ANOVA (HANOVA)

The "hierarchical fixed factor ANOVA" (HANOVA) or "nested ANOVA with fixed factors", more often referred to as "two stage nested design", consists in analysing samples where one of the control factors is not independent but dependent on another control factor (this is why often beginners sometimes hesitate somewhat between a two-factor ANOVA and a two-factor hierarchical ANOVA).

Consider to introduce the concept the historical case of hierarchical ANOVA (agriculture!), two completely independent surfaces: Study Surface A and Study Surface B. Each of these surfaces (named a "whole plots" or "block effect") is separated into 4 distinct study squares (named "split-plots" or "subplots" or "sub-factors") with 5 replicas for each square. So we have a total of 2 whole plot, with 8 split-plots (test surfaces) for a total of 40 individuals[80]:

---

[80] In order to better understand the structure of the simple split-plot design it is advantageous to view it as superimposing one RCBD (for the split-plot treatments) on top of another RCBD (for the whole treatments). We shall refer to this as SPD (RCBD,RCBD). Variations of this form of split-plot designs are possible by using other than both RCBD.

Study Surface A

$S_1(A)$	$S_2(A)$	$S_3(A)$	$S_4(A)$
X	X	X	X
X	X	X	X
X	X	X	X
X	X	X	X
X	X	X	X

Study Surface B

$S_1(B)$	$S_2(B)$	$S_3(B)$	$S_4(B)$
X	X	X	X
X	X	X	X
X	X	X	X
X	X	X	X
X	X	X	X

Table 5.67: **Hierarchical ANOVA illustration**

We are therefore in the particular situation where the effects of the levels of the factor of the second level (squares) have no concrete meaning. For example, these squares depend on the level of the *Surface* factor considered and a study of the main effects of the *Square* factor is here irrelevant!

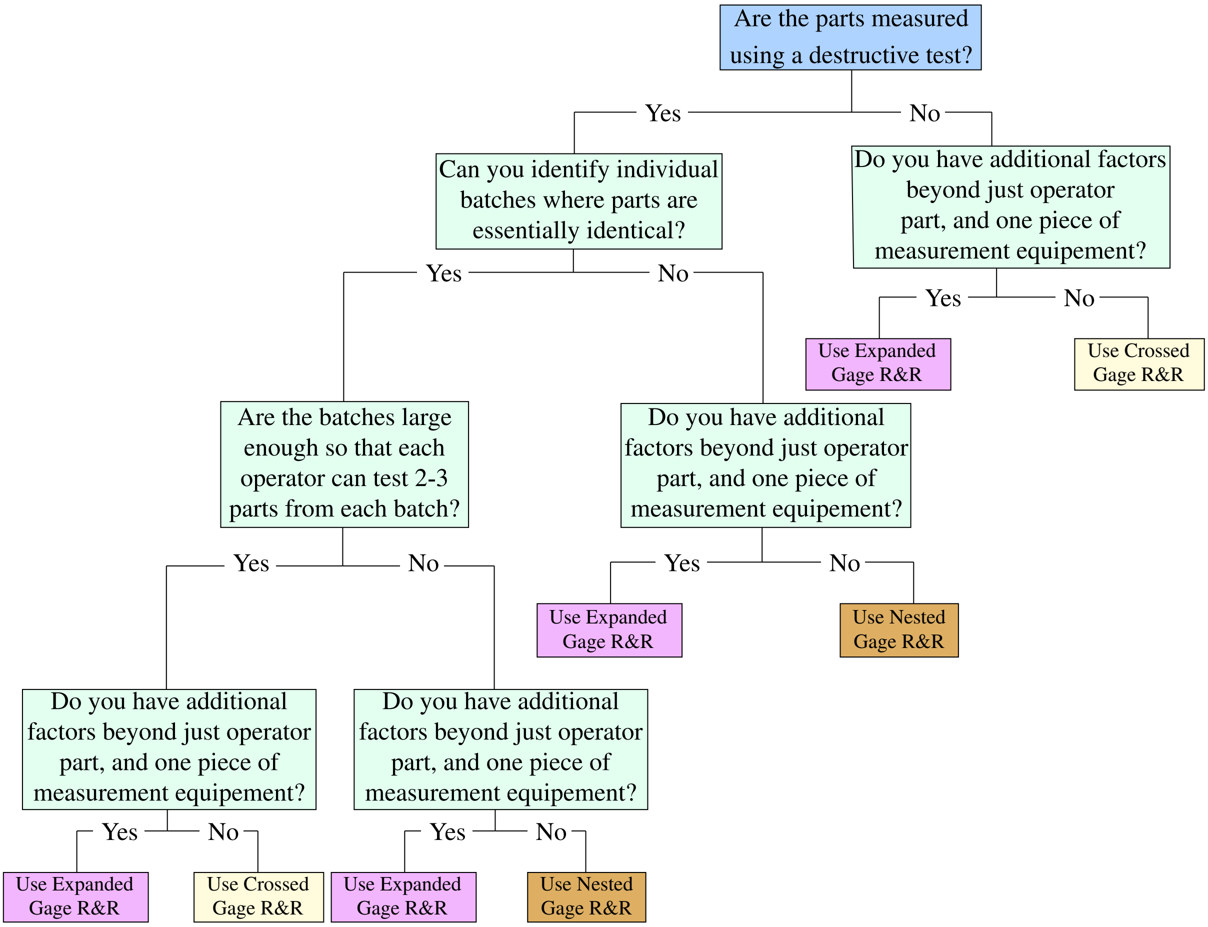
We can consider, for example, that the wholeplot factor represents suppliers, the subplot factor object lot types, and therefore for each supplier a given level of the subplot will physically represent a specific lot for each supplier and therefore not interchangeable.

Or a more common example are the "nested R&R (Repeatability and Reproducibility) Gage studies". Indeed, "measurement systems analysis" (MSA) are essential to the success of any data analysis. If you cannot rely on the tool you're using to take measurements, then why bother collecting data to begin with? It would be like trying to lose weight while relying on a scale that doesn't work. What's the point in weighing yourself?

In MSA studies for continuous measurements (e.g. weight, length, volume) using non-destructive testing, each part can be measured repeatedly. In this case, we can use "crossed Gage studies". However, sometimes we must conduct a MSA where the test required to take the measurement destroys the object or physically changes the characteristic that is being measured.

Suppose again that we are conducting a Gage R&R study for a destructive test with 3 operators and 2 replicates per part. But suppose it is not feasible to obtain 6 specimens that are similar enough to be considered the same part, rather only 2 specimens. Then in this case, you must use a "nested Gage study".

When a nested Gage R&R study is not enough, try an "expanded Gage R&R". Most Gage R&R studies assess the effects of two factors on variation in your measurement system - typically operator and part. However, the effects of operator and part frequently are not enough to provide a complete understanding of the measurement system. Adding a third variable (typically gage) to the standard study is often required. When three or more factors are included in the analysis, we call the study an "expanded Gage R&R". In the following situations, a third factor is crucial to understanding the system.



Are the parts measured using a destructive test?
Yes
No
Can you identify individual batches where parts are essentially identical?
Do you have additional factors beyond just operator part, and one piece of measurement equipement?
Yes
No
Use Expanded Gage R&R
Use Crossed Gage R&R
Yes
No
Are the batches large enough so that each operator can test 2-3 parts from each batch?
Do you have additional factors beyond just operator part, and one piece of measurement equipement?
Yes
No
Use Expanded Gage R&R
Use Nested Gage R&R
Yes
No
Do you have additional factors beyond just operator part, and one piece of measurement equipement?
Do you have additional factors beyond just operator part, and one piece of measurement equipement?
Yes
No
Yes
No
Use Expanded Gage R&R
Use Crossed Gage R&R
Use Expanded Gage R&R
Use Nested Gage R&R

Figure 5.199: **How to select a Gage R&R design**

So keep in mind:

- Crossed R&R studies are mostly related to non-destructive measurements (as explained above)
- Nested R&R studies are mostly related to destructive measurements (as explained above)

Each operator measures a different set of parts. Therefore, each part is said to be "nested" within operator rather than "crossed" since each part is unique to an operator. Let's look at a diagram for another view of crossed versus nested studies:

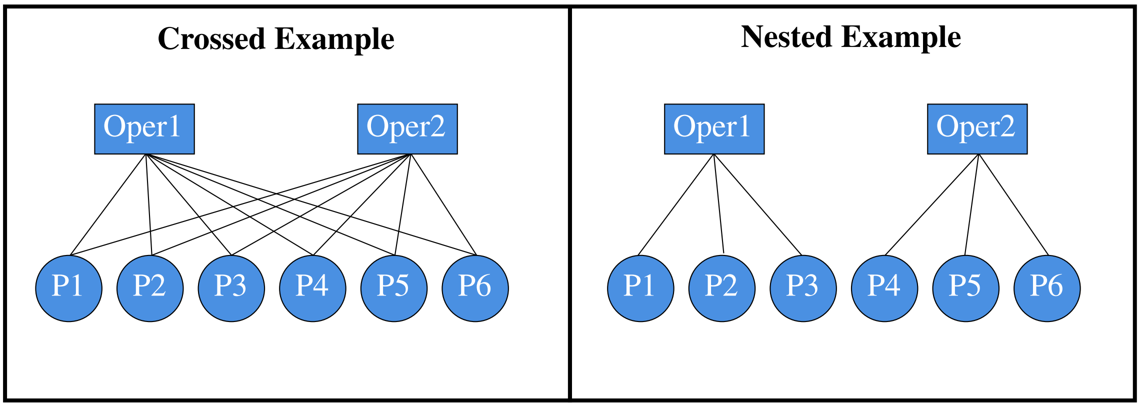


Figure 5.200: **Cross vs Nested studies (source: Minitab)**

The crossed Gage study is associated with a normal fixed factor ANOVA, or a Latin square ANOVA if the measurements are not repeated (see further below page 1074) where the nested Gage study is associated with a nested ANOVA!

It is customary to say that we have a "two-factor split-plot" or a "two-way hierarchical ANOVA" experiment because the behaviour of the squares is not independent of that of the surfaces.

Remarks

R1. To easily differentiate a fixed two-factor ANOVA with a nested fixed two-factor ANOVA with, it is sufficient to note that physically a given level of the first fixed factor represents the same object for each of the levels of the second factor while for the hierarchical ANOVA it is each time a different object specific to the factor under which it is.

R2. We have given above two examples with only one nested level, but it is possible to develop the theory for multiple nesting levels (a level, in a level that is itself in a level, and so on). We are talk then about "multiple hierarchical ANOVA".

A hierarchical experience and the corresponding analysis must first be able to tell us if there is a significant difference between the "whole plots" (controlled factors) and also if there is a significant difference between the "subplots".

It is important to remember that in this type of structure as each level of a factor is present only once in the level of another factor we can not estimate the interactions between the two. Indeed, if we consider that the factor whole-plot is a country and the subplot a lake ... it is difficult then to move the lake in another country ... In taking our example above with the surfaces it is also not very trivial to move a square to another surface...

Remark

We can not use a model where factors are nested unless we have repetitions. In the opposite case where the tests would not be repeated, the effect due to the nested factor can not be studied and the model that we will have to use to analyse the data will be one of those exposed in our study of the analysis of the one-way variance.

In the special case where the statistical study of the hierarchical ANOVA has failed us to highlight a significant difference between the "subplots" of the two "whole plots", but on the other hand has successfully highlight a significant difference between the two "whole plots" this should lead us to conclude to a particular environmental influence.

Denoting by $i=1\ldots M$ the number of levels of the main factor A, $j=i\ldots m$ the number of levels of the nested factor B and $k=1\ldots n$ the number of repeated measurements (thus a total of measurements $M\cdot m\cdot n$) and the averages:

$$\begin{aligned}\bar{x}_{...}&=\frac{1}{Mmn}\sum_{ijk}x_{ijk}=\frac{1}{N}\sum_{ijk}x_{ijk}\\ \bar{x}_{i..}&=\frac{1}{mn}\sum_{jk}x_{ijk}\\ \bar{x}_{ij.}&=\frac{1}{Mmn}\sum_{k}x_{ijk}\end{aligned}\tag{5.7.2094}$$

and under the same assumptions of use as the one-way or two-way ANOVA seen earlier above (independence of the errors ε_{ijk}, the errors have the same variance, the errors follow a Normal law), we write the decomposition of the variance in the form:

$$\begin{aligned}Q_T&=\sum_{ijk}\left(x_{ijk}-\bar{x}_{...}\right)^2=\sum_{ijk}\left(x_{ijk}-\bar{x}_{...}+\bar{x}_{i..}-\bar{x}_{i..}+\bar{x}_{ij.}-\bar{x}_{ij.}\right)^2\\ &=\sum_{ijk}\left((x_{i..}-\bar{x}_{...})+(\bar{x}_{ij.}-\bar{x}_{i..})+(x_{ijk}-\bar{x}_{ij.})\right)^2\\ &=\sum_{ijk}\left((\bar{x}_{i..}-\bar{x}_{...})^2+2(\bar{x}_{i..}-\bar{x}_{...})\left((\bar{x}_{ij.}-\bar{x}_{i..})+(x_{ijk}-\bar{x}_{ij.})\right)+\left((\bar{x}_{ij.}-\bar{x}_{i..})+(x_{ijk}-\bar{x}_{ij.})\right)^2\right)\\ &=\sum_{ijk}\left(\begin{array}{c}(\bar{x}_{i..}-\bar{x}_{...})^2+2(x_{i..}-\bar{x}_{...})\left((\bar{x}_{ij.}-\bar{x}_{i..})+(x_{ijk}-\bar{x}_{ij.})\right)\\ +\left((\bar{x}_{ij.}-\bar{x}_{i..})^2+2(\bar{x}_{ij.}-\bar{x}_{i..})(x_{ijk}-\bar{x}_{ij.})+(x_{ijk}-\bar{x}_{ij.})^2\right)\end{array}\right)\\ &=\sum_{ijk}(\bar{x}_{i..}-\bar{x}_{...})^2+\sum_{ijk}(\bar{x}_{ij.}-\bar{x}_{i..})^2+\sum_{ijk}(x_{ijk}-\bar{x}_{ij.})^2\\ &\quad+2\left[\sum_{ijk}(\bar{x}_{i..}-\bar{x}_{...})\left((\bar{x}_{ij.}-\bar{x}_{i..})+(x_{ijk}-\bar{x}_{ij.})\right)+\sum_{ijk}(\bar{x}_{ij.}-\bar{x}_{i..})(x_{ijk}-\bar{x}_{ij.})\right]\end{aligned}\tag{5.7.2095}$$

But, we have:

$$\sum_{ijk}(\bar{x}_{ij.}-\bar{x}_{i..})(x_{ijk}-\bar{x}_{ij.})=\sum_{ij}\left[(\bar{x}_{ij.}-\bar{x}_{i..})\underbrace{\sum_{k}(x_{ijk}-\bar{x}_{ij.})}_{=0}\right]=0\tag{5.7.2096}$$

and:

$$
\begin{aligned}
\sum_{ijk}(\bar{x}_{i..}-\bar{x}_{...})\left((\bar{x}_{ij.}-\bar{x}_{i..})+(x_{ijk}-\bar{x}_{ij.})\right) &= \sum_{ijk}(\bar{x}_{i..}-\bar{x}_{...})(\bar{x}_{ij.}-\bar{x}_{i..})+\sum_{ijk}(\bar{x}_{i..}-\bar{x}_{...})(x_{ijk}-\bar{x}_{ij.})\\
&= \sum_{ik}(\bar{x}_{i..}-\bar{x}_{...})\underbrace{\sum_{j}(\bar{x}_{ij.}-\bar{x}_{i..})}_{=0}+\sum_{i}\left[(\bar{x}_{i..}-\bar{x}_{...})\sum_{jk}(x_{ijk}-\bar{x}_{ij.})\right]\\
&= \sum_{i}\left[(\bar{x}_{i..}-\bar{x}_{...})\sum_{j}\underbrace{\sum_{k}(x_{ijk}-\bar{x}_{ij.})}_{=0}\right]
\end{aligned}
\tag{5.7.2097}
$$

So it remains in the end:

$$
\begin{aligned}
Q_T=\sum_{ijk}(x_{ijk}-\bar{x}_{...})^2 &= \sum_{ijk}(\bar{x}_{i..}-\bar{x}_{...})^2+\sum_{ijk}(\bar{x}_{ij.}-\bar{x}_{i..})^2+\sum_{ijk}(\bar{x}_{ijk}-\bar{x}_{ij.})^2\\
&= \underbrace{mn\sum_{i=1}^{M}(\bar{x}_{i..}-\bar{x}_{...})^2}_{Q_A}+\underbrace{n\sum_{i=1}^{M}\sum_{j=1}^{m}(\bar{x}_{ij.}-\bar{x}_{i..})^2}_{Q_{(A)B}}+\underbrace{\sum_{i=1}^{M}\sum_{j=1}^{m}\sum_{k=1}^{n}(\bar{x}_{ijk}-\bar{x}_{ij.})^2}_{Q_R}
\end{aligned}
\tag{5.7.2098}
$$

where the summation indices are not traditionally the same as the two-factor ANOVA with repetition (but this is a detail). If we compare with the variance decomposition of the two-factor ANOVA with repetition that was for recall:

$$
\begin{aligned}
Q_T &= \sum_{mij}(x_{mij}-\overline{\overline{x}}_{..})^2\\
&= \underbrace{nk\sum_{j}(\bar{x}_{.j}-\overline{\overline{x}}_{..})^2}_{Q_A}+\underbrace{nr\sum_{i}(\bar{x}_{i.}-\overline{\overline{x}}_{..})^2}_{Q_B}+\underbrace{n\sum_{ij}(\bar{x}_{ij}-\bar{x}_{i.}-\bar{x}_{.j}+\overline{\overline{x}}_{..})^2}_{Q_{A\times B}}+\underbrace{\sum_{mij}(x_{mij}-\bar{x}_{ij})^2}_{Q_R}
\end{aligned}
\tag{5.7.2099}
$$

We notice that the main difference lies in the fact we are not interested in the variance of the interaction of the two factors (which was the goal or say rather a... constraint!) and that we then did not have to make it appear.

Now come the quest of determining the degrees of freedom. For Q_T it's $\text{df}_T=Mmn-1$. For the term Q_A (principal factor), the number of degrees of freedom is the same as for the one-way ANOVA or the two-factor ANOVA with/without repetitions. That is $\text{df}_A=M-1$ degrees of freedom. For the residual term it also comes immediately that it is the same thing as the two-factor ANOVA with repetition and therefore that $\text{df}_R=Mm(n-1)=N-Mm$. Finally, the remaining term $Q_{(A)B}$ is new, but we can easily determine its number of degrees of freedom since we must have:

$$
\text{df}_T=\text{df}_A+\text{df}_{(A)B}+\text{df}_R
\tag{5.7.2100}
$$

Then it comes:

$$
Mmn-1=(M-1)+\text{df}_{(A)B}+Mm(n-1)
\tag{5.7.2101}
$$

Hence:

$$\begin{aligned}\mathrm{df}_{(A)B}&=(Mmn-1)-(M-1)-Mm(n-1)\\&=Mmn-1-M+1-Mmm+Mm=-M+Mm=M(m-1)\end{aligned}\tag{5.7.2102}$$

We then have the following table for the hierarchical ANOVA (according to the most common representation in statistical softwares) that we will comment after:

Sum of squares	χ^2 **df**	**Mean squares**	F	**Critical** F
$Q_A=mn\sum_{i=1}^{M}\sum_{ijk}(\bar{x}_{i..}-\bar{x}_{...})^2$ (due to the surface/bloc)	$M-1$	MSk$A=\dfrac{Q_A}{M-1}$	$\dfrac{\text{MSk}A}{\text{MSk}(A)B}$	$P(F>F_{M-1,Mm(n-1)})$
$Q_{(A)B}=n\sum_{i=1}^{M}\sum_{j=1}^{m}(\bar{x}_{ij.}-\bar{x}_{i..})^2$ (due to the plot in the whole plot)	$M(m-1)$	MSk$(A)B=\dfrac{Q_{(A)B}}{M(m-1)}$	$\dfrac{\text{MSk}(A)B}{\text{MSE}}$	$P(F>F_{M(m-1),Mm(n-1)})$
$Q_R=\sum_{i=1}^{M}\sum_{j=1}^{m}\sum_{k=1}^{n}(x_{ijk}-\bar{x}_{ij.})^2$ (residuals)	$Mm(n-1)$	MSE $=\dfrac{Q_R}{Mm(n-1)}$		
$Q_T=\sum_{ijk}(x_{ijk}-\bar{x}_{...})^2$ (total)	$Mmn-1$	MST $=\dfrac{Q_T}{Mmn-1}$		

Table 5.68: **Hierarchical (random) factor ANOVA table**

So we have two Fisher tests just like the two-factor canonical ANOVA which is relatively intuitive. On the other hand what often surprises the practitioners is the first Fisher test where we have:

$$F_{M-1,Mm(n-1)}=\frac{\text{MSk}A}{\text{MSk}(A)B}\tag{5.7.2103}$$

Instead of what we could have written a little bit too quick:

$$F_{M-1,Mm(n-1)}=\frac{\text{MSk}A}{\text{MSE}}\tag{5.7.2104}$$

So what must be understood here is that there is not one that is right and the other wrong!!!!!!!!! It is necessary to know what we are interested in to make the best choice. Thus, comparing the variance of the blocks with the residual variance of the treatments is not necessarily the most interesting for judging the equality of the average treatments between them. This is why it is better to compare the variance of the blocks with the variance of the treatments.

Therefore in most statistical softwares the table above is say to be the "ANOVA table for random factors" and the table below is the version for fixed factors (in case you really need to compare the variance of the blocks with the residuals variance of the treatments!):

Sum of squares	χ^2 df	Mean squares	F	Critical F
$Q_A=mn\sum_{i=1}^{M}\sum_{ijk}(\bar{x}_{i..}-\bar{x}_{...})^2$ (due to the surface/block)	$M-1$	$\text{MSk}A=\dfrac{Q_A}{M-1}$	$\dfrac{\text{MSk}A}{\text{MSE}}$	$P(F>F_{M-1,Mm(n-1)})$
$Q_{(A)B}=n\sum_{i=1}^{M}\sum_{j=1}^{m}(\bar{x}_{ij.}-\bar{x}_{i..})^2$ (due to the plot in the whole plot)	$M(m-1)$	$\text{MSk}(A)B=\dfrac{Q_{(A)B}}{M(m-1)}$	$\dfrac{\text{MSk}(A)B}{\text{MSE}}$	$P(F>F_{M(m-1),Mm(n-1)})$
$Q_R=\sum_{i=1}^{M}\sum_{j=1}^{m}\sum_{k=1}^{n}(\bar{x}_{ijk}-\bar{x}_{ij.})^2$ (residuals)	$Mm(n-1)$	$\text{MSE}=\dfrac{Q_R}{Mm(n-1)}$		
$Q_T=\sum_{ijk}(x_{ijk}-\bar{x}_{...})^2$ (total)	$Mmn-1$	$\text{MST}=\dfrac{Q_T}{Mmn-1}$		

Table 5.69: **Hierarchical (fixed) factor ANOVA table**

Remark

Let us recall that for an ANOVA with fixed factors without replications we had:

$$x_{ijk}=\mu+\tau_i+\beta_j+\varepsilon_{ij} \tag{5.7.2105}$$

with $i=1\ldots a$, $j=1\ldots b$ where μ is the overall mean, τ_i is the effect of the ith of treatment A, β_j is the effect of the jth level of treatment B (main effects) and ε_{ij} is the habitual random error following $\mathcal{N}(0,\sigma_\varepsilon^2)$.

For nested ANOVA, the β_j will be expanded $\alpha_j+\gamma_{ij}$ and the new model may contain an interaction term representing possible interaction between blocking factor and the treatments. Thus the factor effect model may be written:

$$\boxed{x_{ijk}=\mu+(\alpha_j+\gamma_{ij})+\tau_k+(\alpha\tau)_{ik}+\varepsilon_{ijl}} \tag{5.7.2106}$$

Now before we continue with some other major ANOVA type (especially "ANOVA with blocks" and "split-plot ANOVA") let us give in the form of a figure what we have seen so far and what we will see just after:

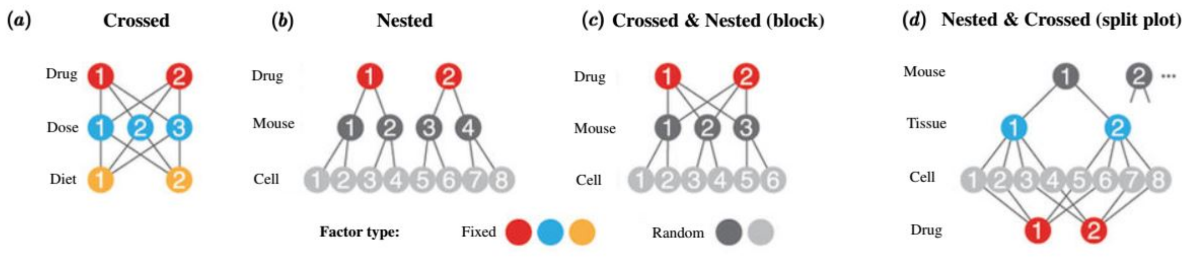

Figure 5.201: **Comparing different some major ANOVA structures**

- *(a)* A crossed design examines every combination of levels for each fixed factor
- *(b)* A nested design can progressively subreplicate a fixed factor with nested levels of a random factor that are unique to the level within which they are nested

(*c*) If a random factor can be reused for different levels of the treatment, it can be crossed with the treatment and modelled as a block

(*d*) A split plot design (also named "mixed-design") is a structure where the fixed effects (tissue, drug) are crossed (each combination of tissue and drug are tested) but themselves nested within replicates.

Thus, in a mixed-design ANOVA model, one factor (a fixed effects factor) is a between-subjects variable and the other (a random effects factor) is a within-subjects variable. Thus, overall, the model is a type of mixed effect model.

Remark

Let us recall that for an ANOVA with fixed factors without replications we had:

$$x_{ijk}=\mu+\tau_i+\beta_j+\varepsilon_{ij} \tag{5.7.2107}$$

with $i=1\ldots a$, $j=1\ldots b$ where μ is the overall mean, τ_i is the effect of the ith of treatment A, β_j is the effect of the jth level of treatment B (main effects) and ε_{ij} is the habitual random error following $\mathcal{N}(0,\sigma_\varepsilon^2)$.

For nested and crossed ANOVA, the β_j will be expanded $\alpha_j+\gamma_{ij}+(\alpha\gamma)_{ij}$ and to inclusion of certain block-treatment interaction terms. Thus the factor effect model may be written:

$$\boxed{x_{ijk}=\mu+(\alpha_j+\gamma_{ij}+(\alpha\gamma)_{ij})+\tau_k+(\alpha\tau)_{ik}+(\gamma\tau)_{jk}+\varepsilon_{ijl}} \tag{5.7.2108}$$

5.7.13.5.6 ANOVA with blocks

With a "randomized block design" (RBD), we have a characteristic of the units-of-analysis that we stratify (block) and then randomize into our treatment conditions within each block. For example, we could block on sex (male and female) and then randomly assign to a treatment and control condition separately for males and females, ensuring balance across the blocks in the number assigned to each group. In this design, we have one factor (treatment/control) and one block (male/female). This design also controls for any variance associated with the block (you would only want to use a block that you have good reason to believe is associated with the dependent variable).

The purpose of the blocking factor is to account for a nuisance factor and/or to reduce the error term used in performing the test for the significance of the treatment effect. For this reason, the significance of the block effect itself is not tested, nor are multiple comparisons done between fixed blocks. Otherwise, a one-way blocked ANOVA is analysed as a two-way ANOVA with no interactions and no replications. That means that the following ANOVA table:

Sum of squares (SSE)	χ^2 df	Mean squares	F	Critical F
$Q_A = k\sum_j (\bar{x}_j - \bar{\bar{x}})^2$	$k-1$	$\text{MSk}A = \dfrac{Q_A}{k-1}$	$\dfrac{\text{MSk}A}{\text{MSE}}$	$P(F > F_{k-1,(k-1)(r-1)})$
$Q_B = r\sum_i (\bar{x}_i - \bar{\bar{x}})^2$	$r-1$	$\text{MSk}B = \dfrac{Q_B}{r-1}$	$\dfrac{\text{MSk}B}{\text{MSE}}$	$P(F > F_{r-1,(k-1)(r-1)})$
$Q_R = \sum_{ij} (x_{ij} - \bar{x}_i - \bar{x}_j + \bar{\bar{x}})^2$	$(k-1)(r-1)$	$\text{MSE} = \dfrac{Q_R}{(k-1)(n-1)}$		
$Q_T = \sum_{ij} (x_{ij} - \bar{\bar{x}})^2$	$N-1$	$\text{MST} = \dfrac{Q_T}{N-1}$		

Table 5.70: **Two-way fixed factor ANOVA table without repetitions**

becomes:

Sum of squares (SSE)	χ^2 df	Mean squares	F	Critical F
$Q_t = k\sum_j (\bar{x}_j - \bar{\bar{x}})^2$ treatments	$k-1$	$\text{MSk}t = \dfrac{Q_t}{k-1}$	$\dfrac{\text{MSk}t}{\text{MSE}}$	$P(F > F_{k-1,(k-1)(r-1)})$
$Q_b = r\sum_i (\bar{x}_i - \bar{\bar{x}})^2$ blocks	$r-1$	$\text{MSk}b = \dfrac{Q_b}{r-1}$	$\dfrac{\text{MSk}b}{\text{MSE}}$	$P(F > F_{r-1,(k-1)(r-1)})$
$Q_R = \sum_{ij} (x_{ij} - \bar{x}_i - \bar{x}_j + \bar{\bar{x}})^2$	$(k-1)(r-1)$	$\text{MSE} = \dfrac{Q_R}{(k-1)(n-1)}$		
$Q_T = \sum_{ij} (x_{ij} - \bar{\bar{x}})^2$	$N-1$	$\text{MST} = \dfrac{Q_T}{N-1}$		

Table 5.71: **One-way blocked ANOVA table**

In practical situations it is sometimes not easy to decide whether block effects should be treated as random effects. For example, are the blocks in a field experiment randomly selected form a larger population of blocks? Most likely they were the only blocks available for the experiment. Of, if the experiment is replicated over two years (setting up a GRBD with nested blocking factors),are those years randomly selected? Certainly not, but still the researcher may want to consider the as "random" years. But if one years turns out to be a dry year and the other to be a wet year, then clearly we have an intrinsic blocking factor with fixed effects. There are obviously many variations of this discussion and thus this question becomes rather philosophical and often controversial. In general, we prefer to make the analysis once by considering them as fixed and once as random (as it is really quick done with computer software), and see if the conclusions are the same.

For two samples, one-way blocked ANOVA is equivalent to the two-sample paired T-test.

5.7.13.5.7 Latin Square ANOVA without repetitions

A "Latin Square ANOVA" is a three factor nested ANOVA but with the subtility that the third nested one has not each of its levels repeated in the levels of the two first but only one time and in such a way that each of its levels appears only one time at each row and each column of the parent level:

1	2	3
3	1	2
2	3	1

4	3	1	2
3	4	2	1
1	2	4	3
2	1	3	4

1	2	4	3	5
4	5	2	1	3
3	4	1	5	2
2	3	5	4	1
5	1	3	2	4

Figure 5.202: Latin squares of orders 3, 4 and 5

The number of level of each factor is imposed as being in equal quantity that is why there is the term "square" in "Latin Square" design! The term "Latin" comes from the fact that no term is repeated on the same line or on the same column! We then logically speak of "balanced Latin square design" or just simply of "Latin square design" (LSD).

So this design (attributed to Leonard Euler in 11783 according to holocene calendar), represents, in some sense, the simplest form of a row-column design as it is used for comparing K treatments in K rows and K columns, where rows and columns represent two blocking factors. They were proposed as experimental design by Ronald Fisher in 11925 (holocene calendar), although François Cretté De Palluel (11788 according to holocene calendar) already utilized the idea of a 4×4 Latin square design for an agricultural experiment.

A complete illustration of such as design can be given by the following example (typical in Gage R&R crossed studies without replications!):

	Operators				
Batch	1	2	3	4	5
1	A=24	B=20	C=19	D=24	E=24
2	B=17	C=24	D=30	E=27	A=36
3	C=18	D=38	E=26	A=27	B=21
4	D=26	E=31	A=26	B=23	C=22
5	E=22	A=30	B=20	C=29	D=31

Table 5.72: Famous Latin square design for the Propellant model of Douglas C. Montgomery

We see why the Latin square ANOVA are relatively rare in practice because they assume that for each object we have the same number of combinations of tests when in reality we could have less or more. Moreover, the Latin squares ANOVA are often designated as incomplete plans, or "incomplete block designs[81]", and thus in extenso economic because if we really had to make all the combinations for a Latin square of dimension n, the number of total combinations would be n^3 whereas in reality the Latin square represents only n^2.

Therefore we can already observe that:

1. The order of performing the trials is random
2. We have many trials (as the example above should have $5 \cdot 5 \cdot 5 = 125$ trials if it were complete)

---

[81] So keep in mind that it is a randomized block design in which every treatment is not present in every block

Note also that for a given dimension a Latin square is not unique. Indeed the following Latin square:

	Cars			
Drivers	1	2	3	4
1	A	B	D	C
2	D	C	A	B
3	B	D	C	A
4	C	A	B	D

is equivalent to that one:

	Cars			
Drivers	1	2	3	4
1	A	B	D	C
2	C	D	B	A
3	B	A	C	D
4	D	C	A	B

The real interest of the Latin square ANOVA is that they are certainly economic since they are incomplete but mainly because they are orthogonal in the sense that they contain the best way of doing the tests by minimizing the quantity of these last ones. Indeed, we see in a Latin square that each letter appears only once in each line and each column (hence the origin of the name!) in order to minimize the error (mathematically there is therefore "orthogonality").

It is customary to represent a Latin square ANOVA in the following more general way:

	1st Factor				
2nd Factor	1	2	3	4	Average of rows
I	y_{111}	y_{122}	y_{134}	y_{143}	$\bar{y}_{1..}$
II	y_{214}	y_{223}	y_{231}	y_{341}	$\bar{y}_{2..}$
III	y_{312}	y_{324}	y_{333}	y_{341}	$\bar{y}_{3..}$
IV	y_{413}	y_{421}	y_{432}	y_{444}	$\bar{y}_{4..}$
Average of columns	$\bar{y}_{.1.}$	$\bar{y}_{.2.}$	$\bar{y}_{.3.}$	$\bar{y}_{.4.}$	$\bar{y}_{...}$

And obviously notice that the number of rows is (obviously!) always equal to the number of columns and for such designs, we also speak of "symmetric designs".

Let us prove that we have:

$$\begin{aligned}\mathrm{Q}_T=&\sum_{i=1}^{K}\sum_{j=1}^{K}\sum_{k=1}^{K}\left(y_{ijk}-\bar{y}_{...}\right)^2\\ =&\underbrace{K\sum_{i=1}^{K}\left(\bar{y}_{i..}-\bar{y}_{...}\right)^2}_{\text{SSE}_{\text{rows}}}+\underbrace{K\sum_{j=1}^{K}\left(\bar{y}_{.j.}-\bar{y}_{...}\right)^2}_{\text{SSE}_{\text{columns}}}+\underbrace{K\sum_{k=1}^{K}\left(\bar{y}_{..k}-\bar{y}_{...}\right)^2}_{\text{SSE}_{\text{treatements}}}\\ &+\underbrace{\sum_{i=1}^{K}\sum_{j=1}^{K}\sum_{k=1}^{K}\left(y_{ijk}-\bar{y}_{i..}-\bar{y}_{.j.}-\bar{y}_{..k}+2\bar{y}_{...}\right)^2}_{\text{SSE}_{\text{residual}}}\\ =&\,\mathrm{Q}_R+\mathrm{Q}_C+\mathrm{Q}_{RC}+\mathrm{Q}_r\end{aligned}\tag{5.7.2109}$$

where R stands for "rows", C for "columns" and r for "residuals".

Well let's go in joy and good mood ...! We first write:

$$\begin{aligned}\sum_{i=1}^{K}\sum_{j=1}^{K}\sum_{k=1}^{K}\left(y_{ijk}-\bar{y}_{...}\right)^2&=\sum_{i,j,k}\left(y_{ijk}-\bar{y}_{...}\right)^2=\sum_{i,j,k}\left(y_{ijk}+\bar{y}_{i..}-\bar{y}_{i..}+\bar{y}_{.j.}-\bar{y}_{.j.}+\bar{y}_{..k}-\bar{y}_{..k}-\bar{y}_{...}\right)^2\\ &=\sum_{i,j,k}\left(y_{ijk}-\bar{y}_{i..}-\bar{y}_{.j.}-\bar{y}_{..k}+2\bar{y}_{...}+\bar{y}_{i..}-\bar{y}_{...}+\bar{y}_{.j.}-\bar{y}_{...}+\bar{y}_{..k}-\bar{y}_{...}\right)^2\\ &=\sum_{i,j,k}\left(y_{ijk}-\bar{y}_{i..}-\bar{y}_{.j.}-\bar{y}_{..k}+2\bar{y}_{...}\right)^2+\sum_{i,j,k}\left(\bar{y}_{i..}-\bar{y}_{...}+\bar{y}_{.j.}-\bar{y}_{...}+\bar{y}_{..k}-\bar{y}_{...}\right)^2\\ &+2\sum_{i,j,k}\left(y_{ijk}-\bar{y}_{i..}-\bar{y}_{.j.}-\bar{y}_{..k}+2\bar{y}_{...}\right)\left(\bar{y}_{i..}+\bar{y}_{.j.}+\bar{y}_{..k}-3\bar{y}_{...}\right)\end{aligned}\tag{5.7.2110}$$

But:

$$\sum_{i,j,k}\left(y_{ijk}-\bar{y}_{i..}-\bar{y}_{.j.}-\bar{y}_{..k}+2\bar{y}_{...}\right)\left(\bar{y}_{i..}+\bar{y}_{.j.}+\bar{y}_{..k}-3\bar{y}_{...}\right)=0\tag{5.7.2111}$$

Indeed, let's start by noticing that:

$$\sum_{i,j,k}y_{ijk}\cdot\bar{y}_{i..}=\sum_{i}\bar{y}_{i..}\sum_{j,k}y_{ijk}=\sum_{i}\bar{y}_{i..}\cdot K\cdot\bar{y}_{i..}=K\sum_{i}(\bar{y}_{i..})^2\tag{5.7.2112}$$

The same calculations show that:

$$\sum_{i,j,k}y_{ijk}\cdot\bar{y}_{.j.}=K\sum_{j}(\bar{y}_{.j.})^2\qquad\text{and}\qquad\sum_{i,j,k}y_{ijk}\cdot\bar{y}_{..k}=K\sum_{k}(\bar{y}_{..k})^2\tag{5.7.2113}$$

Furthermore:

$$\sum_{i,j,k}(-\bar{y}_{i..})\bar{y}_{i..}=-\sum_{i}\sum_{j,k}(\bar{y}_{i..})^2=-K\sum_{i}(\bar{y}_{i..})^2\tag{5.7.2114}$$

and again we have the same result for the indices j and k. That is to say:

$$\sum_{i,j,k}(-\bar{y}_{.j.})\bar{y}_{.j.}=-K\sum_{j}(\bar{y}_{.j.})^2\quad\text{and}\quad\sum_{i,j,k}(-\bar{y}_{..k})\bar{y}_{..k}=-K\sum_{k}(\bar{y}_{..k})^2\tag{5.7.2115}$$

Therefore:

$$\begin{gathered}\sum_{i,j,k}(y_{ijk}-\bar{y}_{i..}-\bar{y}_{.j.}-\bar{y}_{..k}+2\bar{y}_{...})(\bar{y}_{i..}+\bar{y}_{.j.}+\bar{y}_{..k}-3\bar{y}_{...})=\\ \sum_{i,j,k}\left[-3\bar{y}_{...}\cdot y_{ijk}-2\bar{y}_{i..}\bar{y}_{.j.}-2\bar{y}_{i..}\bar{y}_{..k}-2\bar{y}_{.j.}\bar{y}_{..k}+5\bar{y}_{...}(\bar{y}_{i..}+\bar{y}_{.j.}+\bar{y}_{..k})-6(\bar{y}_{...})^2\right]\end{gathered} \tag{5.7.2116}$$

Now, note that:

$$\sum_{i,j,k}\bar{y}_{i..}\cdot\bar{y}_{.j.}=\sum_{i}\bar{y}_{i..}\sum_{j,k}\bar{y}_{.j.}=K\bar{y}\sum_{i}\bar{y}_{i..}=K^2(\bar{y})^2 \tag{5.7.2117}$$

as:

$$\sum_{j,k}\bar{y}_{.j.}=K\bar{y} \tag{5.7.2118}$$

Here again we also have with the same calculations:

$$\sum_{i,j,k}\bar{y}_{i..}\cdot\bar{y}_{..k}=K^2(\bar{y})^2 \quad \text{and} \quad \sum_{i,j,k}\bar{y}_{.j.}\cdot\bar{y}_{..k}=K^2(\bar{y})^2 \tag{5.7.2119}$$

Furthermore:

$$\sum_{i,j,k}(\bar{y}_{...})^2=K^2(\bar{y}_{...})^2 \tag{5.7.2120}$$

Therefore:

$$\begin{gathered}\sum_{i,j,k}(y_{ijk}-\bar{y}_{i..}-\bar{y}_{.j.}-\bar{y}_{..k}+2\bar{y}_{...})(\bar{y}_{i..}+\bar{y}_{.j.}+\bar{y}_{..k}-3\bar{y}_{...})=\\ -12K^2(\bar{y}_{...})^2+\sum_{i,j,k}\left[-3\bar{y}_{...}\cdot y_{ijk}+5\bar{y}_{...}(\bar{y}_{i..}+\bar{y}_{.j.}+\bar{y}_{..k})\right]\end{gathered} \tag{5.7.2121}$$

We have:

$$\sum_{i,j,k}\bar{y}_{...}\cdot y_{ijk}=\bar{y}_{...}\sum_{i,j,k}y_{ijk}=K^2(\bar{y}_{...})^2 \tag{5.7.2122}$$

as:

$$\sum_{i,j,k}y_{ijk}=K\bar{y}_{...} \tag{5.7.2123}$$

Furthermore:

$$\sum_{i,j,k}\bar{y}_{...}\bar{y}_{i..}=\sum_{i}\bar{y}_{...}\sum_{j,k}\bar{y}_{i..}=\sum_{i}\bar{y}_{...}K\cdot\bar{y}_{i..}=K^2(\bar{y}_{...})^2 \tag{5.7.2124}$$

as:

$$\sum_{i}\bar{y}_{i..}=K\bar{y} \tag{5.7.2125}$$

The same result holds for the indexes j and k, i.e.:

$$\sum_{i,j,k} \bar{y}_{...}\bar{y}_{.j.} = K^2(\bar{y}_{...})^2 \qquad \text{and} \qquad \sum_{i,j,k} \bar{y}_{...}\bar{y}_{..k} = K^2(\bar{y}_{...})^2 \tag{5.7.2126}$$

Hence:

$$\sum_{i,j,k} (y_{ijk} - \bar{y}_{i..} - \bar{y}_{.j.} - \bar{y}_{..k} + 2\bar{y}_{...})(\bar{y}_{i..} + \bar{y}_{.j.} + \bar{y}_{..k} - 3\bar{y}_{...}) = 0 \tag{5.7.2127}$$

Back to the beginning...

Then it remains to us:

$$\sum_{i,j,k} (y_{ijk} - \bar{y}_{...})^2 = \sum_{i,j,k} (y_{ijk} - \bar{y}_{i..} - \bar{y}_{.j.} - \bar{y}_{..k} + 2\bar{y}_{...})^2 + \sum_{i,j,k} (\bar{y}_{i..} - \bar{y}_{...} + \bar{y}_{.j.} - \bar{y}_{...} + \bar{y}_{..k} - \bar{y}_{...})^2 \tag{5.7.2128}$$

Let's evaluate the double products in the last sum:

$$\sum_{i,j,k} (\bar{y}_{i..} - \bar{y}_{...})(\bar{y}_{.j.} - \bar{y}_{...}) = \sum_{i,j,k} \bar{y}_{i..}\bar{y}_{.j.} - \sum_{i,j,k} \bar{y}_{...}\bar{y}_{i..} - \sum_{i,j,k} \bar{y}_{...}\bar{y}_{.j.} + \sum_{i,j,k} (\bar{y}_{...})^2 = 0 \tag{5.7.2129}$$

because as seen previously, all these are worth $K^2(\bar{y})^2$.

The other double products are also worth 0 by the same arguments. So:

$$\begin{aligned}\sum_{i,j,k} (y_{ijk} - \bar{y}_{...})^2 =& \sum_{i,j,k} (y_{ijk} - \bar{y}_{i..} - \bar{y}_{.j.} - \bar{y}_{..k} + 2\bar{y}_{...})^2 \\ &+ \sum_{i,j,k} (y_{i..} - \bar{y}_{...})^2 + \sum_{i,j,k} (y_{.j.} - \bar{y}_{...})^2 + \sum_{i,j,k} (y_{..k} - \bar{y}_{...})^2\end{aligned} \tag{5.7.2130}$$

To finish, let us note that:

$$\sum_{i,j,k} (\bar{y}_{i..} - \bar{y}_{...})^2 = \sum_{i} \sum_{j,k} (\bar{y}_{i..} - \bar{y}_{...})^2 = K \sum_{i} (\bar{y}_{i..} - \bar{y}_{...})^2 \tag{5.7.2131}$$

and the same for j and k. Therefore:

$$\begin{aligned}\sum_{i,j,k} (y_{ijk} - \bar{y}_{...})^2 =& K \sum_{i} (\bar{y}_{i..} - \bar{y}_{...})^2 + K \sum_{j} (\bar{y}_{.j.} - \bar{y}_{...})^2 + K \sum_{k} (\bar{y}_{..k} - \bar{y}_{...})^2 \\ &+ \sum_{i,j,k} (y_{ijk} - \bar{y}_{i..} - \bar{y}_{.j.} - \bar{y}_{..k} + 2\bar{y}_{...})^2\end{aligned} \tag{5.7.2132}$$

If we denote by K the dimension of a Latin square, for each of the above terms we have the following degrees of freedom:

$$K^2 - 1 = (K - 1) + (K - 1) + (K - 1) + (K - 1)(K - 2) \tag{5.7.2133}$$

We then have the following ANOVA table:

Sum of squares	χ^2 **df**	**Mean squares**	F	**Critical** F
$Q_R = K\sum_i (\bar{y}_{i..} - \bar{y}_{...})^2$ (rows)	$K-1$	$\text{MSk}R = \dfrac{Q_R}{K-1}$	$\dfrac{\text{MSk}R}{\text{MSE}}$	$P(F > F_{K-1,(K-1)(K-2)})$
$Q_C = K\sum_j (\bar{y}_{.j.} - \bar{y}_{...})^2$ (columns)	$K-1$	$\text{MSk}C = \dfrac{Q_C}{K-1}$	$\dfrac{\text{MSk}C}{\text{MSE}}$	$P(F > F_{K-1,(K-1)(K-2)})$
$Q_{RC} = K\sum_k (\bar{y}_{..k} - \bar{y}_{...})^2$ (treatments)	$K-1$	$\text{MSk}RC = \dfrac{Q_{RC}}{K-1}$	$\dfrac{\text{MSk}RC}{\text{MSE}}$	$P(F > F_{K-1,(K-1)(K-2)})$
$Q_r = \sum_{i,j,k} (y_{ijk} - \bar{y}_{i..} - \bar{y}_{.j.} - \bar{y}_{..k} + 2\bar{y}_{...})^2$ (residuals)	$(K-1)(K-2)$	$\text{MSE} = \dfrac{Q_r}{(K-1)(K-2)}$		
$Q_T = \sum_{i,j,k} (y_{ijk} - \bar{y}_{...})^2$ (total)	K^2-1	$\text{MST} = \dfrac{\text{Q}_\text{T}}{K^2-1}$		

Table 5.73: **Latin square ANOVA table**

Remark

The factor effect model for this design is:

$$\boxed{y_{ijk} = \mu + \alpha_i + \tau_j + \beta_k + \varepsilon_{ijk}} \tag{5.7.2134}$$

where $i, j, k = 1 \ldots N$ and y_{ijk} is the observation in the ith row and kth column for the jth treatment, μ is the overall mean, α_i is the ith row effect, τ_j is the jth treatment effect, β_k is the kth column effect, and ε_{ijk} is a random error.

Notice that only two out of the three subscripts are necessary to identify an observation in the latin square design and that this model is (obviously) purely additive. The assumptions on the effect terms are $\sum_{i=1}^N \alpha_i = 0$, $\sum_{j=1}^N \tau_j = 0$ and $\sum_{k=1}^N \beta_k = 0$.

We are interested (mainly!) for zero treatment effect, that is, $H_0 : \tau_1 = \tau_2 = \ldots = 0$ versus $H_1 : \tau_j \neq 0$.

Keep in mind that the advantage of Latin square designs are:

- They allow experiments with a small number of runs (more economical than crossing all factors)
- Easy to analyse

The disadvantages are:

- The number of levels of each blocking variable must equal the number of levels of the treatment factor
- They assume that there are no interactions between the blocking variables or between the treatment variable and the blocking variable (may be unrealistic)
- It is say that squares smaller than 4×4 or 5×5 generally have too few replications for a desirable level of precision (low power)

- It can be proved that 6×6 Latin square designs are impossible (the proof is actually not in this textbook!)

Remarks

R1. The Latin square designs are part of what we name also sometimes "space filling design" (family that also contains spherical designs, uniform designs with minimum potential designs, or maximum entropy designs or IMSE (integrated mean-square error) Gaussian processes).

R2. There exist also rectangular Latin design for information...

5.7.13.5.8 Graeco-Latin Square ANOVA

A "Graeco-Latin Square ANOVA" is an extension of a Latin square used when the number of block is greater than 2. Concretely, a Graeco-Latin square ANOVA can control up to two nuisance factors and one treatment factor (three sources of extraneous variability...) as represented below:

	Column			
Row	1	2	3	4
1	Aα	Bβ	Cγ	Dδ
2	Bδ	Aγ	Dβ	Cα
3	Cβ	Dα	Aδ	Bγ
4	Dγ	Cδ	Bα	Aβ

Table 5.74: **Graeco-Latin square of order** 4

Use of these designs results in exceptional saving of time and means, as the total number of design points has been drastically reduced as if we consider n level for each of the three factor we have only n^2 experimental points, when compared to n^4 (since there are four factors!!!!) design points in full factorial design. However similar to Latin squares, these designs may be used only when interactions are statistically insignificant.

To figure out a Graeco-Latin square, we consider initially a Latin square $K \otimes K$ on which we superimposed another Latin square $K \otimes K$ which this time is denoted by Greek letters. Afterwards in a second time during the superposition, we must ensure that the following property is respected, "each row and each column can only contain couple of letters (Latin, Greek) that are distincts". Thus, if this property is verified (as shown in the diagram below) we say that the two orthogonal Latin squares are orthogonals:

4×4 **Latin square**
Latin letters

A	B	C	D
B	A	D	C
C	D	A	B
D	C	B	A

4×4 **Latin square**
Greek letters

α	β	γ	δ
δ	γ	β	α
β	α	δ	γ
γ	δ	α	β

4×4 **Graeco-Latin square**

	Columns			
Rows	1	2	3	4
1	Aα	Bβ	Cγ	Dδ
2	Bδ	Aγ	Dβ	Cα
3	Cβ	Dα	Aδ	Bγ
4	Dγ	Cδ	Bα	Aβ

Figure 5.203: **Merge of two Latin square designs**

Remark

The Graeco-Latin square designs are also part of what we name also sometimes "space filling design" as for the Latin square designs.

As you can notice, the Graeco-Latin square design allows the analysis of 4 factors (row, column, Latin letter, Greek letter), each factor having K levels for only $K \otimes K$ or K^2 possible combinations.

For the need of the analysis of variance, we have to define certain variables:

- K the number of levels for each factor
- $N = K^2$, the total number of observations $y_{i,j,k,l}$ in the Graeco-Latin square, where i is the i-th level of the factor represented in row, j the j-th level of the factor represented in column, k the k-th level of the factor represented by Latin letters and the l the l-th level of the factor represented by Greek letters.

Thus, one can formulate as follows:

- The sum and the average of observations:

$$y_{....} = \sum_{i=1}^{K}\sum_{j=1}^{K}\sum_{k=1}^{K}\sum_{l=1}^{K} y_{ijkl} = \sum_{i=1}^{K}\sum_{j=1}^{K} y_{ij..} \qquad \bar{y}_{....} = \frac{y_{....}}{K^2} \tag{5.7.2135}$$

- The sum and average for each row:

$$y_{i...} = \sum_{j=1}^{K} y_{ij..} \qquad \bar{y}_{i...} = \frac{y_{i...}}{K} \tag{5.7.2136}$$

- The sum and average for each columns:

$$y_{.j..} = \sum_{i=1}^{K} y_{ij..} \qquad \bar{y}_{.j..} = \frac{y_{.j..}}{K} \tag{5.7.2137}$$

- The sum and average for each Latin letter:

$$y_{..k.} = \sum_{i=1}^{K}\sum_{j=1}^{K} y_{ijk.} \qquad \bar{y}_{..k.} = \frac{y_{..k.}}{K} \tag{5.7.2138}$$

- The sum and average for each Greek letter:

$$y_{...l} = \sum_{i=1}^{K}\sum_{j=1}^{K} y_{ij.l} \qquad \bar{y}_{...l} = \frac{y_{...l}}{K} \tag{5.7.2139}$$

For the development, we will prefer this notation $\sum\limits_{i,j,k,l}^{K}$ to that one $\sum\limits_{i=1}^{K}\sum\limits_{j=1}^{K}\sum\limits_{k=1}^{K}\sum\limits_{l=1}^{K}$ in order to simplify the notations.

Let us deal now with the decomposition of the total variance! Let us prove that the latter:

$$\sum_{i=1}^{K}\sum_{j=1}^{K}\sum_{k=1}^{K}\sum_{l=1}^{K}(y_{ijkl}-\bar{y}_{....})^2=\sum_{i,j,k,l}^{K}(y_{ijkl}-\bar{y}_{....})^2 \qquad (5.7.2140)$$

can be written:

$$\begin{aligned}\sum_{i,j,k,l}^{K}(y_{ijkl}-\bar{y}_{....})^2 &= K\sum_{i}^{K}(\bar{y}_{i...}-\bar{y}_{....})^2+K\sum_{j}^{K}(\bar{y}_{.j..}-\bar{y}_{....})^2+K\sum_{k}^{K}(\bar{y}_{..k.}-\bar{y}_{....})^2+K\sum_{l}^{K}(\bar{y}_{...l}-\bar{y}_{....})^2\\ &+\sum_{i,j,k,l}^{K}(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....})^2\end{aligned}$$

For that, let us first put:

$$\sum_{i,j,k,l}^{K}(y_{ijkl}-\bar{y}_{....})^2=\sum_{i,j,k,l}^{K}(y_{ijkl}-\bar{y}_{i...}+\bar{y}_{i...}-\bar{y}_{.j..}+\bar{y}_{.j..}-\bar{y}_{..k.}+\bar{y}_{..k.}-\bar{y}_{...l}+\bar{y}_{...l}-\bar{y}_{....})^2 \qquad (5.7.2141)$$

Let's put some $\bar{y}_{....}$ in it like this:

$$\begin{aligned}&=\sum_{i,j,k,l}^{K}(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....}+\bar{y}_{i...}-\bar{y}_{....}+\bar{y}_{.j..}-\bar{y}_{....}+\bar{y}_{..k.}-\bar{y}_{....}+\bar{y}_{...l}-\bar{y}_{....})^2\\ &=\sum_{i,j,k,l}^{K}[(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....})+(\bar{y}_{i...}-\bar{y}_{....}+\bar{y}_{.j..}-\bar{y}_{....}+\bar{y}_{..k.}-\bar{y}_{....}+\bar{y}_{...l}-\bar{y}_{....})]^2\end{aligned} \qquad (5.7.2142)$$

At this level, we fall back on our famous remarkable identity $(a+b)^2=a^2+b^2+2ab$. Thus in the framework our development, we get:

$$\begin{aligned}&=\sum_{i,j,k,l}^{K}\Big[(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....})^2+(\bar{y}_{i...}-\bar{y}_{....}+\bar{y}_{.j..}-\bar{y}_{....}+\bar{y}_{..k.}-\bar{y}_{....}+\bar{y}_{...l}-\bar{y}_{....})\\ &\quad+2\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k}+\bar{y}_{...l}-4\bar{y}_{....}\right)\left(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....}\right)\Big]\\ &=\sum_{i,j,k,l}^{K}(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....})^2+\sum_{i,j,k,l}^{K}(\bar{y}_{i...}-\bar{y}_{....}+\bar{y}_{.j..}-\bar{y}_{....}+\bar{y}_{..k.}-\bar{y}_{....}+\bar{y}_{...l}-\bar{y}_{....})^2\\ &\quad+2\sum_{i,j,k,l}^{K}\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k.}+\bar{y}_{...l}-4\bar{y}_{....}\right)\left(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....}\right)\end{aligned}$$

Let us consider now the 3th member of this expression $2\sum ab$:

$$\sum_{i,j,k,l}^{K}\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k}+\bar{y}_{...l}-4\bar{y}_{....}\right)\left(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....}\right) \qquad (5.7.2143)$$

And let us show that the result of that latter is equal to 0. Let's start by developing it as below:

$$\begin{aligned}
&= \sum_{i,j,k,l}^{K} \bar{y}_{i...}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right)^{(a)}\\
&\quad + \sum_{i,j,k,l}^{K} \bar{y}_{.j..}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right)^{(b)}\\
&\quad + \sum_{i,j,k,l}^{K} \bar{y}_{..k.}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right)^{(c)}\\
&\quad + \sum_{i,j,k,l}^{K} \bar{y}_{...l}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right)^{(d)}\\
&\quad - 4\sum_{i,j,k,l}^{K} \bar{y}_{....}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right)^{(e)}
\end{aligned}$$

Let us develop the first term above denoted by the exponent ${}^{(a)}$:

$$\begin{aligned}
\sum_{i,j,k,l}^{K} \bar{y}_{i...}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right) &= \sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot y_{ijkl} - \sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot\bar{y}_{i...} - \sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot\bar{y}_{.j..}\\
&\quad - \sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot\bar{y}_{..k.} - \sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot\bar{y}_{...l} + 3\sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot\bar{y}_{....}
\end{aligned}$$

Let us evaluate each of the six terms above separately:

$$\begin{aligned}
&\sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot y_{ijkl} = \sum_{i}^{K} \bar{y}_{i...}\cdot\sum_{j,k,l}^{K} y_{ijkl} = K\cdot\bar{y}_{i...}\cdot\bar{y}_{i...} = K\sum_{i}^{K}\left(\bar{y}_{i...}\right)^2\\
&-\sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot\bar{y}_{i...} = -K\sum_{i}^{K}\left(\bar{y}_{i...}\right)^2\\
&-\sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot\bar{y}_{.j..} = -\sum_{i}^{K} \bar{y}_{i...}\cdot\sum_{j,k,l}^{K} y_{.j..} = -K\bar{y}_{....}\cdot K\bar{y}_{....} = -K^2\left(\bar{y}_{....}\right)^2\\
&-\sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot\bar{y}_{..k.} = \ldots = -K^2\left(\bar{y}_{....}\right)^2\\
&-\sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot\bar{y}_{...l} = \ldots = -K^2\left(\bar{y}_{....}\right)^2\\
&+3\sum_{i,j,k,l}^{K} \bar{y}_{i...}\cdot\bar{y}_{....} = \ldots = +3K^2\left(\bar{y}_{....}\right)^2
\end{aligned}\tag{5.7.2144}$$

So finally we get that the original term denoted by the exponent ${}^{(a)}$:

$$\sum_{i,j,k,l}^{K} \bar{y}_{i...}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right)\tag{5.7.2145}$$

is equal to:

$$\sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot y_{ijkl} - \sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot \bar{y}_{i...} - \sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot \bar{y}_{.j..} - \sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot \bar{y}_{..k.} - \sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot \bar{y}_{...l} + 3\sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot \bar{y}_{....} \tag{5.7.2146}$$

That gives:

$$K\sum_{i}^{K} \left(\bar{y}_{i...}\right)^2 - K\sum_{i}^{K} \left(\bar{y}_{i...}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 + 3K^2\left(\bar{y}_{....}\right)^2 = 0 \tag{5.7.2147}$$

Thus, by the same boring mathematical process, we can prove that each of the other four remaining terms are also equal to zero. Thus:

$$(b)\ \sum_{i,j,k,l}^{K} \bar{y}_{.j..}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right) =$$

$$K\sum_{j}^{K} \left(\bar{y}_{.j..}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 - K\sum_{j}^{K} \left(\bar{y}_{.j..}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 + 3K^2\left(\bar{y}_{....}\right)^2 = 0$$

$$(c)\ \sum_{i,j,k,l}^{K} \bar{y}_{..k.}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right) =$$

$$K\sum_{k}^{K} \left(\bar{y}_{..k.}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 - K\sum_{k}^{K} \left(\bar{y}_{..k.}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 + 3K^2\left(\bar{y}_{....}\right)^2 = 0$$

$$(d)\ \sum_{i,j,k,l}^{K} \bar{y}_{...l}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right) =$$

$$K\sum_{l}^{K} \left(\bar{y}_{...l}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 - K\sum_{l}^{K} \left(\bar{y}_{...l}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 - K^2\left(\bar{y}_{....}\right)^2 + 3K^2\left(\bar{y}_{....}\right)^2 = 0$$

$$(e)\ -4\sum_{i,j,k,l}^{K} \bar{y}_{....}\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right) =$$

$$-4K^2\left(\bar{y}_{....}\right)^2 + 4K^2\left(\bar{y}_{....}\right)^2 + 4K^2\left(\bar{y}_{....}\right)^2 + 4K^2\left(\bar{y}_{....}\right)^2 + 4K^2\left(\bar{y}_{...l}\right)^2 - 12K^2\left(\bar{y}_{....}\right)^2 = 0$$

Now that we have proved that $2\sum ab = 0$, that is to say:

$$2\sum_{i,j,k,l}^{K} \left(\bar{y}_{i...} + \bar{y}_{.j..} + \bar{y}_{..k} + \bar{y}_{...l} - 4\bar{y}_{....}\right)\left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right) = 0 \tag{5.7.2148}$$

Let us come back to the beginning (...):

$$\begin{aligned}
&\sum_{i,j,k,l}^{K}\left(y_{ijkl}-\bar{y}_{....}\right)^2\\
&=\sum_{i,j,k,l}^{K}\left(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....}\right)^2+\sum_{i,j,k,l}^{K}\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k}+\bar{y}_{...l}-4\bar{y}_{....}\right)^2\\
&+2\sum_{i,j,k,l}^{K}\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k.}+\bar{y}_{...l}-4\bar{y}_{....}\right)\left(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....}\right)
\end{aligned}$$

Since the 3rd term is equal to it remains obviously only:

$$\sum_{i,j,k,l}^{K}\left(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....}\right)^2+\sum_{i,j,k,l}^{K}\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k.}+\bar{y}_{...l}-4\bar{y}_{....}\right)^2 \tag{5.7.2149}$$

Let us take the 2nd term of the above expression:

$$\begin{aligned}
&\sum_{i,j,k,l}^{K}\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k.}+\bar{y}_{...l}-4\bar{y}_{....}\right)^2\\
&=\sum_{i,j,k,l}^{K}\left(\bar{y}_{i...}-\bar{y}_{....}+\bar{y}_{.j..}-\bar{y}_{....}+\bar{y}_{..k.}-\bar{y}_{....}+\bar{y}_{...l}-\bar{y}_{....}\right)^2\\
&=\sum_{i,j,k,l}^{K}\left[\left(\bar{y}_{i...}-\bar{y}_{....}\right)+\left(\bar{y}_{.j..}-\bar{y}_{....}\right)+\left(\bar{y}_{..k.}-\bar{y}_{....}\right)+\left(\bar{y}_{...l}-\bar{y}_{....}\right)\right]^2\\
&=\sum_{i,j,k,l}^{K}\left(\bar{y}_{i...}-\bar{y}_{....}\right)^2+\sum_{i,j,k,l}^{K}\left(\bar{y}_{.j..}-\bar{y}_{....}\right)^2+\sum_{i,j,k,l}^{K}\left(\bar{y}_{..k.}-\bar{y}_{....}\right)^2+\sum_{i,j,k,l}^{K}\left(\bar{y}_{...l}-\bar{y}_{....}\right)^2\\
&+\sum_{i,j,k,l}^{K}\left(\bar{y}_{i...}-\bar{y}_{....}\right)\cdot\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k.}+\bar{y}_{...l}-4\bar{y}_{....}\right)\\
&+\sum_{i,j,k,l}^{K}\left(\bar{y}_{.j..}-\bar{y}_{....}\right)\cdot\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k.}+\bar{y}_{...l}-4\bar{y}_{....}\right)\\
&+\sum_{i,j,k,l}^{K}\left(\bar{y}_{..k.}-\bar{y}_{....}\right)\cdot\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k.}+\bar{y}_{...l}-4\bar{y}_{....}\right)\\
&+\sum_{i,j,k,l}^{K}\left(\bar{y}_{...l}-\bar{y}_{....}\right)\cdot\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k.}+\bar{y}_{...l}-4\bar{y}_{....}\right)
\end{aligned}$$

In the above development let us consider the following expression:

$$\sum_{i,j,k,l}^{K}\left(\bar{y}_{i...}-\bar{y}_{....}\right)\left(\bar{y}_{i...}+\bar{y}_{.j..}+\bar{y}_{..k.}+\bar{y}_{...l}-4\bar{y}_{....}\right) \tag{5.7.2150}$$

And let us prove that it is equal to zero:

$$\begin{aligned}
&\sum_{i,j,k,l}^{K} \left(\bar{y}_{i...} - \bar{y}_{....}\right) \cdot \left(\bar{y}_{i...} + \bar{y}_{.j..} + \bar{y}_{..k.} + \bar{y}_{...l} - 4\bar{y}_{....}\right) \\
&= \sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot \bar{y}_{i...} + \sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot \bar{y}_{.j..} + \sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot \bar{y}_{..k.} \\
&+ \sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot \bar{y}_{...l} - \sum_{i,j,k,l}^{K} \bar{y}_{i...} \cdot 4\bar{y}_{....} - \sum_{i,j,k,l}^{K} \bar{y}_{....} \cdot \bar{y}_{i...} \\
&- \sum_{i,j,k,l}^{K} \bar{y}_{....} \cdot \bar{y}_{.j..} - \sum_{i,j,k,l}^{K} \bar{y}_{....} \cdot \bar{y}_{..k.} - \sum_{i,j,k,l}^{K} \bar{y}_{....} \cdot \bar{y}_{...l} + \sum_{i,j,k,l}^{K} \bar{y}_{....} \cdot 4\bar{y}_{....} \\
&= K^2 \left(\bar{y}_{....}\right)^2 + K^2 \left(\bar{y}_{....}\right)^2 + K^2 \left(\bar{y}_{....}\right)^2 + K^2 \left(\bar{y}_{....}\right)^2 \\
&- 4K^2 \left(\bar{y}_{....}\right)^2 - K^2 \left(\bar{y}_{....}\right)^2 - K^2 \left(\bar{y}_{....}\right)^2 - K^2 \left(\bar{y}_{....}\right)^2 \\
&- K^2 \left(\bar{y}_{....}\right)^2 + 4K^2 \left(\bar{y}_{....}\right)^2 \\
&= 0
\end{aligned}$$

Consequently, each of the following expressions:

$$\sum_{i,j,k,l}^{K} \left(\bar{y}_{.j..} - \bar{y}_{....}\right) \cdot \left(\bar{y}_{i...} + \bar{y}_{.j..} + \bar{y}_{..k.} + \bar{y}_{...l} - 4\bar{y}_{....}\right) \tag{5.7.2151}$$

$$\sum_{i,j,k,l}^{K} \left(\bar{y}_{..k.} - \bar{y}_{....}\right) \cdot \left(\bar{y}_{i...} + \bar{y}_{.j..} + \bar{y}_{..k.} + \bar{y}_{...l} - 4\bar{y}_{....}\right) \tag{5.7.2152}$$

$$\sum_{i,j,k,l}^{K} \left(\bar{y}_{...l} - \bar{y}_{....}\right) \cdot \left(\bar{y}_{i...} + \bar{y}_{.j..} + \bar{y}_{..k.} + \bar{y}_{...l} - 4\bar{y}_{....}\right) \tag{5.7.2153}$$

is equal to 0.

Finally it remains:

$$\begin{aligned}
\sum_{i,j,k,l}^{K} \left(y_{ijkl} - \bar{y}_{....}\right)^2 = &\sum_{i,j,k,l}^{K} \left(\bar{y}_{i...} - \bar{y}_{....}\right)^2 + \sum_{i,j,k,l}^{K} \left(\bar{y}_{.j..} - \bar{y}_{....}\right)^2 + \sum_{i,j,k,l}^{K} \left(\bar{y}_{..k.} - \bar{y}_{....}\right)^2 + \sum_{i,j,k,l}^{K} \left(\bar{y}_{...l} - \bar{y}_{....}\right)^2 \\
&+ \sum_{i,j,k,l}^{K} \left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right)^2 \\
= &\sum_{i}^{K} \sum_{j,k,l}^{K} \left(\bar{y}_{i...} - \bar{y}_{....}\right)^2 + \sum_{j}^{K} \sum_{i,k,l}^{K} \left(\bar{y}_{.j..} - \bar{y}_{....}\right)^2 + \sum_{k}^{K} \sum_{i,j,l}^{K} \left(\bar{y}_{..k.} - \bar{y}_{....}\right)^2 + \sum_{l}^{K} \sum_{i,j,k}^{K} \left(\bar{y}_{...l} - \bar{y}_{....}\right)^2 \\
&+ \sum_{i,j,k,l}^{K} \left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right)^2 \\
= &K \sum_{i}^{K} \left(\bar{y}_{i...} - \bar{y}_{....}\right)^2 + K \sum_{j}^{K} \left(\bar{y}_{.j..} - \bar{y}_{....}\right)^2 + K \sum_{k}^{K} \left(\bar{y}_{..k.} - \bar{y}_{....}\right)^2 + K \sum_{l}^{K} \left(\bar{y}_{...l} - \bar{y}_{....}\right)^2 \\
&+ \sum_{i,j,k,l}^{K} \left(y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....}\right)^2
\end{aligned}$$

If we denote as usual SSE as the sum of the squares of the deviations then we can rewrite our result in this form:

$$\text{SSE}_T=\text{SSE}_R+\text{SSE}_C+\text{SSE}_l+\text{SSE}_g+\text{SSE}_r \tag{5.7.2154}$$

where:

$$\begin{aligned}\text{SSE}_T&=\sum_{i=1}^{K}\sum_{j=1}^{K}\sum_{k=1}^{K}\sum_{l=1}^{K}\left(y_{ijkl}-\bar{y}_{....}\right)^2\\ \text{SSE}_R&=K\sum_{i}^{K}\left(\bar{y}_{i...}-\bar{y}_{....}\right)^2\\ \text{SSE}_C&=K\sum_{j}^{K}\left(\bar{y}_{.j..}-\bar{y}_{....}\right)^2\\ \text{SSE}_l&=K\sum_{k}^{K}\left(\bar{y}_{..k.}-\bar{y}_{....}\right)^2\\ \text{SSE}_g&=K\sum_{l}^{K}\left(\bar{y}_{...l}-\bar{y}_{....}\right)^2\end{aligned} \tag{5.7.2155}$$

and:

$$\text{SSE}_r=\sum_{i,j,k,l}^{K}\left(y_{ijkl}-\bar{y}_{i...}-\bar{y}_{.j..}-\bar{y}_{..k.}-\bar{y}_{...l}+3\bar{y}_{....}\right)^2=\text{SSE}_T-\text{SSE}_L-\text{SSE}_C-\text{SSE}_l-\text{SSE}_g \tag{5.7.2156}$$

With for degrees of freedom:

$$\text{df}_T=\text{df}_R+\text{df}_C+\text{df}_l+\text{df}_g+\text{df}_r$$

$$K^2-1=(K-1)+(K-1)+(K-1)+(K-1)+(K-1)\,(K-3)$$

The degree of freedom for the squares of the residual differences is obtained by posing:

$$K^2-1-[(K-1)+(K-1)+(K-1)+(K-1)]=(K-1)\,(K-3)$$

We then have the following ANOVA table:

Sum of squares (SSE)	χ^2 **df**	**Mean squares**	F	**Critical** F
$Q_R = K\sum_i^K (\bar{y}_{i...} - \bar{y}_{....})^2$ (rows)	$K-1$	$\text{MSk}R = \dfrac{Q_R}{K-1}$	$\dfrac{\text{MSk}R}{\text{MSE}}$	$P(F > F_{K-1,(K-1)(K-3)})$
$Q_C = K\sum_j (\bar{y}_{.j.} - \bar{y}_{...})^2$ (columns)	$K-1$	$\text{MSk}C = \dfrac{Q_C}{K-1}$	$\dfrac{\text{MSk}C}{\text{MSE}}$	$P(F > F_{K-1,(K-1)(K-3)})$
$Q_l = K\sum_k^K (\bar{y}_{..k.} - \bar{y}_{....})^2$ (latin letter)	$K-1$	$\text{MSk}l = \dfrac{\text{Q}_\text{l}}{K-1}$	$\dfrac{\text{MSk}l}{\text{MSE}}$	$P(F > F_{K-1,(K-1)(K-3)})$
$Q_g = K\sum_l^K (\bar{y}_{...l} - \bar{y}_{....})^2$ (greek letter)	$K-1$	$\text{MSk}g = \dfrac{Q_l}{K-1}$	$\dfrac{\text{MSk}g}{\text{MSE}}$	$P(F > F_{K-1,(K-1)(K-3)})$
$Q_r = \sum_{i,j,k,l}^K (y_{ijkl} - \bar{y}_{i...} - \bar{y}_{.j..} - \bar{y}_{..k.} - \bar{y}_{...l} + 3\bar{y}_{....})^2$ (residuals)	$(K-1)(K-3)$	$\text{MSE} = \dfrac{Q_r}{(K-1)(K-3)}$		
$Q_T = \sum_{i=1}^K\sum_{j=1}^K\sum_{k=1}^K\sum_{l=1}^K (y_{ijkl} - \bar{y}_{....})^2$ (total)	K^2-1	$\text{MSk}T = \dfrac{Q_T}{K^2-1}$		

Table 5.75: **Greaco-Latin square ANOVA table**

Notice that in the Graeco-Latin Square Design as in the Latin Square Design it is assumed that no interaction among the factors exist. This is an even stronger assumption in the Graeco-Latin Square Design because we have an additional factor and, hence, more possible interactions.

Remark

The factor effect model for this design is (purely additive!):

$$\boxed{y_{ijkl} = \mu + \theta_i + \tau_j + \omega_k + \phi_l + \varepsilon_{ijkl}} \tag{5.7.2157}$$

where $i, j, k, l = 1 \ldots N$ and where y_{ijkl} is the observation in the ith row, Latin letter j, Greek letter k, and lth column, μ is the overall mean, θ_i is the ith row effect, τ_j is the effect of the Latin letter j treatment, ω_k is the effect of Greek letter k, ϕ_l is the lth column effect, and ε_{ijkl} are i.i.d. $\mathcal{N}(0, \sigma_\varepsilon^2)$ errors. Notice that as for the Latin square design two subscripts suffice to identify an observation and 6×6 Graeco-Latin designs are impossible.

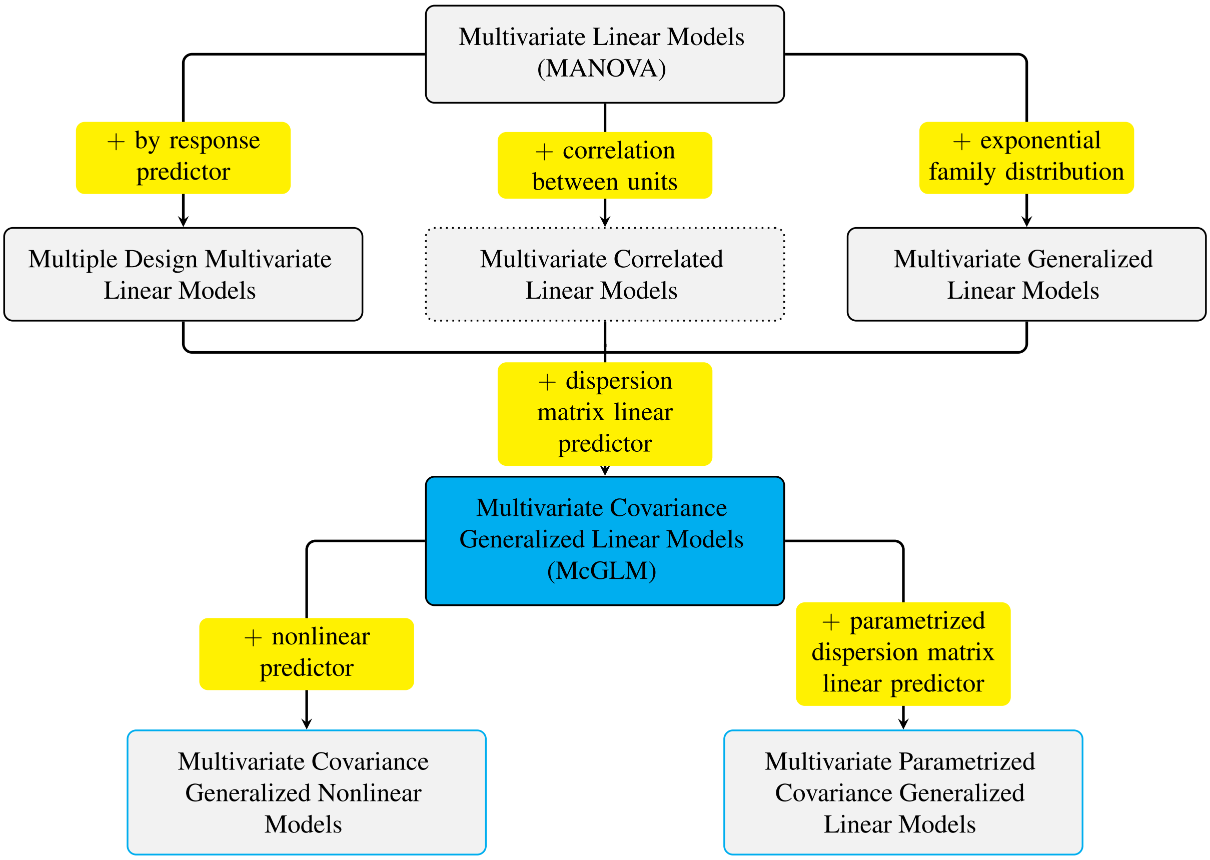
We are (mainly!) interested in testing for zero treatment effect, that is, $H_0 : \tau_1 = \tau_2 = \ldots = \tau_N = 0$ versus $H_1 : \tau_j \neq 0$.

Many softwares return only the first Fisher test (that for Q_R, i.e. the treatments) since the blocks of the Greaco-Latin design represent restrictions on randomization and that therefore the other tests may not be appropriate.

5.7.13.5.9 Multivariate ANOVA (MANOVA)

The "Multivariate Analysis of Variance" is an extension of ANOVA where we assume that the categorical variables are linearly dependent and we test whether there is a significant difference in the averages (variables supposed to be of the continuous type) through the different groups under the interdependence of the categorical explanatory variables.

Again, as for the ANOVA, the MANOVA and Multivariate Linear Models are the two facets of a same coin are the ground foundations of a more field of statistics as depicted in the flowchart below (actually in the book, only Multivariate Generalized Linear Models are treated in details in the section of Numerical Methods!):



Multivariate Linear Models (MANOVA)
+ by response predictor
+ correlation between units
+ exponential family distribution
Multiple Design Multivariate Linear Models
Multivariate Correlated Linear Models
Multivariate Generalized Linear Models
+ dispersion matrix linear predictor
Multivariate Covariance Generalized Linear Models (McGLM)
+ nonlinear predictor
+ parametrized dispersion matrix linear predictor
Multivariate Covariance Generalized Nonlinear Models
Multivariate Parametrized Covariance Generalized Linear Models

Figure 5.204: **Families of Multivariate Linear Models**

If it is not clear (...), the mathematical notation may be more explicit to the reader. Let us recall first that in the case of the canonical ANOVA with 1 fixed factor at k levels, the null hypothesis was of the form:

$$H_0:\ \bar{x}_1=\bar{x}_2=\ldots=\bar{x}_k \tag{5.7.2158}$$

For the one-way MANOVA, the null hypothesis is:

$$H_0:\ \vec{\mu}_1=\vec{\mu}_2=\vec{\mu}_3=\ldots=\vec{\mu}_k \tag{5.7.2159}$$

where we have therefore "mean vectors" for a given number of dependent group variables in a quantity k.

Thus explicitly for k groups and p categorical variables:

$$H_0 : \begin{pmatrix} \bar{x}_{11} \\ \bar{x}_{21} \\ \vdots \\ \bar{x}_{p1} \end{pmatrix} = \begin{pmatrix} \bar{x}_{12} \\ \bar{x}_{22} \\ \vdots \\ \bar{x}_{p2} \end{pmatrix} = \begin{pmatrix} \bar{x}_{13} \\ \bar{x}_{23} \\ \vdots \\ \bar{x}_{p3} \end{pmatrix} = \ldots = \begin{pmatrix} \bar{x}_{1k} \\ \bar{x}_{2k} \\ \vdots \\ \bar{x}_{pk} \end{pmatrix} \qquad (5.7.2160)$$

As the reader will see in the developments below, the one-way MANOVA has nine assumptions (hypothesis):

H1. Our two or more dependent variables should be measured at a continuous level (i.e., they are interval or ratio variables)

H2. Our independent variable should consist of two or more categorical, independent (unrelated) groups

H3. We should have independence of observations, which means that there is no relationship between the observations in each group or between the groups themselves

H4. We should have an adequate sample size. At least need to have more cases (e.g., participants) in each group of the independent variable than the number of dependent variables we are analysing

H5. There are no univariate or multivariate outliers. First, there can be no (univariate) outliers in each group of the independent variable for any of the dependent variables

H6. There is multivariate Normality

H7. There is a linear relationship between each pair of dependent variables for each group of the independent variable

H8. There is a homogeneity of variance-covariance matrices

H9. There is no multicollinearity

Let us now recall that in the one-factor ANOVA we compute the p-value of the ratio of the estimated variances assuming the true variances as equals:

$$F_{k-1,N-k} = \dfrac{\dfrac{Q_A}{k-1}}{\dfrac{Q_R}{N-k}} = \dfrac{\dfrac{\text{SSB}}{k-1}}{\dfrac{\text{SSA}}{N-k}} \qquad (5.7.2161)$$

The next step in understanding MANOVA is the recognition that mathematicians are lazy and sometimes do engineering statistics... So first we simplify this ratio by multiplying left and right by $(k-1)/(N-1)$. This gives what we name an "A-statistics":

$$A = \dfrac{k-1}{N-1} F_{k-1,N-k} = \dfrac{k-1}{N-1} \dfrac{\dfrac{\text{SSB}}{k-1}}{\dfrac{\text{SSA}}{N-k}} = \dfrac{\text{SSB}}{\text{SSW}} \qquad (5.7.2162)$$

But this is not enough as we are still with independent variables! So the idea is to used variance-covariance like matrix and to get a similar expression of as a ratio we take the determinant... This brings us to write a multivariate like Fisher test for variances (......):

$$\Lambda=\frac{\det(W)}{\det(T)}=\frac{\det(W)}{\det(B+W)} \tag{5.7.2163}$$

better known in the following form:

$$\boxed{\Lambda=\frac{|W|}{|B+W|}=\frac{|W|}{|T|}} \tag{5.7.2164}$$

where W and T are respectively the determinants of the square matrices of the sum of the squares of the within (W) and global (Total: T) deviations. Which means that if the part "within" (Between: B) is really large, then Λ tends to zero. In contrast, if B is very small, tends Λ tends to 1.

To prove that this ratio does not depend on the covariance matrix of the dependent variables, let us recall that considering the structure of W and $B+W$ we can make a spectral decomposition (see further below our study of principal component analysis) in the form:

$$\Lambda=\frac{|W|}{|B+W|}=\frac{|S||W||S^T|}{|S||B+W||S^T|}=\frac{|W|}{|B+W|} \tag{5.7.2165}$$

It can be demonstrated with some approximations that Λ follows a distribution named "Wilk's distribution" (of "Samuel Stanley Wilks").

It should be noted that Wilk's Λ can be expressed as a function of the eigenvalues of $W^{-1}B$. From the definition of Λ, it follows using the properties of the determinant (see section Linear Algebra page 1961) that:

$$\frac{1}{\Lambda}=\frac{|T|}{|W|}=\left|W^{-1}(W+B)\right|=\left|\mathbb{1}_p+W^{-1}B\right| \tag{5.7.2166}$$

We recognize here the determinant of the "eigenvalue equations" (see section Linear Algebra page 1998) on $W^{-1}B$ but with $\lambda=1$. Indeed:

$$\det(A-\lambda I_n)=\prod_{i=1}^{n}(\lambda_i-\lambda) \tag{5.7.2167}$$

So in our case here we have $\lambda=-1$ therefore:

$$\det(A-\lambda I_n)=\prod_{i=1}^{n}(\lambda_i+1) \tag{5.7.2168}$$

Therefore:

$$\frac{1}{\Lambda}=\frac{|T|}{|W|}=\prod_{i=1}^{k}(1+\lambda_i) \tag{5.7.2169}$$

and consequently:

$$\Lambda=\frac{1}{\prod\limits_{i=1}^{k}(1+\lambda_i)}=\prod_{i=1}^{k}\frac{1}{1+\lambda_i} \qquad (5.7.2170)$$

Also, it follows that:

$$\ln(\Lambda)=\ln\left(\frac{1}{\prod\limits_{i=1}^{k}(1+\lambda_i)}\right)=-\sum_{i=1}^{k}(1+\lambda_i) \qquad (5.7.2171)$$

When Wilk's Λ approaches 1, we showed that it means that the difference in means is negligible. This is the case when $\ln(\Lambda)$ approaches 0. However, when Λ approaches 0 or $\ln(\Lambda)$ approaches 1, it means that the difference is large. Therefore, a large value of $\ln(\Lambda)$ (i.e., close to 0) is an indication of the significance of the difference between the means.

Remark

The bad news is that there are in fact four different multivariate tests that are made from the above relation. The reason for four different statistics and four approximations is that the mathematics of MANOVA get so complicated in some cases that no one has ever been able to solve them as far as we know...

Let us see now a companion detailed example:

✍**Example:**

We consider the following set of two dependent variables on three groups of independent variables:

K_1		K_2		K_3	
x_1	x_2	x_1	x_2	x_1	x_2
2	3	4	8	7	6
3	4	5	6	8	7
5	4	6	7	10	8
2	5			9	5
				7	6
$\bar{x}_{11}=3$	$\bar{x}_{21}=4$	$\bar{x}_{12}=5$	$\bar{x}_{22}=7$	$\bar{x}_{13}=8.2$	$\bar{x}_{23}=6.4$

with:

$$\bar{x}_1=\frac{3+5+8.2}{3}=5.4 \qquad \bar{x}_2=\frac{4+7+6.4}{3}=5.8 \qquad (5.7.2172)$$

Now we calculate:

$$W=W_1+W_2+W_3=\begin{bmatrix}\text{SSE}_1 & \text{SSE}_{12}\\ \text{SSE}_{12} & \text{SSE}_2\end{bmatrix}+\begin{bmatrix}\text{SSE}_1 & \text{SSE}_1\\ \text{SSE}_{22} & \text{SSE}_2\end{bmatrix}+\begin{bmatrix}\text{SSE}_1 & \text{SSE}_{32}\\ \text{SSE}_{32} & \text{SSE}_2\end{bmatrix} \qquad (5.7.2173)$$

We then have for example for the first group:

$$\text{SSE}_i = \sum_{j=1}^{n}(x_{ij} - \bar{x}_{i1})^2 : \begin{cases} \text{SSE}_1 = \sum_{j=1}^{n}(x_{1j} - \bar{x}_{11})^2 \\ \text{SSE}_2 = \sum_{j=1}^{n}(x_{2j} - \bar{x}_{21})^2 \end{cases}$$
$$\text{SSE}_{ij} = \text{SSE}_{ji} = \sum_{j=1}^{n}(x_{ij} - \bar{x}_{11})(x_{2j} - \bar{x}_{21}) \qquad (5.7.2174)$$

Which gives us in our case (very easy to check with any spreadsheet software):

$$W = \begin{bmatrix} 6 & 0 \\ 0 & 2 \end{bmatrix} + \begin{bmatrix} 2 & -1 \\ -1 & 2 \end{bmatrix} + \begin{bmatrix} 6.8 & 2.6 \\ 2.6 & 5.2 \end{bmatrix} = \begin{bmatrix} 14.8 & 1.6 \\ 1.6 & 9.2 \end{bmatrix} \qquad (5.7.2175)$$

And we have (we notice that we assume that over all the x_1 and x_2 the number of measurement are $N_1 = N_2 = N$):

$$T = B + W = \begin{bmatrix} \sum_{i=1}^{N}(x_{i1} - \bar{x}_1)^2 & \sum_{i=1}^{N}(x_{i1} - \bar{x}_1)(x_{i2} - \bar{x}_2) \\ \sum_{i=1}^{N}(x_{i1} - \bar{x}_1)(x_{i2} - \bar{x}_2) & \sum_{i=1}^{N}(x_{i2} - \bar{x}_2)^2 \end{bmatrix} = \begin{bmatrix} 76.72 & 26.00 \\ 26.00 & 28.25 \end{bmatrix} \qquad (5.7.2176)$$

and therefore:

$$\Lambda = \frac{|W|}{|T|} = \frac{\begin{vmatrix} 14.8 & 1.6 \\ 1.6 & 9.2 \end{vmatrix}}{\begin{vmatrix} 76.72 & 26.00 \\ 26.00 & 28.25 \end{vmatrix}} = 0.0897 \qquad (5.7.2177)$$

After the calculation of the p-value is more delicate and we will ask the reader to refer to the Minitab or `R` companion books for the computational details and the final conclusion.

So we could use a one-way MANOVA to determine whether students' short-term and long-term recall of facts differed based on three different lengths of lecture (i.e., the two dependent variables are "short-term memory recall" and "long-term memory recall", whilst the independent variable is "lecture duration", which has four independent groups: "30 minutes", "60 minutes", "90 minutes" and "120 minutes"). Alternately, a one-way MANOVA could be used to determine whether there is a difference in salary and bonuses based on degree type (i.e., the two dependent variables are "salary" and "bonuses", whilst the independent variable is "degree type", which has five groups: "business studies", "psychology", "biological sciences", "engineering" and "law").

When there is a statistically significant difference between the groups of the independent variable, it is possible to determine which specific groups were significantly different from each other using post hoc tests. You need to conduct these post hoc tests because the one-way MANOVA is an omnibus[82] test statistic and cannot tell you which specific groups were significantly different from each other; it only tells you that at least two groups were different.

---

[82] "omnibus" derives from the Latin word "for all". In plain language, you can interpret an omnibus test or omnibus statistic like an "overall test" - it is testing a number of things at once.

5.7.13.5.9.1 Hotelling's T-squared Test

The "Hotelling's T-squared test" (Hotelling, 11931 according to holocene calendar) is the multivariate counterpart of the T-test. For example, let's say we wanted to compare how well two different sets of students performed in school. We could compare univariate data (e.g. mean test scores) with a T-test. Or, we could use Hotelling's T-squared to compare multivariate data (e.g. the multivariate mean of test scores, GPA, and class grades).

Hotelling's T-squared test is based on Hotelling's T^2 distribution and forms the basis for various multivariate control charts in Industrial Engineering. As the reader will understand it at then end of the development presented below, Hotelling's T-squared test is simply a special case of MANOVA, in which only two batches (groups) are compared!

More technically speaking Hotelling's T^2 test makes it possible to analyse whether the measures of random variables supposed to jointly follow a multivariate Normal law and therefore having a possible correlation (variance-covariance matrix) deviate considerably from Normality or not.

To introduce this test, let us recall that we have demonstrated in the section of Statistics that the Multivariate Normal law could be written:

$$f\left(X_1,X_2\right)=\frac{1}{2\pi|\Sigma|^{1/2}}\exp\left(-\frac{1}{2}\overrightarrow{(x-\mu)}^T\Sigma^{-1}\overrightarrow{(x-\mu)}\right) \tag{5.7.2178}$$

We see that the following term in the parenthesis:

$$D=\overrightarrow{(x-\mu)}^T\Sigma^{-1}\overrightarrow{(x-\mu)} \tag{5.7.2179}$$

giving a scalar can be seen as the unique random variable of the bivariate distribution (as we can do with the square of the random variable in the reduced centered univariate Normal law). So for a given value of D, we are "at a certain height" of the multidimensional Gaussian distribution.

What will interest us here is that when we work with a multivariate distribution some variables have less weight than others because of their large standard deviation and the correlated variables tend to reduce the amplitude Y.

Therefore, a very interesting subject in industrial practice (Hotelling control card and regressions) is then to know that it is the distribution law which describes:

$$D=\overrightarrow{(x-\mu)}^T\Sigma^{-1}\overrightarrow{(x-\mu)} \tag{5.7.2180}$$

So let us deal now with this topic!

The "Mahalanobis distance" between two points $\vec{x}$ and $\vec{y}$ is defined as

$$d(\vec{x},\vec{y})=\sqrt{(\vec{x}-\vec{y})^\top\Sigma^{-1}(\vec{x}-\vec{y})} \tag{5.7.2181}$$

Thus, the squared Mahalanobis distance of a random vector $\vec{x}=\mathcal{N}(\vec{\mu},\Sigma)$ and the center $\vec{\mu}$ of a multivariate Gaussian distribution is defined as:

$$D=d(\vec{x},\vec{\mu})^2=(\vec{x}-\vec{\mu})^T\Sigma^{-1}(\vec{x}-\vec{\mu}) \tag{5.7.2182}$$

where Σ is a $n \times n$ covariance matrix and $\vec{\mu}$ is the mean vector. In order to achieve a different representation of D one can first perform an eigenvalue decomposition on Σ^{-1} which is with (see section Linear Algebra page 2023):

$$\Sigma^{-1} = U\Lambda^{-1}U^{-1} = U\Lambda^{-1}U^{T} = \sum_{k=1}^{n} \lambda_k^{-1}\vec{u}_k\vec{u}_k^{T} \tag{5.7.2183}$$

where for recall $\vec{u}_k$ is the kth eigenvector of the corresponding eigenvalue λ_k. Plugging the above relation back into:

$$D = d(\vec{x},\vec{\mu})^2 = (\vec{x}-\vec{\mu})^T\Sigma^{-1}(\vec{x}-\vec{\mu}) \tag{5.7.2184}$$

results in:

$$\begin{aligned} D &= (\vec{x}-\vec{\mu})^T\Sigma^{-1}(\vec{x}-\vec{\mu}) \\ &= (\vec{x}-\vec{\mu})^T\left(\sum_{k=1}^{n}\lambda_k^{-1}\vec{u}_k\vec{u}_k^{T}\right)(\vec{x}-\vec{\mu}) \\ &= \sum_{k=1}^{n}\lambda_k^{-1}(\vec{x}-\vec{\mu})^T\vec{u}_k\vec{u}_k^{T}(\vec{x}-\vec{\mu}) \end{aligned} \tag{5.7.2185}$$

Using the properties of transposed (see section Linear Algebra page 1951) matrices we get:

$$D = \sum_{k=1}^{n}\lambda_k^{-1}\left[\vec{u}_k^{T}(\vec{x}-\vec{\mu})\right]^2 = \sum_{k=1}^{n}\left[\lambda_k^{-\frac{1}{2}}\vec{u}_k^{T}(\vec{x}-\vec{\mu})\right]^2 = \sum_{k=1}^{n}Y_k^2 \tag{5.7.2186}$$

where Y_k is a new random variable based on an affine linear transform of the random vector $\vec{x}$. Indeed, we have:

$$Z = (\vec{x}-\vec{\mu}) = \mathcal{N}(\vec{0},\Sigma) \tag{5.7.2187}$$

If we set:

$$\vec{a}_k^{T} := \lambda_k^{-1/2}\vec{u}_k^{T} \tag{5.7.2188}$$

then we get:

$$Y_k = \lambda_k^{-\frac{1}{2}}\vec{u}_k^{T}(\vec{x}-\vec{\mu}) = \lambda_k^{-1/2}\vec{u}_k^{T}Z = \vec{a}_k^{T}Z \tag{5.7.2189}$$

We can the say that Y_k is the result of an affine transformation of Z.

Note that Y_k is now a random variable drawn from a univariate Normal distribution $Y_k = \mathcal{N}\left(0,\sigma_k^2\right)$, where, according to:

$$\begin{aligned} \Sigma_y &= \mathrm{E}\left\{(\vec{y}-\vec{\mu}_y)(\vec{y}-\vec{\mu}_y)^T\right\} \\ &= \mathrm{E}\left\{\left[(A\vec{x}+\vec{b})-\left(A\vec{\mu}_x+\vec{b}\right)\right]\left[(A\vec{x}+\vec{b})-\left(A\vec{\mu}_x+\vec{b}\right)\right]^T\right\} \\ &= \mathrm{E}\left\{\left[A\left(\vec{x}-\vec{\mu}_x\right)\right]\left[A\left(\vec{x}-\vec{\mu}_x\right)\right]^T\right\} = \mathrm{E}\left\{A\left(\vec{x}-\vec{\mu}_x\right)\left(\vec{x}-\vec{\mu}_x\right)^T A^T\right\} \\ &= A\mathrm{E}\left\{\left(\vec{x}-\vec{\mu}_x\right)\left(\vec{x}-\vec{\mu}_x\right)^T\right\}A^T = A\mathbf{\Sigma}_x A^T \end{aligned} \tag{5.7.2190}$$

Therefore we get:

$$\sigma_k^2=\vec{a}_k^T\Sigma\vec{a}_k=\lambda_k^{-1/2}\vec{u}_k^T\Sigma\lambda_k^{-1/2}\vec{u}_k=\lambda_k^{-1}\vec{u}_k^T\Sigma\vec{u}_k \tag{5.7.2191}$$

If we insert into that last relation the following one:

$$\Sigma=\sum_{j=1}^{n}\lambda_j\vec{u}_j\vec{u}_j^T \tag{5.7.2192}$$

we get:

$$\begin{aligned}\sigma_k^2&=\lambda_k^{-1}\vec{u}_k^T\Sigma\vec{u}_k=\lambda_k^{-1}\vec{u}_k^T\left(\sum_{j=1}^{n}\lambda_j\vec{u}_j\vec{u}_j^T\right)\vec{u}_k\\&=\sum_{j=1}^{n}\lambda_k^{-1}\vec{u}_k^T\lambda_j\vec{u}_j\vec{u}_j^T\vec{u}_k=\sum_{j=1}^{n}\lambda_k^{-1}\lambda_j\vec{u}_k^T\vec{u}_j\vec{u}_j^T\vec{u}_k\end{aligned} \tag{5.7.2193}$$

since all eigenvectors $\vec{u}_i$ are pairwise orthonormal the dotted products $\vec{u}_k^T\vec{u}_j$ and $\vec{u}_j^T\vec{u}_k$ will be zero for $j\neq k$. Only for the case $j=k$ we get:

$$\begin{aligned}\sigma_k^2&=\lambda_k^{-1}\lambda_k\vec{u}_k^T\vec{u}_k\vec{u}_k^T\vec{u}_k\\&=\lambda_k^{-1}\lambda_k\|\vec{u}_k\|^2\|\vec{u}_k\|^2\\&=\lambda_k^{-1}\lambda_k\|\vec{u}_k\|^2\|\vec{u}_k\|^2\\&=1\end{aligned} \tag{5.7.2194}$$

since the norm $\|\vec{u}_k\|$ of a orthonormal eigenvector is equal to 1. The squared Mahalanobis distance can then be expressed as:

$$D=d(\vec{x},\vec{\mu})^2=(\vec{x}-\vec{\mu})^T\Sigma^{-1}(\vec{x}-\vec{\mu})=\sum_{k=1}^{n}Y_k^2=\sum_{k=1}^{n}(\mathcal{N}(0,1))^2 \tag{5.7.2195}$$

Now the Chi-square distribution with n degrees of freedom is exactly defined as being the distribution of a variable which is the sum of the squares of n random variables being standard normally distributed. Hence, D is Chi-square distributed with n degrees of freedom.

So if the random variables are really jointly Normally distributed according to a correlation matrix Σ we then have:

$$\boxed{T^2=(\vec{x}-\vec{\mu})^T\Sigma^{-1}(\vec{x}-\vec{\mu})=\sum_{k=1}^{n}(\mathcal{N}(0,1))^2=\chi_n^2} \tag{5.7.2196}$$

which is named the "Hotelling T^2 statistics".

Then to a given confidence threshold we then have:

$$P\left((\vec{x}-\vec{\mu})^T\Sigma^{-1}(\vec{x}-\vec{\mu})\leq\chi_{n-1}^2\right) \tag{5.7.2197}$$

that is the probability associated with a certain height (isocline) in the special case of the Normal bivariate distribution. So each quantile of the χ^2 law corresponds for example in the bivariate special case to an elliptical isocline in the general case (when seen from above) or to a circle when the correlation is zero.

So here what we are testing is:

$$H_0 : \begin{pmatrix} \mu_{11} \\ \mu_{12} \\ \vdots \\ \mu_{1p} \end{pmatrix} = \begin{pmatrix} \mu_{21} \\ \mu_{22} \\ \vdots \\ \mu_{2p} \end{pmatrix} \text{ against } H_1 : \begin{pmatrix} \mu_{11} \\ \mu_{12} \\ \vdots \\ \mu_{1p} \end{pmatrix} \neq \begin{pmatrix} \mu_{21} \\ \mu_{22} \\ \vdots \\ \mu_{2p} \end{pmatrix}$$

Or, in other words:

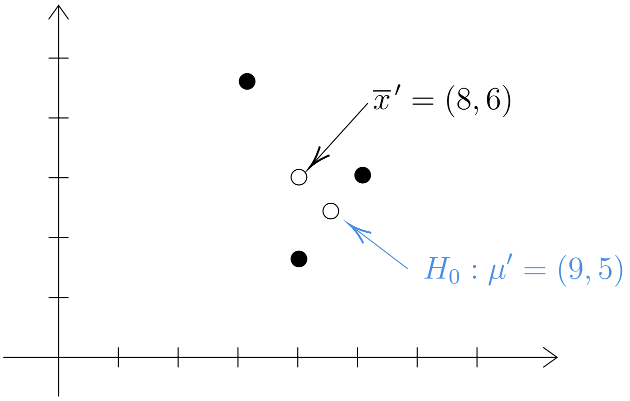
$$H_0 : \mu_{11} = \mu_{21} \text{ and } \mu_{12} = \mu_{22} \text{ and } \ldots \text{ and } \mu_{1p} = \mu_{2p}$$

For the null hypothesis, that is fine only if the population means are identical for all of the variables. The alternative is that at least one pair of these means is different. This is expressed below:

$$H_1 : \mu_{1k} \neq \mu_{2k} \text{ for at least one } k \in \{1, 2, \cdots, p\}$$

✍**Example:**

Consider:



The data are given by:

$$X = \begin{pmatrix} 6 & 9 \\ 10 & 6 \\ 8 & 3 \end{pmatrix} \tag{5.7.2198}$$

and the null hypothesis will be:

$$H_0 : \quad \vec{\mu}_0 = \begin{pmatrix} 9 \\ 5 \end{pmatrix} \tag{5.7.2199}$$

Assuming data come from a multivariate Normal distribution and independent observations (don't forget that S is the traditional notation for the estimate of Σ):

$$\vec{\bar{x}}=\begin{pmatrix}8\\6\end{pmatrix}\quad S=\begin{pmatrix}4&-3\\-3&9\end{pmatrix}\tag{5.7.2200}$$

We have:

$$S^{-1}=\frac{1}{4(9)-(-3)(-3)}\begin{pmatrix}9&3\\3&4\end{pmatrix}=\begin{pmatrix}1/3&1/9\\1/9&4/27\end{pmatrix}\tag{5.7.2201}$$

Hence:

$$\begin{aligned}T^2&=\left(\vec{\bar{x}}-\vec{\mu}_0\right)'S^{-1}\left(\vec{\bar{x}}-\vec{\mu}_0\right)\\&=((8-9),(6-5))\begin{pmatrix}1/3&1/9\\1/9&4/27\end{pmatrix}\begin{pmatrix}(8-9)\\(6-5)\end{pmatrix}\\&=(-1,1)\begin{pmatrix}1/3&1/9\\1/9&4/27\end{pmatrix}\begin{pmatrix}-1\\1\end{pmatrix}=7/27\cong 0.259\end{aligned}\tag{5.7.2202}$$

The value we need for a threshold of 5% is:

$$\chi^2_{n,1-\alpha}=\chi^2_{2,1-5\%}=\chi^2_{2,95\%}\cong 5.991\tag{5.7.2203}$$

We can compare our T^2 to 5.991. We see already that we can't reject H_0 (see how close $\vec{\bar{x}}$ and $\vec{\mu}$ and in the figure).

Alternatively we could compute the p-value easily with any spreadsheet software. This lead us to a p-value of 0.878.

5.7.13.6 Equivalence Tests

As the reader will probably have understood it from the preceding paragraphs, hypotheses tests (NHST) applied to the search for differences between groups do not technically allow us to conclude an equivalence simply because we do not reject the null hypothesis H_0. Yet we also showed that if the power of the test was typically above 80% it did not make a problem to consider the null hypothesis H_0 as true but the problem is that for this we need most of times to consider large samples and in practice this is not always feasible and it can also lead to absurdities since the maths show that with large samples we almost systematically reject the null hypothesis H_0.

The p-value can be used only to statistically reveal a posteriori the rejection of the null hypothesis H_0 in the vast majority of cases. To summarize this problem: «*The absence of evidence, does not imply evidence of absence*». Expressed in other words in a very common case this gives (particular example!) that the non-rejection of the null hypothesis H_0 of equality of two means (for example) does not imply the equality of means!!!

Remark

Some people quite often state wrongly that « *Absence of evidence is NOT evidence of absence.*» Why do they do that? Perhaps because they do not know better? And with the proof below they get the possibility of knowing for sure that "Absence of evidence IS evidence of absence!" and nothing else....

Definitions:

D1. A is evidence of B: $P(B\mid A)>P(B\mid\neg A)$

D2. Absence of evidence: $a=\neg A$

D3. Absence $b=\neg B$

$$\begin{gathered}P(B\mid A)>P(B\mid\neg A)\quad\Leftrightarrow\quad 1-P(\neg B\mid A)>1-P(\neg B\mid\neg A)\\ \Downarrow\\ P(\neg B\mid\neg A)>P(\neg B\mid\neg\neg A)\quad\Leftrightarrow\quad P(\neg B\mid A)<P(\neg B\mid\neg A)\\ \Downarrow\\ P(b\mid a)>P(b\mid\neg a)\end{gathered}\tag{5.7.2204}$$

■ Q.E.D.

An absence of evidence can be evidence of absence when we can reasonably expect evidence to exist (see further below the bayesian approach that confirms this conclusion)!

With the advent of generic medicines from the 11960s (holocene calendar) in the pharmaceutical field, the importance of highlighting equivalences (we are talking instead of "bioequivalences") has taken a growing place and organizations like the F.D.A. (Federal Drug Administration in U.S.A.), EMA (European Medicines Agency) or WHO (World Health Organization) have common guidelines that lead to the approval of generic only if the equivalence is shown under certain empirical conditions but at least standardized according to a consensus of experts.

Thus, most often the following three conditions are required[83]:

1. A comparison criterion is required
2. A confidence interval is required
3. An a priori limit of bioequivalence is required

Let us see a companion example to grasp the concept:

✍**Example:**

Let us consider the Student's T test of the difference of the averages of two unpaired samples $\{$Test, Reference$\}$ which we had demonstrated above:

$$T_{\alpha/2,n_1+n_2-2}=\frac{(\bar{X}_T-\bar{X}_R)-(\mu_T-\mu_R)}{\hat{\sigma}_D\sqrt{\dfrac{1}{n_1}+\dfrac{1}{n_2}}} \tag{5.7.2205}$$

We then know the following two bounds of the confidence interval:

$$\begin{aligned}\text{LCL}&=(\bar{X}_T-\bar{X}_T)-T_{\alpha/2,n_1+n_2-2}\hat{\sigma}_D\sqrt{\frac{1}{n_1}+\frac{1}{n_2}}\\ \text{UCL}&=(\bar{X}_T-\bar{X}_T)+T_{\alpha/2,n_1+n_2-2}\hat{\sigma}_D\sqrt{\frac{1}{n_1}+\frac{1}{n_2}}\end{aligned} \tag{5.7.2206}$$

Remark

We recognize here a special case of "TOST" test for "Two-One Sided Test" seen earlier.

We will assume that the F.D.A. request:

$$\begin{aligned}\text{LSL}&=-0.2\mu_R\\ \text{USL}&=+0.2\mu_R\\ \delta_L&=80\%\\ \delta_U&=120\%\end{aligned} \tag{5.7.2207}$$

Consider that the measurement have given us:

$$\begin{aligned}\bar{X}_T&=80.272\\ \bar{X}_R&=82.559\\ n_1&=n_2=12\\ T_{\alpha/2,n_1+n_2-2}&=T_{5\%,22}=1.717\\ \hat{\sigma}_D&=9.145\end{aligned} \tag{5.7.2208}$$

Therefore, we have the equivalence limits that will be:

$$\left.\begin{aligned}\text{LSL}&=-0.2\mu_R\\ \text{USL}&=+0.2\mu_R\end{aligned}\right\}=0.2\cdot 82.559\cong\pm 16.61 \tag{5.7.2209}$$

---

[83] Still by respecting the scientific publication rules introduced at the beginning of this textbook

The confidence intervals are given by:

$$(80.272 - 82.559) \pm 1.717 \cdot 9.145\sqrt{0.167} \qquad (5.7.2210)$$

Therefore:

$$(\text{LCL}, \text{UCL}) = (-8.698, 4.123) \qquad (5.7.2211)$$

As we have:

$$(\text{LCL}, \text{UCL}) \subset (\text{LSL}, \text{USL}) \qquad (5.7.2212)$$

The equivalence is then considered by experts consensus as "proven".

Now let us come back to the « *Absence of evidence is NOT evidence of absence.*» based on a bayesian approach.

There's a difference between not looking and therefore not seeing any X, and looking and not seeing any X. The latter is 'evidence', the former is not.

So the hypothesis under test is «*There is a unicorn in that field behind the hill.*» Alice stays where she is and doesn't look. If there is a unicorn in the field, Alice sees no unicorns. If there is no unicorn in the field, Alice sees no unicorns. $P(\text{sees no unicorn} \mid \text{is unicorn}) = P(\text{sees no unicorn} \mid \text{no unicorn}) = 1$. When the hypothesis makes no difference to the observation, the 'evidence' contributed by the observation to belief in the hypothesis is zero.

Bob climbs to the top of the hill and looks down on the field, and sees no unicorn. If there is a unicorn in the field, Bob would see it. If there is no unicorn in the field, Bob would see no unicorn. $P(\text{sees no unicorn} \mid \text{is unicorn}) \neq P(\text{sees no unicorn} \mid \text{no unicorn})$. When the hypothesis being true or false changes the probability of the observation, evidence is contributed. Looking and seeing no unicorns in the field is positive evidence that there are no unicorns in the field.

We can quantify evidence using Bayesian probability:

$$\begin{aligned} P(H_1 \mid O) &= \frac{P(O \mid H_1)\,P(H_1)}{P(O)} \\ P(H_2 \mid O) &= \frac{P(O \mid H_2)\,P(H_2)}{P(O)} \end{aligned} \qquad (5.7.2213)$$

where H_1 is «*there is no unicorn in that field*». H_2 is «*there is a unicorn in that field*», and O is «*I see no unicorn*». Divide one by the other:

$$\frac{P(H_1 \mid O)}{P(H_2 \mid O)} = \frac{P(O \mid H_1)}{P(O \mid H_2)}\frac{P(H_1)}{P(H_2)} \qquad (5.7.2214)$$

Take logarithms to make the multiplication additive:

$$\log\left(\frac{P(H_1 \mid O)}{P(H_2 \mid O)}\right) = \log\left(\frac{P(O \mid H_1)}{P(O \mid H_2)}\right) + \log\left(\frac{P(H_1)}{P(H_2)}\right) \qquad (5.7.2215)$$

We interpret this as saying that the Bayesian belief in favour of H_1 over H_2 after the observation is equal to the evidence in favour of H_1 over H_2 arising from the observation plus the Bayesian belief in favour of H_1 over H_2 before the observation. The additive evidence arising from the experiment is quantified as:

$$\log\left(\frac{P\left(O \mid H_1\right)}{P\left(O \mid H_2\right)}\right) \tag{5.7.2216}$$

The dictum is based on people claiming things like that there are no unicorns in the universe based on having looked at only a tiny portion of it and having seen none. Strictly speaking, there is non-zero evidence arising from this, but it's near zero, being related to the log of the volume of space and time searched divided by the volume of the universe.

Distilled to a sentence: absence of evidence is evidence of absence, but the strength of that evidence depends on how strong your test is (how likely it would be to succeed if the thing did exist).

5.7.13.7 Cochran C-test

The Cochran C-test has for purpose to verify the homogeneity of variances for several populations. This is a preliminary or subsequent test (post hoc) helpful test to do before making a balanced ANOVA (balanced) analysis and is recommended by the standard ISO 5725 (as the Tukey's test that we will see much further at page 1207) !

Although the idea of the Cochran C-test is empirical, it is nevertheless intuitive as are the definitions of Dixon and Grubbs tests. Why then do we present in this textbook in details the proof of the Cochran C-test when we have mentioned that we would not do this for the test of Grubbs and Dixon because the approach of these latter was also empirical? The reason is simple in fact: the test of Grubbs and Dixon require, at least as far as we know, Monte Carlo simulations to determine the critical values of rejection or acceptance of the null hypothesis, while the critical value of Cochran C-test can be obtained relatively easily analytically.

That said ... we define the Cochran C-test by the ratio:

$$C_j=\frac{S_j^2}{\displaystyle\sum_{i=1}^{N} S_i^2} \tag{5.7.2217}$$

where the S_i are the unbiased variances of the N different sources of data, each composed of n samples and the null hypothesis is intuitively the equality of variances against the alternative hypothesis that one of the variance is too big (that is to say: bad) and dismissed because considered as an outlier variance.

The ISO 5725 recommends to repeat this test until there is no longer any aberrant variance (therefore too large AND far from other variances).

To determine the critical value, let us invert the definition of Cochran C-test and do some basic algebraic manipulations:

$$C_j^{-1}=\frac{\displaystyle\sum_{i=1}^{N} S_i^2}{S_j^2}=\frac{S_j^2+\left(\displaystyle\sum_{i=1}^{N} S_i^2-S_j^2\right)}{S_j^2}=1+\frac{\displaystyle\sum_{i=1,i\neq j}^{N} S_i^2}{S_j^2} \tag{5.7.2218}$$

We note that pretty much the second term of the last equality looks like a Fisher law. As the Fisher law is not stable by the addition, we should find a way to turn the term:

$$\sum_{i=1,i\neq j}^{N} S_i^2 \tag{5.7.2219}$$

into a single variance. The idea is then relatively simple but still had someone to think about it... We know the S_i are non-biased variances equation with a factor $1/(n-1)$. Therefore if the N samples (levels) are independent, the overall variance is then by stability of the Normal distribution and by taking the traditional notations of the ANOVA:

$$\begin{aligned}S^2_{\text{global}-j} &= \frac{1}{N-1}\sum_{i=1,i\neq j}^{N} S_i^2 = \frac{1}{N-1}\sum_{i=1,i\neq j}^{N}\frac{Q_i}{n-1} = \frac{1}{(N-1)(n-1)}\sum_{i=1,i\neq j}^{N} Q_i\\ &= \frac{1}{(N-1)(n-1)}Q_{\text{global}-j} = \frac{Q_{\text{global}-j}}{(N-1)(n-1)}\end{aligned} \tag{5.7.2220}$$

Therefore:

$$C_j^{-1} = 1+\frac{\frac{N-1}{N-1}\displaystyle\sum_{i=1}^{N} S_i^2}{S_j^2} = 1+(N-1)\frac{\frac{1}{N-1}\displaystyle\sum_{i=1}^{N} S_i^2}{S_j^2} = 1+(N-1)\frac{\frac{Q_{\text{global}-j}}{(N-1)(n-1)}}{\frac{Q_j}{n-1}} \tag{5.7.2221}$$

We recognize in the last equality the ratio of two squared variances. We then have identically to what we've proved in our study of the one-way fixed factor ANOVA without replication:

$$F_{n-1,(N-1)(n-1)} = \frac{S_j^2}{S^2_{\text{global}-j}} = \frac{\frac{Q_j}{n-1}}{Q_{\text{global}-j}}(N-1)(n-1) \tag{5.7.2222}$$

and therefore it comes:

$$C_j^{-1} = 1+\frac{N-1}{F_{n-1,(N-1)(n-1)}} \tag{5.7.2223}$$

which is therefore independent of j and therefore the left-tail Cochran' C-test (since by definition the Cochran's ratio should be as small as possible) will have for critical value:

$$C(\alpha,N,n) = \left(1+\frac{N-1}{F_{n-1,(N-1)(n-1)}}\right)^{-1} \tag{5.7.2224}$$

If we consider a test with a significance level of $1-\alpha$ (thus corresponding to the cumulative probability of not making a Type I error) and we reiterate it independently again as second time. Then, if the tests are independent, following the axiom of probabilities, the probability of not making a Type I error will be given by the product of probabilities:

$$(1-\alpha)(1-\alpha) = (1-\alpha)^2 \tag{5.7.2225}$$

and so on for n tests. We notice so quickly that the cumulative probability of not making a Type I error decreases very quickly. For example, for 10 independent repeated tests with a 5% level, then we have:

$$(1-\alpha)^n = (1-5\%)^{10} \cong 59\% \tag{5.7.2226}$$

which is catastrophic! So if we want a level of confidence on repeated tests of a certain value which we will denote α_r, it is clear that we must solve the following equation:

$$(1-\alpha)^n=(1-\alpha_r) \quad (5.7.2227)$$

Therefore (relation sometimes named "Šidàk equation"):

$$\alpha=1-(1-\alpha_r)^{1/n}=1-\frac{1}{(1-\alpha_r)^n} \quad (5.7.2228)$$

and with a Taylor expansion to the second order it comes (see section Sequences and Series page 1696):

$$\alpha=1-(1-\alpha_r)^{1/n}\cong 1-(1-n\alpha_r)=n\alpha_r \quad (5.7.2229)$$

that we name "Bonferroni approximation" or sometimes also "Boole approximation" or "Dunn approximation".

Remark

In statistics, "family-wise error rate" (FWER) is the probability of making one or more false discoveries, or type I errors when performing multiple hypotheses tests (typically during meta-analysis).

So in the end, we have for the Cochran C-test:

$$C(\alpha,N,n)=\left(1+\frac{N-1}{F_{\alpha/N,n-1,(N-1)(n-1)}}\right)^{-1} \quad (5.7.2230)$$

that we can compute with the English version of Microsoft® Excel® 14.0.6123 using the following formula:

```
=1/(1+(N-1)/FINV(ALPHA/N,n-1,(N-1)*(n-1)))
```

Remark

We benefit here from assuming that all tests are independent of each other. In practical applications, that is often not the case. Depending on the correlation structure of the tests, the Bonferroni correction could be extremely conservative, leading to a high rate of false negatives!!!

5.7.13.8 Family-wise error rate (adjusted p-values)

Definitions (#5.7.152):

D1. The "family-wise error rate" (FWER) (or "per-experiment error rate") is the probability of making any Type I errors at all (typically during meta-analysis).

D2. The "false discovery rate" (FDR) is the expected proportion of false rejections out of all rejections (typically also during meta-analysis).

Before doing the maths, let us recall the famous case of Nosek's team that invited researchers to take part in a crowd-sourcing data analysis project. The setup was simple. Participants were all given the same data set and prompt: Do soccer referees give more red cards to dark-skinned players than light-skinned ones? They were then asked to submit their analytical approach for feedback from other teams before diving into the analysis.

Twenty-nine teams with a total of 61 analysts took part. The researchers used a wide variety of methods, ranging - for those of you interested in the methodological gore - from simple linear regression techniques to complex multilevel regressions and Bayesian approaches. They also made different decisions about which secondary variables to use in their analyses.

Despite analysing the same data, the researchers got a variety of results. Twenty teams concluded that soccer referees gave more red cards to dark-skinned players, and nine teams found no significant relationship between skin color and red cards.

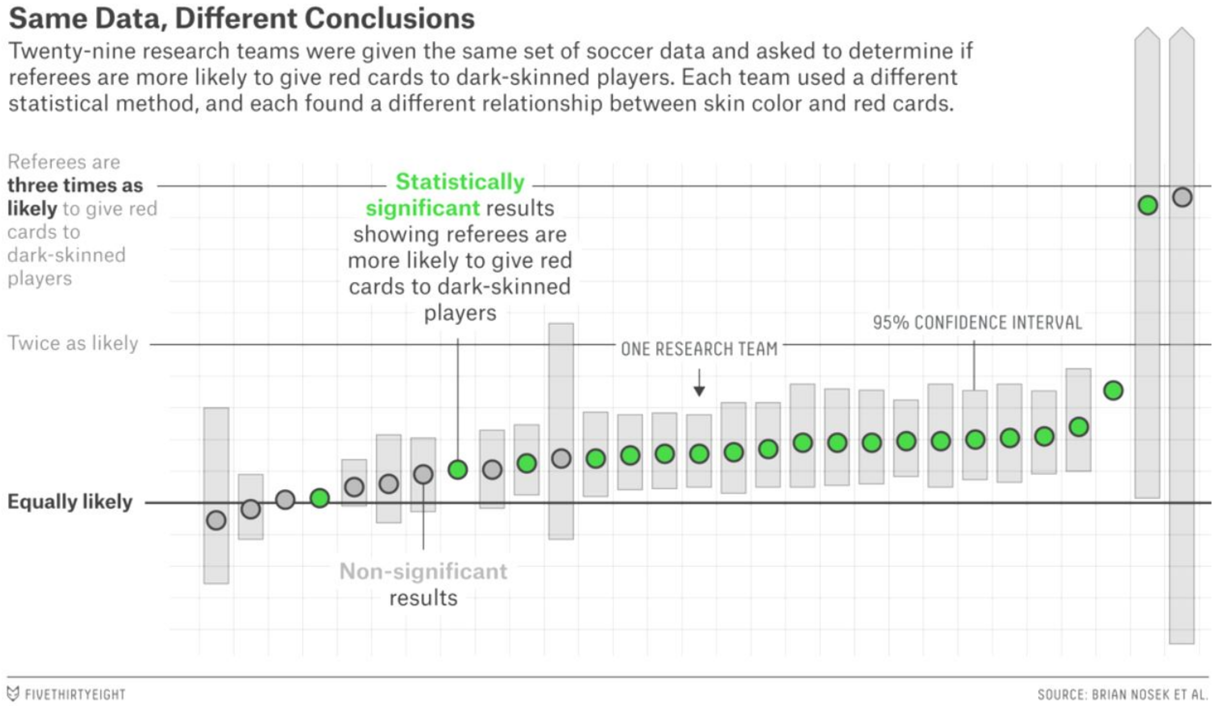


Figure 5.205: **Same data, different conclusions (purpose of meta-analysis)**

The variability in results wasn't due to fraud or sloppy work. These were highly competent analysts who were motivated to find the truth, said Eric Luis Uhlmann, a psychologist at the Insead business school in Singapore and one of the project leaders. Even the most skilled researchers must make subjective choices that have a huge impact on the result they find.

That's why knowing how to deal with multiple p-value is critical and especially when lives are concerned by the result (remember the meta-analysis for the influence of Hydroxychloroquine during the COVID-19 period in year 12020 according to holocene calendar).

The most commonly used method which controls FWER at level α is the Bonferroni's method seen just earlier above. Let us make some recall about that latter!

- The probability of making a Type I error when dealing only with a specific test is denoted $\alpha[\text{PT}]$ (pronounced "alpha per test"). It is also named the "testwise alpha".
- The probability of making at least one Type I error for the whole family of tests denoted $\alpha[\text{PF}]$ (pronounced "alpha per family of tests"). It is also named the "familywise alpha" or the "experimentwise alpha".

During our study of the Cochran C-test earlier above (see page 1105) we have seen that the Bonferroni correction for multiple tests was then written by (assuming independence!):

$$\boxed{\alpha[\text{PF}] = 1 - (1 - \alpha[\text{PT}])^n} \tag{5.7.2231}$$

where n is the number of tests.

Also during our study of the Cochran C-test above we have derived the following first order Taylor approximation:

$$\alpha[\text{PF}] \cong n\alpha[\text{PT}] \tag{5.7.2232}$$

The Šidàk-Bonferonni equations can be used to find the value of $\alpha[\text{PT}]$ when $\alpha[\text{PF}]$ is fixed. For example, suppose that we want to perform four independent tests, and we want to limit the risk of making at least one Type I error to an overall value of $\alpha[\text{PF}] = 0.05$, we will consider a test significant if its associated probability is smaller than (in the case of four associated tests):

$$\alpha[\text{PT}] = 1 - (1 - \alpha[\text{PF}])^{1/n} = 1 - (1 - 0.05)^{1/4} = 0.0127 \tag{5.7.2233}$$

With the Bonferonni approximation, a test reaches significance if its associated probability is smaller than:

$$\alpha[\text{PT}] = \frac{\alpha[\text{PF}]}{n} = \frac{0.05}{4} = 0.0125 \tag{5.7.2234}$$

Remark

Sometimes we may have:

$$\alpha[\text{PF}] \cong n\alpha[\text{PT}] > 1 \tag{5.7.2235}$$

This is why it is not uncommon in the literature to find that latter relation under the form:

$$\alpha[\text{PF}] \cong \{n\alpha[\text{PT}], 1\}_1 \tag{5.7.2236}$$

or:

$$\alpha[\text{PF}] \cong \min\{n\alpha[\text{PT}], 1\} \tag{5.7.2237}$$

that simply means that if $n\alpha[\text{PT}] > 1$, then we replace it by 1.

✍**Example:**

Consider four null hypotheses $H_1, \ldots, H_4$ with p-values:

$$p_1 = 0.01, p_2 = 0.04, p_3 = 0.03, p_4 = 0.005$$

to be tested at significance level $\alpha = 0.05$. First we test $0.01 \cdot 4 = 0.04 < 0.05$: reject $H_{0(1)}$. After we test $0.04 \cdot 4 = 0.16 > 0.05$: Don't reject $H_{0(2)}$. After we test $0.03 \cdot 4 = 0.12 > 0.05$: Don't reject $H_{0(3)}$. Finally we test $0.005 \cdot 4 = 0.02 < 0.05$: Reject $H_{0(4)}$.

The Bonferroni method is guaranteed to control FWER, but it has a big problem. It greatly reduces our power to detect real differences. For example, suppose the effect size is 2 and we are doing a Student T-test, rejecting the null hypothesis for $p < 0.05$. With 10 observations per group, the power is 99%. Now suppose we have $1,000$ tests, and use the Bonferroni method. That means that to reject the null hypothesis, we need $p < 0.00005$. The power is now only 29%. If we have $10,000$ tests (which is small for genomics studies) the power is only 10%.

5.7.13.8.1 Holm-Bonferroni Correction

The "Holm-Bonferroni correction" method is as follows:

- Let $H_1, \ldots, H_m$ be a family of m null hypotheses and $p_1, \ldots, p_m$ the corresponding p-values.
- Start by ordering the p-values (from lowest to highest) $p_{(1)} \ldots p_{(m)}$ and let the associated hypotheses be $H_{(1)}, \ldots, H_{(m)}$.
- For a given significance level α, let k be the minimal index such that $p_{(k)} > \frac{\alpha}{m+1-k}$.
- Reject the null hypotheses $H_{(1)}, \ldots, H_{(k-1)}$ and do not reject $H_{(k)}, \ldots, H_{(m)}$.
- If $k = 1$ then do not reject any of the null hypotheses and if no such k exist then reject all of the null hypotheses.

This method ensures that FWER $\leq \alpha$, where FWER is the family-wise error rate.

Proof 5.48.6. Holm-Bonferroni controls the FWER as follows: Let $H_{(1)}, \ldots, H_{(m)}$ be a family of hypotheses, and $p_{(1)} \leq p_{(2)} \leq \ldots \leq p_{(m)}$ be the sorted p-values. Let I_0 be the set of indices corresponding to the (unknown) true null hypotheses, having m_0 members.

Let us assume that we wrongly reject a true hypothesis. We have to prove that the probability of this event is at most α.

Let h be the first rejected true hypothesis (first in the ordering given by the Holm-Bonferroni test). Then $H_{(1)}, \ldots, H_{(h-1)}$ are all rejected false hypotheses and $h - 1 \leq m - m_0$. From there, we get:

$$\frac{1}{m-h+1} \leq \frac{1}{m_0} \tag{5.7.2238}$$

as h is rejected, we have:

$$p_{(h)} \leq \frac{\alpha}{m-h+1} \tag{5.7.2239}$$

by definition of the test. Using the previous relation the right hand side is at most α/m_0. Thus, if we wrongly reject a true hypothesis, there has to be a true hypothesis with p-value at most α/m_0.

So let us define the random variable $A = \left\{P_i \leq \frac{\alpha}{m_0} \text{ for } i \in I_0\right\}$. Whatever the (unknown) set of true hypotheses I_0 is, we have $P(A) \leq \alpha$ (by the Bonferroni inequalities). Therefore, the probability to reject a true hypothesis is at most α.

■ Q.E.D.

✍**Example:**

Consider four null hypotheses $H_1, \ldots, H_4$ with p-values:

$$p_1 = 0.01, p_2 = 0.04, p_3 = 0.03, p_4 = 0.005$$

to be tested at significance level $\alpha = 0.05$. Since the procedure is step-down, we first test $H_4 = H_{(1)}$, which has the smallest p-value $p_4 = p_{(1)} = 0.005$. The p-value is compared to:

$$\frac{\alpha}{m+1-k} = \frac{\alpha}{4+1-1} = \frac{0.05}{4} = 0.0125$$

the null hypothesis is rejected and we continue to the next one. Since $p_1 = p_{(2)} = 0.01$ and:

$$\frac{\alpha}{m+1-k} = \frac{\alpha}{4+1-2} = \frac{0.05}{3} = 0.0167$$

we reject $H_1 = H_{(2)}$ as well as $0.01 < 0.167$ and continue. The next hypothesis H_3 is not rejected since $p_3 = p_{(3)} = 0.03$ and:

$$\frac{\alpha}{m+1-k} = \frac{\alpha}{4+1-3} = \frac{0.05}{2} = 0.025$$

then $0.03 > 0.025$. We have our k that is equal to $k = 3$. We stop testing and conclude that H_1 and H_4 are rejected and H_2 and H_3 are not rejected while controlling the family-wise error rate at level $\alpha = 0.05$. Note that even though $p_2 = p_{(4)} = 0.04 < 0.05 = \alpha$ applies, H_2 is not rejected. This is because the testing procedure stops once a failure to reject occurs.

5.7.13.8.2 Holm–Šidák Correction

As we know the Bonferroni correction seen earlier above is only an approximation (first order Taylor series) of the Šidák correction.

Therefore it is possible to replace:

$$\frac{\alpha}{m},\frac{\alpha}{m-1},\ldots,\frac{\alpha}{1} \tag{5.7.2240}$$

with:

$$1-(1-\alpha)^{1/m},1-(1-\alpha)^{1/(m-1)},\ldots,1-(1-\alpha)^{1} \tag{5.7.2241}$$

resulting in a slightly more powerful test and named the "Holm–Šidák Correction".

5.7.13.9 Adequation Tests (Goodness of Fit tests)

The goodness of fit (GoF) of a statistical model describes how well it fits a set of observations. Measures of goodness of fit typically summarize the discrepancy between observed values and the values expected under the model in question. Such measures can be used in statistical hypothesis testing, e.g. to test for normality of residuals, to test whether two samples are drawn from identical distributions (see Kolmogorov–Smirnov test further below), or whether outcome frequencies follow a specified distribution (see Pearson's chi-squared test below).

5.7.13.9.1 Pearson's Chi-squared GoF Test

We will study here our first GoF nonparametric test, certainly one of the most known and most simple one (which applies only to non-censored data as far as we know).

To introduce this test, assume that a random variable follow a probability distribution P. If we draw a sample from the population corresponding to this law, the observed distribution, named "sampling distribution", always deviate more or less of the theoretical distribution, taking into account the sampling fluctuations.

Generally, we do not know the shape of the law P, nor the value of its parameters. It is the nature of the studied phenomenon and the analysis of the observed distribution that allow to choose a law likely to be adequate and afterwards to estimate the parameters.

The differences between the theoretical law and the observed distribution can be attributed either to sampling fluctuations, or to the fact that the phenomenon does not follow, in reality, the supposed law.

Basically, if the gaps are small enough, we will assume they are due to random fluctuations and we will accept (not reject in fact!) the supposed law. On the contrary, if the gaps are too high, we conclude that they can not be explained solely by the fluctuations and the phenomenon does not follow the supposed law (reject the null hypothesis).

To assess these gaps and to make a decision, we need:

1. Define the measure of the distance between the empirical distribution and the theoretical resulting from the retention law.

2. Determine the probability law followed by the random variable giving the distance (in fact sadly not reject the null hypothesis).

3. State a decision rule to tell from the observed distribution, if the law chosen is acceptable or not.

First, we will need for this purpose the central limit theorem and secondly recall that during the construction of the Normal distribution, we have proved that the variable:

$$x=\frac{k-np}{\sqrt{npq}}=\frac{k-np}{\sqrt{np(1-p)}} \tag{5.7.2242}$$

follow a Normal distribution centered reduced when n approaches infinity (Laplace condition) and the probability p was very small.

In practice, the approximation is quite acceptable... in some companies... and when $np>5$ and $p\leq 0.5$ therefore (it was one of the terms that needed to tend to zero when we made the proof):

$$\frac{q}{\sqrt{npq}}\cong 0.3 \tag{5.7.2243}$$

For example in the two figures below where we represented the binomial laws approached by the Normal associated laws, we have on the left $n=60,p=1/6,np=10$ and on the right $n=40,p=0.05,np=2$:

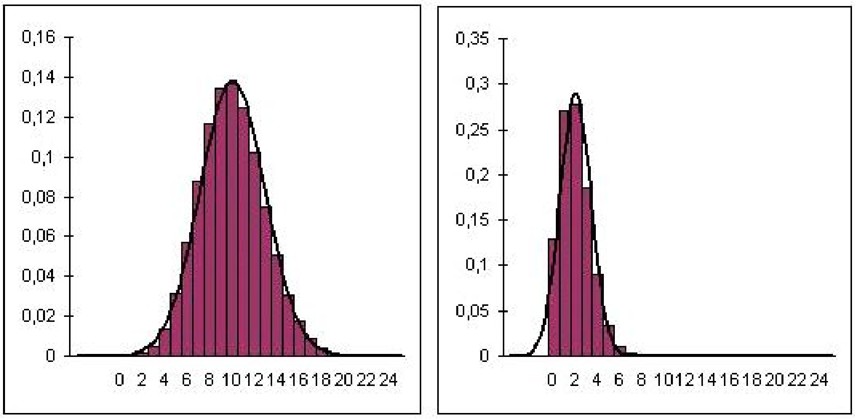

Figure 5.206: **Approach of binomial functions by associated Normal functions**

Finally, remember that we have proved that the sum of squares of n linearly independent reduced centered Normal random variable follows a chi-square with n degrees of freedom denoted by $\chi^2(n)$.

Now consider a random variable X that follows a theoretical distribution function (continuous or discrete) P and let us draw a sample of size n in the population corresponding to this law P.

The n observations are distributed along k terms (class values) $C_1,C_2,\ldots,C_k$, whose probabilities $p_1,p_2,\ldots,p_k$ are determined by the distribution function P (refer to the example with the Henry straight line at page 726).

For each modality C_i, the empirical sample size is a binomial random variable k_i of parameters:

$$\beta(n, p_i) \tag{5.7.2244}$$

This number k_i corresponds indeed to the number of successful events: "result equal to the modality C_i" of probability p_i, obtained during the sampling on n items of the experimental batch (and not in the population of the theoretical law as before!).

We have proved earlier above during our the study of the binomial law that his expected mean was:

$$\text{E}(k_i) = np_i \tag{5.7.2245}$$

represents the expected theoretical sample size of the modality C_i and its variance is given by (when n is very big and p_i very small):

$$\text{V}(k_i) = np_iq_i = np_i(1 - p_i) \cong np_i \tag{5.7.2246}$$

Its standard deviation is therefore:

$$\sigma_{k_i} = \sqrt{np_i} \tag{5.7.2247}$$

Under these conditions, provided that the modality C_i has a size np_i of at least equal to 5, the reduced centered variable:

$$E_i = \frac{k_i - np_i}{\sqrt{np_i}} = \frac{k_i - \mu_i}{\sigma_i} \tag{5.7.2248}$$

between empirical and theoretical sample size can be approximately regarded as a reduced centered Normal variable as we have proved it earlier above. It is also named the "Pearson's residual" for value i, and it compares the observed with the expected counts. The sign (positive or negative) indicates whether the observed frequency k_i is higher or lower than the value fitted under the model, and the magnitude indicates the degree of departure. When data do not fit a model, examination of the Pearson residuals often helps to diagnose where the model has failed.

We now define the variable:

$$D = \sum_{i=1}^{N} E_i^2 = \sum_{i=1}^{N} \frac{(k_i - np_i)^2}{np_i} \tag{5.7.2249}$$

where k_i is often named "experimental frequency" and np_i "theoretical frequency".

If we take the square it is because that in a simple sum certain terms would cancel by opposing effects and thus would mask the differences, if we take the sum of the absolute values the statistical table of D would be difficult to build and the test would be not very robust because of the small gap of distances. The square allows not only to have an easy statistical table of D which is simple since it is based on a law with a single parameter, as we shall see, and the square also sufficiently increases the test's robustness.

Note that this variable is also sometimes (somewhat unfortunately) denoted by:

$$D = \sum_{i=1}^{N} \frac{(n_i - n_i')^2}{n_i'} \tag{5.7.2250}$$

or more often (the E_i below is not the same as the previous E_i just above!!!):

$$\boxed{D=\sum_{i=1}^{N}\dfrac{(O_i-E_i)^2}{E_i}} \tag{5.7.2251}$$

where:

$$\dfrac{(O_i-E_i)^2}{E_i} \tag{5.7.2252}$$

is commonly named, as already mentioned earlier above, the "Pearson's residual".

This variable D, sum of squared variables E_i, provides a measure of a "distance" between empirical and theoretical distribution and empirical distribution. Let us note however that this is not a distance in the usual mathematical sense (topological).

Recall that D can therefore also be written:

$$D=\sum_{i=1}^{N}\dfrac{(k_i-np_i)^2}{np_i}=\sum_{i=1}^{N}\dfrac{(k_i-\mu_i)^2}{\sigma_i^2} \tag{5.7.2253}$$

D is therefore the sum of squares of N reduced centered Normal random variables linked by the single linear relation:

$$k_1+k_2+\ldots+k_N=n \tag{5.7.2254}$$

where n is the sample size. So D follows a chi-square distribution, but with $N-1$ degrees of freedom, so a degree less because of the unique linear relation between them! Indeed, recall that the degree of freedom is the number of independent variables in the sum and not just the number of summed terms.

Therefore:

$$\boxed{D=\chi^2(N-1)=\chi^2_{N-1}=\sum_{i=1}^{N}\dfrac{(k_i-np_i)^2}{np_i}} \tag{5.7.2255}$$

We name this test the "nonparametric Chi-square test" or "Pearson's Chi-square test" or "Chi-square test of adjustment" or "Karl Pearson's test" or "goodness of fit Chi-square test"...

Remark

There are plenty of statistical tests with that contains "chi-square" in it. For example:

- Chi-square Goodness-of-fit test (allow us to determine whether a specified population distribution is valid)
- Chi-square test of association/independence (allow us to determine whether the distribution of one variable has been influenced by another variable)
- Chi-square test of homogeneity (allow us to compare two or more population proportions)

- Chi-square test for outliers (allow us to detect if there is at least one outlier in comparison of a specific distribution)
- Chi-square test for difference of two count data (special case of homogeneity test with only one category!)

Even if all those tests have different purposes, their mathematical framework and procedure are EXACTLY the same and therefore any of these four tests can be run to get at the same time the four conclusions with the same p-values and the same critical chi-square values!!!

We also see by the way that the squared Pearson residual is the individual contribution to the Pearson χ^2 statistic.

Then, the usage is to determine the value of the Chi-square distribution with $N-1$ degrees of freedom with a 5% probability of being exceeded. Thus, in the hypothesis that the studied phenomenon, follows the theoretical distribution P, so there is a 95% cumulative probability that the variable D takes a value less than the one given by the Chi-Square distribution.

If the value of the law of Chi-square obtained from the sample is smaller than that corresponding to 95% of cumulative probability, we do not reject the null hypothesis that the phenomenon follows the law P.

Remarks

R1. The fact that the assumption of the law P is accepted does not mean that this hypothesis is true, merely that the information given by the sample does not allow to reject it. Similarly, the fact that the assumption of the law P is rejected does not necessarily mean that this assumption is false but that the information provided by the sample rather lead to the conclusion that the inadequacy of such a law.

R2. For the variable D to follow a chi-square law, it is necessary that the theoretical values np_i of the different modalities C_i are at least equal to 5, that the sample was drawn randomly (no correlation) and that the probabilities p_i are not close to zero.

This goodness of fit test however suffers from a major issue: it requires to group the measurements in classes C_i and in practice there is no absolute theorem (at least as far we know) to choose the number of classes (and in full width) excepted the Sturge Rule proved earlier. It is this reason that make the chi-squared goodness of fit test is reserved for discrete distributions where the problem of the choice of classes not arise.

However, we will need to create goodness of fit tests that do not require the use of classes and we will see just after ad hoc tools for this purpose (Kolmogorov-Smirnov or Anderson-Darling to name only the most important one).

✍**Example:**

Suppose that the births in a hospital for a period of time, are as follows:

Day	**M**	**T**	**W**	**T**	**F**	**S**	**S**	**Total**
Observations	120	130	125	128	80	70	75	728

We note that there were a total of 728 births. We ask then the following question: How many should there be births, in theory, every day if there is no difference between days? This represents the null hypothesis H_0. In fact the null hypothesis states that the differences between the observed frequencies and conceptual frequencies are relatively small. We take for granted that if there is no difference there should be the same number of births each day. Since there are a total of 728 births for 7 days in theory there should be $728/7 = 104$ births every day. So now we have the following table:

Day	**M**	**T**	**W**	**T**	**F**	**S**	**S**	**Total**
Observations	120	130	125	128	80	70	75	728
Expected	104	104	104	104	104	104	104	104

The total of observed frequencies equals the total expected frequencies. The purpose is therefore to examine the difference between the observed and expected frequencies (assumed to follow a uniform law in this special case) using the Chi-square relation. In other words, we do a fit test between an empirical distribution function (observed) and the uniform distribution function. Then we have:

$$\begin{aligned}
\chi^2(N-1) &= \sum_{i=1}^{N} \frac{(O_i - E_i)^2}{E_i} \\
&= \frac{(120-104)^2}{104} + \frac{(130-104)^2}{104} + \frac{(125-104)}{104^2} + \frac{(128-104)^2}{104} \\
&+ \frac{(80-104)^2}{104} + \frac{(70-104)^2}{104} + \frac{(75-104)^2}{104} \\
&= \frac{16^2}{104} + \frac{26^2}{104} + \frac{21^2}{104} + \frac{24^2}{104} + \frac{(-24)^2}{104} + \frac{(-34)^2}{104} + \frac{(-29)^2}{104} \\
&= \frac{256}{104} + \frac{676}{104} + \frac{441}{104} + \frac{576}{104} + \frac{576}{104} + \frac{1156}{104} + \frac{841}{104} \\
&= 2.46 + 6.5 + 4.24 + 5.54 + 5.54 + 11.12 + 8.09 = 43.49
\end{aligned} \tag{5.7.2256}$$

The χ^2 is therefore 43.49. As such this number means little. This result should be interpreted with the help of the table of critical values of the χ^2_6. Without using the table we understand that it is very unlikely that the observed frequency and theoretical frequency are identical. We accept that there may be some difference (we therefore reject the null hypothesis H_0 in favour of the alternative hypotheses H_A).

So do not forget that this test only applies to uncensored data, that is to say for which the intervals are closed!

Remark

The above test is also used a feature selection technique in Machine Learning and is then named "χ^2 feature selection". The idea is that if we have a dataset with too many columns (categorical or continuous), we which to eliminated some of them by investigating if they are statistically dependent (then we can eliminate one of them) or independent (then we can't eliminate any of them). Notice that to run this technique on continuous variables (columns), we can just group them into bins!

5.7.13.9.2 G-test GoF

We use the "G–test of goodness-of-fit" or also named "G^2-test" (that is a special case of the "likelihood ratio test" or "log-likelihood ratio test" as we will see further below at page 1150) when we have one nominal variable and that we want to see whether the number of observations in each category fits a theoretical expectation, and the sample size is large and the observed total of counts and the expected total of counts is equal!

The statistical null hypothesis is that the number of observations in each category is equal to that predicted by a theory, and the alternative hypothesis is that the observed numbers are different from the expected. The null hypothesis is usually an extrinsic hypothesis, where we know the expected proportions before doing the experiment.

The G-test statistic is proportional to the Kullback–Leibler divergence (see section Statistical Mechanics page 3542) of the theoretical distribution from the empirical distribution:

$$\boxed{G=2\sum_i O_i\cdot\ln\left(\frac{O_i}{E_i}\right)=2\sum_i No_i\cdot\ln\left(\frac{No_i}{Ne_i}\right)=2N\sum_i o_i\cdot\ln\left(\frac{o_i}{e_i}\right)=2N\,D_{\text{KL}}(o\|e)} \tag{5.7.2257}$$

Let us put now:

$$O_i=E_i+\delta_i \tag{5.7.2258}$$

with the constraint that:

$$\sum_i \delta_i \tag{5.7.2259}$$

so that the total number of counts stays the same (i.e. $\sum_i O_i=\sum_i E_i=N$). The G-test is then:

$$G=2\sum_i(E_i+\delta_i)\log\left(\frac{E_i+\delta_i}{E_i}\right)=2\sum_i(E_i+\delta_i)\log\left(1+\frac{\delta_i}{E_i}\right) \tag{5.7.2260}$$

If we Taylor expand this around:

$$\frac{\delta_i}{E_i}\cong 0 \tag{5.7.2261}$$

noticing that this assume $E_i \gg \delta_i$ and hence $E_i \gg 0$ (as for the chi-square test of adequation seen just earlier), then we know that for the logarithm (see section Sequences and Series page 1703):

$$\log(1+x) \cong x - \frac{x^2}{2} \qquad (5.7.2262)$$

Then we get:

$$\begin{aligned}
G &= 2\sum_i (E_i+\delta_i)\log\left(1+\frac{\delta_i}{E_i}\right) \cong 2\sum_i (E_i+\delta_i)\left(\frac{\delta_i}{E_i}-\frac{1}{2}\frac{\delta_i^2}{E_i^2}\right)\\
&= 2\sum_i\left(\delta_i-\frac{1}{2}\frac{\delta_i^2}{E_i}+\frac{\delta_i^2}{E_i}-\frac{1}{2}\frac{\delta_i^3}{E_i^2}\right) = 2\sum_i\left(\delta_i+\frac{1}{2}\frac{\delta_i^2}{E_i}+\frac{1}{2}\frac{\delta_i^3}{E_i^2}\right)\\
&\cong 2\sum_i\left(\delta_i+\frac{1}{2}\frac{\delta_i^2}{E_i}\right) = 2\sum_i\left(\frac{2E_i\delta_i+\delta_i}{2E_i}\right) = \sum_i\left(\frac{2E_i\delta_i+\delta_i^2}{E_i}\right) = \sum_i\left(\frac{(E_i+\delta_i)^2-E_i^2}{E_i}\right)\\
&= \sum_i\left(\frac{O_i^2-E_i^2}{E_i}\right)
\end{aligned} \qquad (5.7.2263)$$

and so, we see that $G=\chi^2$ when:

- O_i is close to E_i
- $\sum_i E_i = \sum_i O_i = N$
- $E_i \gg \delta_i$ i.e. $E_i \gg 0$

However, the more O_i and E_i are different, the less well this approximation will work, and the χ^2 will tend to compute erroneous answers. The effects of a single outlier in a small sample set will be more pronounced, which explains why the χ^2 often fails in situations with little data.

Since the χ^2 value is just an approximation to the G-value, the G-value can also be used in the chi-squared probability test. It seems that actually the G-test p-value need to be computed using Monte Carlo techniques.

Remark

If the expected number of observations in any category is too small, the G–test may give inaccurate results, and we should use an exact test instead (Fisher exact test in case of independence as seen at page 1254, McNemar test in case of dependence as seen at page 1264). In practice, it's a good idea to compute both χ^2 and G to see if they lead to similar results. If the resulting p-values are close, then we can be fairly confident that the large-sample approximation is working well. Obviously the G–test of goodness-of-fit assumes independence!

5.7.13.9.3 Kolmogorov-Smirnov GoF Test

In statistics, the Kolmogorov-Smirnov test is also a goodness of fit test (especially well known as normality test) based on an empirical distance used to determine whether the distribution of a sample follows a well known law given by a continuous distribution function (or for comparing two samples and check if they are dependent or not as similar or not). This test, as well as that of chi-squared GoF test is only valid for non-censored data (at least not without correction obtained by numerical simulations).

To introduce this test, we chose the Lilliefors approach that give the possibility to avoid complex calculations. Furthermore, softwares that provide the "Lilliefors GoF test" do not offer the Kolmogorov-Smirnov test since the latter is correct only asymptotically (which is the case of the software Tanagra 4.14).

Imagine we want to build a nonparametric GoF test who works for both discrete and continuous laws without suffering the same problem as the Chi-square GoF test (clustering in classes).

To build this test, we start from the empirical distribution function already defined at the beginning of this section and given for reminder by:

$$\hat{F}_n(x)=\frac{1}{n}\sum_{i=1}^{n}1_{x_i\leq x}=\frac{1}{n}\sum_{i=1}^{n}\delta_{x_i\leq x}=\frac{\#(i:x_i\leq x)}{n} \tag{5.7.2264}$$

that obviously belong to the interval $[0,1]$.

Let us now denote by $F(x)$, the true supposed law which analytical expression is known and with which we would like to compare $\hat{F}(x)$ and build the distance:

$$D_n(x)=\hat{F}_n(x)-F(x) \tag{5.7.2265}$$

The reference distribution may, however, also originate from another measurement sample. The idea is then simply to compare two empirical distributions. We speak then of "Kolmogorov-Smirnov test for 2 independent samples". Some softwares also manage empirically the case where the two samples do not have the same size.

The problem with this choice of distance is ... what x should we then choose to make a test? Well to answer it is simple to see that it would be foolish to take a x for which this distance is minimal, because have a D_n that can be almost zero does not add much information... Therefore, we rather postponed towards the greatest absolute deviation. Which brings us to redefine the distance D_n as follows:

$$\boxed{D_n(x)=\sup\left|\hat{F}_n(x)-F(x)\right|=\sup\left|\frac{1}{n}\sum_{i=1}^{n}1_{x_i\leq x}-F(x)\right|} \tag{5.7.2266}$$

where D_n is named "Kolmogorov-Smirnov empirical distribution" (for sure we should prove rigorously that it is really a distribution ... but for now it is too complex in terms of the content of this textbook however this can be verified by numerical simulations!). Before going further with respect to the theory, let's look at a practical example (because the example is long we will not put it into the conventional box).

Suppose we measured the following five values:

$$-1.2, 0.2, -0.6, 0.8, -1.0 \tag{5.7.2267}$$

thus ordered:

$$x_1 = -1.2, x_2 = -1.0, x_3 = -0.6, x_4 = 0.2, x_5 = 0.8 \tag{5.7.2268}$$

We want to test the following null hypothesis:

$$H_0 : \hat{F}(x) = \Phi(x) \tag{5.7.2269}$$

where $\Phi(x)$ is as usual the distribution function of the Normal centered reduced distribution.

The empirical distribution function will be given by:

$$\hat{F}(x) = \begin{cases} 0 = \dfrac{0}{n} = \dfrac{0}{5} & \text{for} \quad x < -1.2 \\ 0.2 = \dfrac{1}{n} = \dfrac{1}{5} & \text{for} \quad -1.2 < x < -1 \\ 0.4 = \dfrac{2}{n} = \dfrac{2}{5} & \text{for} \quad -1.0 < x < -0.6 \\ 0.6 = \dfrac{3}{n} = \dfrac{3}{5} & \text{for} \quad -0.6 < x < +0.2 \\ 0.8 = \dfrac{4}{n} = \dfrac{4}{5} & \text{for} \quad +0.2 < x < +0.8 \\ 1 = \dfrac{5}{n} = \dfrac{5}{5} & \text{for} \quad x > +0.8 \end{cases} \tag{5.7.2270}$$

Then we traditionally build the following table:

x	$\hat{F}(x)$	$\Phi(x)$	$\lvert\hat{F}(x) - \Phi(x)\rvert$
-1.2^{-}	0	0.115	0.115
-1.2	0.2	0.115	0.085
-1.0^{-}	0.2	0.159	0.041
-1.0	0.4	0.159	0.241
-0.6^{-}	0.4	0.274	0.126
-0.6	0.6	0.274	**0.326**
$+0.2^{-}$	0.6	0.580	0.020
$+0.2$	0.8	0.580	0.220
$+0.8^{-}$	0.8	0.788	0.012
$+0.8$	1	0.788	0.212

Often associated with the following graph comparing empirical (in red) and theoretical (in blue) distributions:

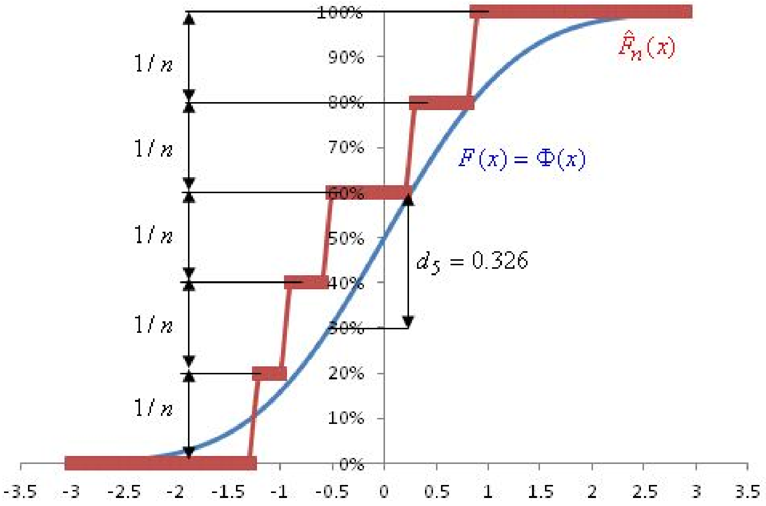

Figure 5.207: **Representation of the approach of the Kolmogorov-Smirnov GoF**

We then observe that the maximum deviation is 0.326. We will denote that for after:

$$d_5 = 0.326 \tag{5.7.2271}$$

that some softwares such as Minitab or `R` denote with the abbreviation: KS.

The reader will have noticed that the biggest deviation above the curve is measured by:

$$D_n^+ = \sup_{i=1}^{n} \left\{ \frac{i}{n} - F(x_i) \right\} = \sup_{i=1}^{n} \left\{ \frac{i}{n} - y_i \right\} \tag{5.7.2272}$$

The largest deviation below the curve is measured by:

$$D_n^+ = \sup_{i=1}^{n} \left\{ F(x_i) - \frac{i-1}{n} \right\} = \sup_{i=1}^{n} \left\{ y_i - \frac{i-1}{n} \right\} \tag{5.7.2273}$$

The biggest deviation is then:

$$D_n = \sup_{i=1}^{n} \left\{ D_n^-, D_n^+ \right\} = \sup_{i=1}^{n} \left\{ \frac{i}{n} - y_i, y_i - \frac{i-1}{n} \right\} \tag{5.7.2274}$$

But what can we do with this value? To what can we compare it? Well the idea is relatively simple and involves generating n values (thus 5 in our example) from the distribution law $F(x)$ of the null hypothesis H_0 and compare them to themselves. In other words, to make a Monte Carlo simulation (see section Numerical Methods page 6708).

Thus, in our example, we generate 5 random value values of $\mathcal{N}(0,1)$ which gives us example with Microsoft® Excel® 11.8346:

```
=NORM.S.INV(RANDBETWEEN(0,1000000)/1000000)
```

We obtain then 5 values of Z (remember it is the usual notation of a random variable of a Normal centered reduced distribution) which ordered will be for example:

$$-1.427, 0.082, 0.162, 0.294, 1.292 \tag{5.7.2275}$$

and we repeat the same table as before:

x	$\hat{F}(x)$	$\Phi(x)$	$\lvert\hat{F}(x)-\Phi(x)\rvert$
-1.427^-	0	0.077	0.115
-1.427	0.2	0.077	0.085
$+0.082^-$	0.2	0.533	0.041
$+0.082$	0.4	0.533	0.241
$+0.162^-$	0.4	0.564	0.126
$+0.162$	0.6	0.564	**0.326**
$+0.294^-$	0.6	0.616	0.020
$+0.294$	0.8	0.616	0.220
$+1.292^-$	0.8	0.902	0.012
$+1.292$	1	0.902	0.212

And so we have the maximum deviation that is 0.333. Either with Microsoft® Excel® 14.0.6123:

	A	B	C	D	E
1	i/n	Z Random values	Ordered Z values	Normal $\Phi(x)$	Delta
2	0	1.292	-1.426	0.077	0.077
3	0.2	1.292	-1.426	0.077	0.123
4	0.2	0.082	0.082	0.533	0.333
5	0.4	0.082	0.082	0.533	0.133
6	0.4	-1.427	0.162	0.564	0.164
7	0.6	-1.427	0.162	0.564	0.036
8	0.6	0.162	0.294	0.616	0.016
9	0.8	0.162	0.294	0.616	0.184
10	0.8	0.294	1.292	0.902	0.102
11	1	0.294	1.292	0.902	0.098
12				Max	0.332677

Figure 5.208: Calculations in Microsoft® Excel® 14.0.6123

with the explicit formulas:

	A	B	C	D	E
1	i/n	Z Random values	Ordered Z values	Normal $\Phi(x)$	Delta
2	0	=NORM.S.INV(RANDBETWEEN(0,1000000)/1000000)		=NORM.S.DIST(C2,1)	=ABS(D2-A2)
3	0.2	=B2		=NORM.S.DIST(C3,1)	=ABS(D3-A3)

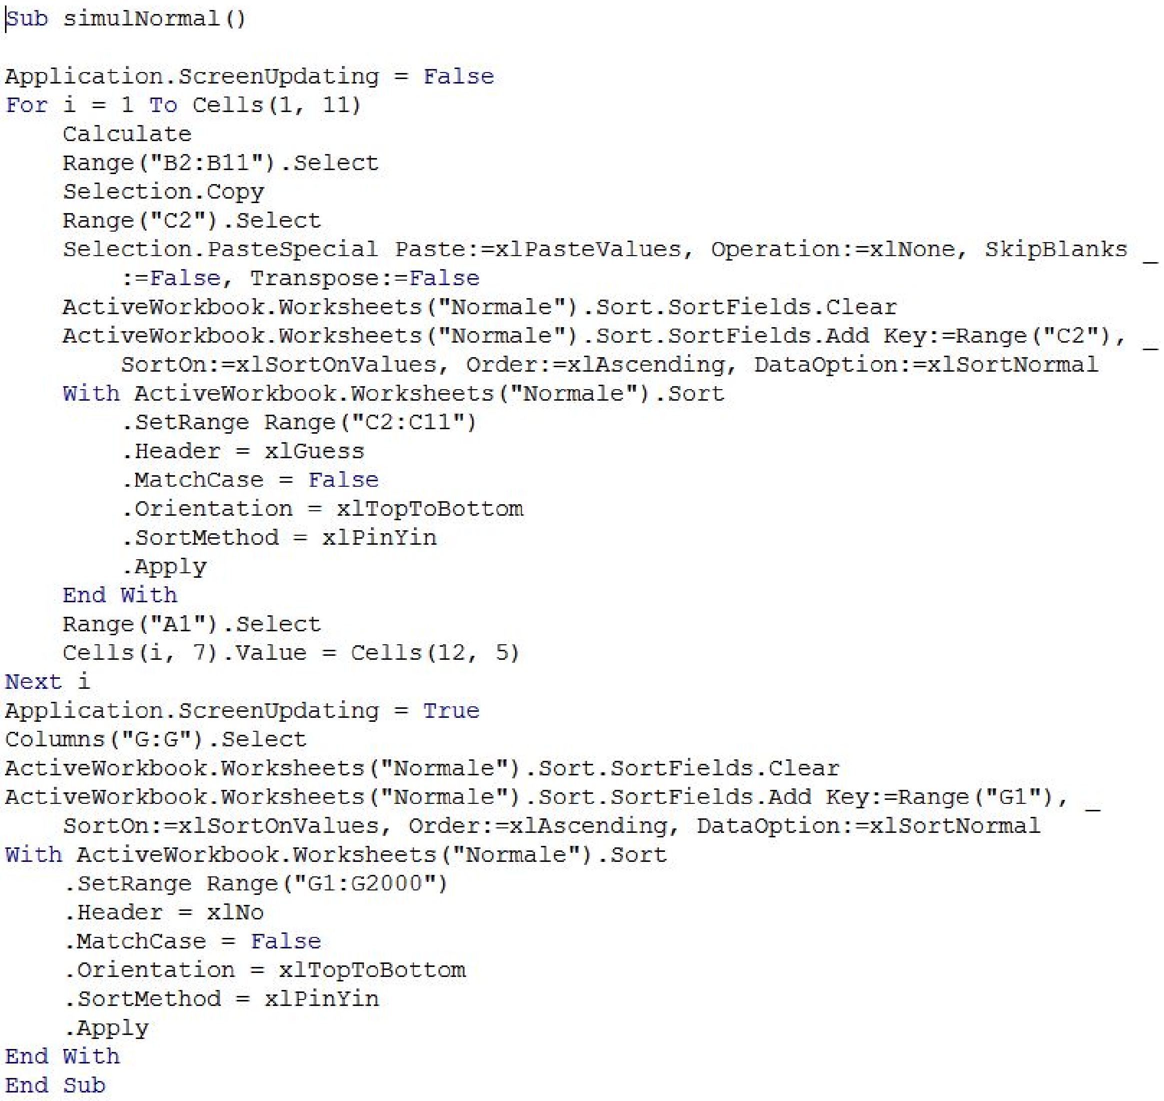
11	1	=B10		=NORM.S.DIST(C11,1)	=ABS(D11-A11)
12				Max	=MAX(E2:E11)

Figure 5.209: Explicit calculations in Microsoft® Excel® 14.0.6123

with the small corresponding VBA routine quickly and poorly made that will take the number of iterations required in the cell `K1` and will put the empirical distribution of Kolmogorov-Smirnov in column `G` of the active sheet:



```
Sub simulNormal()

Application.ScreenUpdating = False
For i = 1 To Cells(1, 11)
    Calculate
    Range("B2:B11").Select
    Selection.Copy
    Range("C2").Select
    Selection.PasteSpecial Paste:=xlPasteValues, Operation:=xlNone, SkipBlanks _
        :=False, Transpose:=False
    ActiveWorkbook.Worksheets("Normale").Sort.SortFields.Clear
    ActiveWorkbook.Worksheets("Normale").Sort.SortFields.Add Key:=Range("C2"), _
        SortOn:=xlSortOnValues, Order:=xlAscending, DataOption:=xlSortNormal
    With ActiveWorkbook.Worksheets("Normale").Sort
        .SetRange Range("C2:C11")
        .Header = xlGuess
        .MatchCase = False
        .Orientation = xlTopToBottom
        .SortMethod = xlPinYin
        .Apply
    End With
    Range("A1").Select
    Cells(i, 7).Value = Cells(12, 5)
Next i
Application.ScreenUpdating = True
Columns("G:G").Select
ActiveWorkbook.Worksheets("Normale").Sort.SortFields.Clear
ActiveWorkbook.Worksheets("Normale").Sort.SortFields.Add Key:=Range("G1"), _
    SortOn:=xlSortOnValues, Order:=xlAscending, DataOption:=xlSortNormal
With ActiveWorkbook.Worksheets("Normale").Sort
    .SetRange Range("G1:G2000")
    .Header = xlNo
    .MatchCase = False
    .Orientation = xlTopToBottom
    .SortMethod = xlPinYin
    .Apply
End With
End Sub
```

Figure 5.210: **Small VBA script for K-S GoF test**

We therefore reiterate the procedure a thousand times and we get the following distribution function (obtained simply by making a scatter chart type in Microsoft® Excel® 14.0.6123 with $2,000$ simulations):

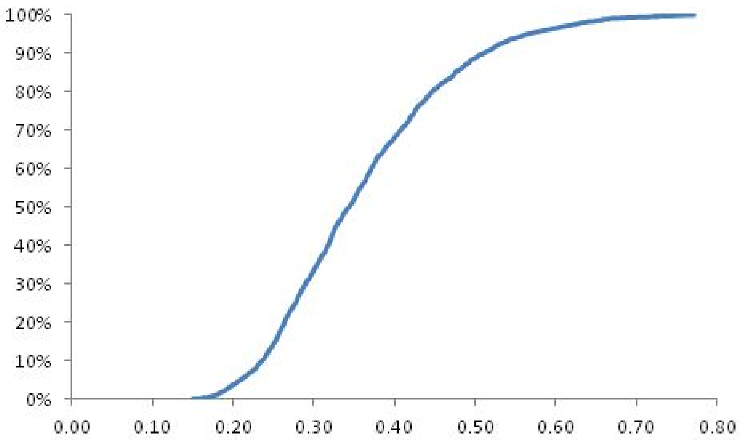


Figure 5.211: **K-S GoF distribution simulation**

and applying a one-sided test with a threshold of $\alpha = 5\%$ we get for the 95th percentile:

$$D_{5,\alpha} \cong 0.564 \tag{5.7.2276}$$

The reader will find the same value in the Kolmogorov-Smirnov tables available in many books. A few thousand simulations are therefore sufficient to restore the values of the tables!

And now, we compare:

$$(D_{5,\alpha} \cong 0.564) > (d_0 \cong 0.326) \tag{5.7.2277}$$

and therefore we do not reject the null hypothesis.

But ... we must still take care with only five values, it is quite likely that the null hypothesis H_0 is not rejected for other distribution laws that the Normal distribution.

Thus, as the reader will have noticed, for each null hypothesis H_0 associated with a particular distribution law, we must tabulate the empirical distribution of Kolmogorov-Smirnov for different values of n and of α using numerical methods. In the majority of books there is only one table with a powerful theorem that shows that in reality, the critical values will be the same.

Remark

Kolmogorov and Smirnov have proved that when n goes very large and that the law of the null hypothesis is continuous, it is no longer necessary to tabulate a Kolmogorov-Smirnov table for each law because we have then:

$$\lim_{n\rightarrow+\infty} P\left(\sqrt{n}D_n \leq x\right) = 1 - 2\sum_{i=1}^{+\infty}(-1)^{k-1}e^{-2\text{i}^2x^2} \tag{5.7.2278}$$

therefore D_n is independent of the distribution law of the null hypothesis H_0. By simulating with the Monte Carlo method, we observe an effective convergence when n exceeds a hundred. But in practice, the vast majority of the time, it is unthinkable to have such a number of measures. Hence the fact that this theoretical result is little used in practice and justifies the absence of proof in this textbook.

To conclude on the K-S GoF test, let us notice to the reader that he will find the mathematical proof of the Anderson-Darling GoF further below.

KOLMOGOROV-SMIRNOV ONE-SIDED TEST

n	0.2	0.1	0.05	0.02	0.01

> 40	$1.07/\sqrt{n}$	$1.22/\sqrt{n}$	$1.36/\sqrt{n}$	$1.52/\sqrt{n}$	$1.63/\sqrt{n}$

Caution! Let us remind what the normality tests answer: *Is there convincing evidence of any deviation from the Gaussian ideal?* With moderately large real data sets, the answer is almost always yes.

The question engineers and scientists often expect the normality test to answer is: *Do the data deviate enough from the Gaussian ideal to "forbid" use of a test that assumes a Gaussian distribution?* Scientists and engineers often want the normality test to be the referee that decides when to abandon conventional (ANOVA, etc.) tests and instead analyze transformed data or use a rank-based nonparametric test or a resampling or bootstrap approach. For this purpose, normality tests are not very useful as many of these tests are robust to some kind of non-normality.

5.7.13.9.4 Ryan-Joiner GoF Test

Consider a random variable X which we know the sampling distribution and for which we would like to check the Normality or not and consider an ordered random variable Y generated by a Normal centered reduced distribution (that's why Ryan-Joiner test is especially well known as normality test). To compare X and Y, we will center X and order its values in ascending order.

For a same given sample size, if the ordered values of X and Y taken in pairs follow the same law, a linear regression based on the other should give a fairly close correlation coefficient of 1. Taking the definition of the squared correlation coefficient, we have then:

$$\rho_{X,Y}^2=\left(\frac{\text{cov}(X,Y)}{\sqrt{\text{V}(X)\text{V}(Y)}}\right)^2 \tag{5.7.2279}$$

Y is assumed to follow a centered reduced Normal distribution. It comes then:

$$\rho_{X,Y}^2=\left(\frac{\text{cov}(X,Y)}{\sqrt{\text{V}(X)\text{V}(Y)}}\right)^2=\left(\frac{\text{E}(XY)-\text{E}(X)\text{E}(Y)}{\sqrt{\text{V}(X)\text{V}(Y)}}\right)^2=\left(\frac{\text{E}(XY)}{\sqrt{\text{V}(X)}}\right)^2=\frac{(\text{E}(XY))^2}{\text{V}(X)} \tag{5.7.2280}$$

and if we take the estimator of the correlation coefficient:

$$R_{X,Y}^2=\frac{\left(\dfrac{1}{n}\displaystyle\sum_{i=1}^n x_iy_i\right)^2}{\dfrac{1}{n}\displaystyle\sum_{n=1}^n x_i^2} \tag{5.7.2281}$$

Therefore after simplification:

$$R_{X,Y}^2=\frac{\left(\dfrac{1}{n}\displaystyle\sum_{i=1}^n x_iy_i\right)^2}{\dfrac{1}{n}\displaystyle\sum_{n=1}^n x_i^2}=\frac{\left(\dfrac{\sqrt{n}}{n}\displaystyle\sum_{i=1}^n x_iy_i\right)^2}{\displaystyle\sum_{n=1}^n x_i^2}=\frac{\left(\displaystyle\sum_{i=1}^n \left(\frac{y_i}{\sqrt{n}}\right)x_i\right)^2}{\displaystyle\sum_{n=1}^n x_i^2}=\frac{\left(\displaystyle\sum_{i=1}^n a_ix_i\right)^2}{\displaystyle\sum_{n=1}^n x_i^2} \tag{5.7.2282}$$

This is the Ryan-Joiner approach (implemented in Minitab for example) of the Shapiro-Wilk test. The results of both tests are very similar. The coefficients a_i can be easily obtained using any spreadsheet software by using a Monte Carlo simulation (see section Numerical Methods page 6708). If our reader wish it we will detail how to get the coefficients a_i with Microsoft® Excel® for a given n.

✍**Example:**

Consider the 10 measures of column `A` already sorted in ascending order:

	A	B	C	D	E
3	Measures	Rank	Probability	Exact Normal Score a_i	Z-Score X_i
4	0.1685	1.00	0.0610	-1.5480	-1.947246
5	0.1705	2.00	0.1585	-1.0055	-0.927745
6	0.1708	3.00	0.2561	-0.6551	-0.77482
7	0.1713	4.00	0.3537	-0.3726	-0.519945
8	0.1728	5.00	0.4512	-0.1205	0.2446801
9	0.1732	6.00	0.5488	0.1230	0.4485802
10	0.1735	7.00	0.6463	0.3798	0.6015052
11	0.1739	8.00	0.7439	0.6585	0.8054053
12	0.1740	9.00	0.8415	1.0056	0.8563803
13	0.1747	10.00	0.9390	1.5429	1.2132054

Figure 5.212: **Example of ordered measures, ranks, RJ coefficient and Z-score**

The corresponding formulas are:

	A	B	C	D	E

10	0.1735	=RANK(A10,A$4:A$13,1)+(SUM(1*(A10=A$4:A$13))-1)/2	=(B10-0.375)/(COUNT(A$4:A$13)+0.25)	=Coeff_MonteCarlo!Q1	=(A10-AVERAGE($A$4:$A$13))/STDEV($A$4:$A$13)
11	0.1739	=RANK(A11,A$4:A$13,1)+(SUM(1*(A11=A$4:A$13))-1)/2	=(B11-0.375)/(COUNT(A$4:A$13)+0.25)	=Coeff_MonteCarlo!R1	=(A11-AVERAGE($A$4:$A$13))/STDEV($A$4:$A$13)
12	0.174	=RANK(A12,A$4:A$13,1)+(SUM(1*(A12=A$4:A$13))-1)/2	=(B12-0.375)/(COUNT(A$4:A$13)+0.25)	=Coeff_MonteCarlo!S1	=(A12-AVERAGE($A$4:$A$13))/STDEV($A$4:$A$13)
13	0.1747	=RANK(A13,A$4:A$13,1)+(SUM(1*(A13=A$4:A$13))-1)/2	=(B13-0.375)/(COUNT(A$4:A$13)+0.25)	=Coeff_MonteCarlo!T1	=(A13-AVERAGE($A$4:$A$13))/STDEV($A$4:$A$13)

Figure 5.213: **Formulas in Microsoft® Excel® 14.0.6123 of previous screen shot**

and therefore we have in a sheet named *CoeffMonteCarlo* Monte Carlo simulations to determine the 10 coefficients a_i traditionally denoted in the case of 10 measurements in the tables as following: $\left\{a_{1/10}, a_{2/10}, \ldots, a_{10/10}\right\}$. First we must generate 10 columns with Normal centered reduced variables on almost $10,000$ rows with the following Microsoft® Excel® formula:

	A	B	C	D	E	F	G	H	I	J
1										
2	Val1	Val2	Val3	Val4	Val5	Val6	Val7	Val8	Val9	Val10

Figure 5.216: **Microsoft® Excel® 14.0.6123 formulas of previous screenshot**

Finally, it only remains to calculate the correlation coefficient between the columns `D` and `E` of the first screenshot:

	G
3	Coefficient de Corrélation Ryan-Joiner (RJ):
4	=CORREL(D4:D13,E4:E13)

Figure 5.217: **Final calculation of the RJ correlation coefficient with Microsoft® Excel® 14.0.6123**

That gives:

	G
3	Coefficient de Corrélation Ryan-Joiner (RJ):
4	0.963285023

where the square of this value is very very close to the Shapiro-Wilk test.

Then, to know if we can reject or not the null hypothesis H_0 of Normality assumption, we should repeat the same procedure with in place of the measurements use random values generated from a Normal distribution and then determine the critical value of acceptance/rejection (it is very simple to make but we can detail on readers request).

After calculations in this special case we sadly do not reject the null hypothesis.

5.7.13.9.5 Anderson-Darling GoF Test

It is surprising that a test reasonably strong (robust) as the Kolmogorov-Smirnov test can be designed based on only a single observation and a single point of the function of candidate distribution!!! It would seem, with more hindsight, more efficient to measure the difference between the two distribution functions by comparing these functions on their entire domain, that is to say from $-\infty$ to $+\infty$.

It exist a family of tests which the statistics are based on the integral of the square of the difference (these tests are often considered as nonparametric but in my opinion wrongly and same for the Kolmogorov-Smirnov GoF test that is also considered as nonparametric):

$$\left(\hat{F}_n(x)-F_n(x)\right)^2 \tag{5.7.2283}$$

between the empirical distribution function and the reference distribution function. The simplest of these statistics is:

$$S=\int\limits_{-\infty}^{+\infty}\left(\hat{F}_n(x)-F_n(x)\right)^2\mathrm{d}x \tag{5.7.2284}$$

which is simply the area between the empirical distribution function and the reference distribution function. Either, by taking the above graph used during our study of the Kolmogorov-Smirnov GoF:

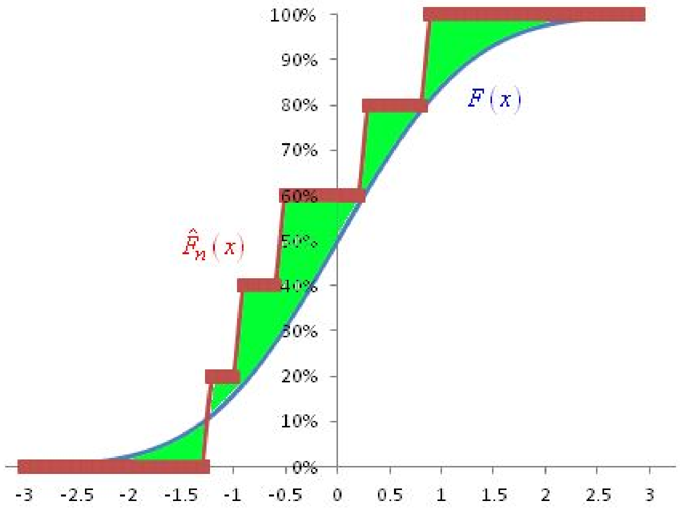

Figure 5.218: Idea behind the Anderson-Darling GoF

However, arbitrarily, we can choose something other than the measurement x for the integral. Thus, a conventional choice is to take the theoretical distribution function itself as a basic measure of the integral. It comes as follows:

$$W^2=n\int\limits_{-\infty}^{+\infty}\left(\hat{F}_n(x)-F_n(x)\right)^2\mathrm{d}F(x) \tag{5.7.2285}$$

Statistic resulting therefrom is named "Cramér-von Mises statistic". However it suffers from a major flaw of robustness when measuring points are on the tails of the distribution.

It then was proposed the following measure that is somewhat less sensitive to measurement points on the tails:

$$\frac{1}{n}W^2=\int\limits_{-\infty}^{+\infty}\frac{\left(\hat{F}_n(x)-F_n(x)\right)^2}{F(x)(1-F(x))}\mathrm{d}F(x)\tag{5.7.2286}$$

named "Anderson-Darling statistic" which was the most used in the late 120th century (holocene calendar) and remains dominant in the early 121st century also (at least while the sample is a fair size!). It is more robust by construction that the Cramér-von Mises statistics , and Kolmogorov-Smirnov simulations, but numerical studies have shown that it is less robust than the Shapiro-Wilk test or Ryan-Joiner test.

Remark

We can put the three statistics next to each other for comparisons purposes (with their traditional notation):

$$D_n(x)=\sup\left|\hat{F}_n(x)-F(x)\right| \qquad W^2=n\int\limits_{-\infty}^{+\infty}\left(\hat{F}_n(x)-F_n(x)\right)^2\mathrm{d}F(x) \qquad A^2=\int\limits_{-\infty}^{+\infty}\frac{\left(\hat{F}_n(x)-F_n(x)\right)^2}{F(x)(1-F(x))}\mathrm{d}F(x)\tag{5.7.2287}$$

Remembering that the definition of the empirical distribution $\hat{F}_n(x)$ in our study of the Kolmogorov-Smirnov GoF test implies that:

$$\hat{F}_n(x)=0\tag{5.7.2288}$$

if $x\in[-\infty,x_1]$ and:

$$\hat{F}_n(x)=\frac{n}{k}\tag{5.7.2289}$$

if $x\in[x_k,x_{k+1}]$ and:

$$\hat{F}_n(x)=1\tag{5.7.2290}$$

if $x\in[x_n,+\infty]$. We then have assuming in addition that F is continuous:

$$\begin{aligned}\frac{1}{n}W^2&=n\int\limits_{-\infty}^{+\infty}\frac{\left(\hat{F}_n(x)-F_n(x)\right)^2}{F(x)(1-F(x))}\mathrm{d}F(x)\\&=\int\limits_{-\infty}^{x_1}\frac{F(x)^2}{F(x)(1-F(x))}\mathrm{d}F(x)+\int\limits_{x_1}^{x_2}\frac{\left(\dfrac{1}{n}-F(x)\right)^2}{F(x)(1-F(x))}\mathrm{d}F(x)+\int\limits_{x_2}^{x_3}\frac{\left(\dfrac{2}{n}-F(x)\right)^2}{F(x)(1-F(x))}\mathrm{d}F(x)+\\&\quad\ldots+\int\limits_{x_n}^{+\infty}\frac{(1-F(x))^2}{F(x)(1-F(x))}\mathrm{d}F(x)\end{aligned}\tag{5.7.2291}$$

Then we make the change of variable $u=F(x)$ and therefore:

$$\mathrm{d}u=\mathrm{d}F(x) \tag{5.7.2292}$$

and without forgetting that the integral bound change as:

$$F(-\infty)=0 \quad \text{and} \quad F(+\infty)=1 \tag{5.7.2293}$$

Therefore we get:

$$\begin{aligned}\frac{1}{n}W^2=&\int\limits_0^{u_1}\frac{u^2}{u(1-u)}\mathrm{d}u+\int\limits_{u_1}^{u_2}\frac{\left(\dfrac{1}{n}-u\right)^2}{u(1-u)}\mathrm{d}u+\int\limits_{u_2}^{u_3}\frac{\left(\dfrac{2}{n}-u\right)^2}{u(1-u)}\mathrm{d}u+\\&\ldots+\int\limits_u^1\frac{(1-u)^2}{u(1-u)}\mathrm{d}u\\=&\int\limits_0^{u_1}\frac{}{u(1-u)}\mathrm{d}u+\int\limits_{u_1}^{u_2}\frac{\left(\dfrac{1}{n}-u\right)^2}{u(1-u)}\mathrm{d}u+\int\limits_{u_2}^{u_3}\frac{\left(\dfrac{2}{n}-u\right)^2}{u(1-u)}\mathrm{d}u+\ldots+\int\limits_u^1\frac{1-u}{u}\mathrm{d}u\end{aligned} \tag{5.7.2294}$$

where we of course have put:

$$u_j=F(x_j) \tag{5.7.2295}$$

We must now calculate these integrals. So we look for the primitive of a function of the type:

$$\frac{(a-u)^2}{u(1-u)}=\frac{a^2-2au+u^2}{u(1-u)}=\frac{a^2}{u(1-u)}-\frac{2a}{1-u}+\frac{u}{1-u} \tag{5.7.2296}$$

The primitive of the following terms:

$$\frac{1}{u(1-u)} \qquad \frac{1}{1-u} \tag{5.7.2297}$$

have been proved in their general form in the section of Differential and Integral Calculus and primitives are respectively:

$$\begin{aligned}&a^2\int\frac{1}{u(1-u)}\mathrm{d}u=a^2\ln\left|\frac{u}{1-u}\right|=a^2\ln|u|-a^2\ln|1-u|=a^2\ln(u)-a^2\ln(1-u)\\&2a\int\frac{1}{1-u}\mathrm{d}u=-2a\ln(1-u)\end{aligned} \tag{5.7.2298}$$

because in view of the possible values of u, then it is unnecessary to indicate the absolute values.

So we have only to calculate the primitive:

$$\frac{u}{1-u} \tag{5.7.2299}$$

where an obvious change of variables (if you want details feel free to ask us) gives us the primitive without the constant:

$$\int \frac{u}{1-u}\mathrm{d}u = -u - \ln(1-u) \tag{5.7.2300}$$

Then we have finally:

$$\begin{aligned}\int \frac{(a-u)^2}{u(1-u)^2}\mathrm{d}u &= \frac{a^2}{u(1-u)} - \frac{2a}{1-u} + \frac{u}{1-u}\\ &= a^2\ln(u) - a^2\ln(1-u) - (-2a\ln(1-u)) - u - \ln(1-u)\\ &= -u + a^2\ln(u) - (a-1)^2\ln(1-u)\end{aligned} \tag{5.7.2301}$$

Therefore we have:

$$\begin{aligned}&\frac{1}{n}W_n^2 = \int\limits_0^{u_1}\frac{u}{1-u}\mathrm{d}u + \sum_{j=1}^{n-1}\left(-u + \left(\frac{j}{n}\right)^2\ln(u) - \left(\frac{j}{n}-1\right)^2\ln(1-u)\right)\Bigg|_{u_j}^{u_{j+1}} + \int\limits_{u_n}^{1}\frac{1-u}{u}\mathrm{d}u\\ &= -u_1 - \ln(1-u_1) + \sum_{j=1}^{n-1}\left(-u + \left(\frac{j}{n}\right)^2\ln(u) - \left(\frac{j}{n}-1\right)^2\ln(1-u)\right)\Bigg|_{u_j}^{u_{j+1}} - 1 + u_n - \ln(u_n)\\ &= -u_1 - \ln(1-u_1) - 1 + u_n - \ln(u_n)\\ &+ \sum_{j=1}^{n-1}\left(-u_{j+1} + u_j + \left(\frac{j}{n}\right)^2\ln(u_{j+1}) - \left(\frac{j}{n}\right)^2\ln(u_j) - \left(\frac{j}{n}-1\right)^2\ln(1-u_{j+1}) + \left(\frac{j}{n}-1\right)^2\ln(1-u_j)\right)\end{aligned} \tag{5.7.2302}$$

We can already notice that in the last equality:

$$-u_1 + u_n + \sum_{j=1}^{n-1}(-u_{j+1} + u_j) = 0 \tag{5.7.2303}$$

Therefore it remains:

$$\begin{aligned}\frac{1}{n}W_n^2 &= -\ln(1-u_1) - 1 - \ln(u_n)\\ &+ \sum_{j=1}^{n-1}\left(\left(\frac{j}{n}\right)^2\ln(u_{j+1}) - \left(\frac{j}{n}\right)^2\ln(u_j) - \left(\frac{j}{n}-1\right)^2\ln(1-u_{j+1}) + \left(\frac{j}{n}-1\right)^2\ln(1-u_j)\right)\\ &= -\ln(1-u_1) - 1 - \ln(u_n) + \frac{1}{n^2}\sum_{j=1}^{n-1}j^2\ln(u_{j+1}) - \frac{1}{n^2}\sum_{j=1}^{n-1}j^2\ln(u_j)\\ &- \frac{1}{n^2}\sum_{j=1}^{n-1}(j-n)^2\ln(1-u_{j+1})\\ &+ \frac{1}{n^2}\sum_{j=1}^{n-1}(j-n)^2\ln(1-u_j)\end{aligned} \tag{5.7.2304}$$

We now make some tricky algebraic manipulations (but simple) to condense the writing of the latter equality.

First, notice that we can write the first sum as (the reader can check the two sums are equal by developing for a small value of n to make an example):

$$\sum_{j=1}^{n-1} j^2\ln(u_{j+1})=\sum_{j=1}^{n}(j-1)^2\left(\ln(u_j)\right) \tag{5.7.2305}$$

which is equivalent to put $j=j-1$.

We transform also the second sum:

$$\sum_{j=1}^{n-1} j^2\ln(u_j)=\left(\sum_{j=1}^{n} j^2\ln(u_j)\right)-n^2\ln(u_n) \tag{5.7.2306}$$

and the reader can check that the equality below for the third sum is verified (if you problems for this don't hesitate to contact us):

$$\sum_{j=1}^{n-1}(j-n)^2\ln(1-u_{j+1})=-n^2\ln(1-u_1)-\left(\sum_{j=1}^{n}(j-1-n)^2\ln(1-u_j)\right) \tag{5.7.2307}$$

which also is equivalent to put $j=j-1$.

Finally, we transform the fourth sum (since in any case when j is equal to n then the term of the sum is zero ...):

$$\sum_{j=1}^{n-1}(j-n)^2\ln(1-u_j)=\sum_{j=1}^{n}(j-n)^2\ln(1-u_j) \tag{5.7.2308}$$

Therefore we have:

$$\begin{aligned}\frac{1}{n}W_n^2=&-\ln(1-u_1)-1-\ln(u_n)+\frac{1}{n^2}\sum_{j=1}^{n}(j-1)^2\left(\ln(u_j)\right)-\frac{1}{n^2}\left[\left(\sum_{j=1}^{n} j^2\ln(u_j)\right)-n^2\ln(u_n)\right]\\&-\frac{1}{n^2}\left[-n^2\ln(1-u_1)-\left(\sum_{j=1}^{n}(j-1-n)^2\ln(1-u_j)\right)\right]+\frac{1}{n^2}\sum_{j=1}^{n}(j-n)^2\ln(1-u_j)\end{aligned} \tag{5.7.2309}$$

Either by eliminating the terms that vanish:

$$\begin{aligned}\frac{1}{n}W_n^2=&-1+\frac{1}{n^2}\sum_{j=1}^{n}(j-1)^2\left(\ln(u_j)\right)-\frac{1}{n^2}\sum_{j=1}^{n} j^2\ln(u_j)+\frac{1}{n^2}\sum_{j=1}^{n}(j-1-n)^2\ln(1-u_j)\\&+\frac{1}{n^2}(j-n)^2\ln(1-u_j)\end{aligned} \tag{5.7.2310}$$

And by grouping the terms with the same form of logarithm:

$$\begin{aligned}\frac{1}{n}W_n^2&=-1-\frac{1}{n^2}\sum_{j=1}^{n}(2j-1)\ln(u_j)+\frac{1}{n^2}\sum_{j=1}^{n}(2j-2n-1)\ln(1-u_j)\\&=-1-\frac{1}{n^2}\sum_{j=1}^{n}\left[(2j-1)\ln(u_j)+(2(j-n)-1)\ln(1-u_j)\right]\end{aligned} \tag{5.7.2311}$$

Therefore:

$$W_n^2 = -n - \frac{1}{n}\sum_{j=1}^{n}\left[(2j-1)\ln(u_j) + (2(j-n)-1)\ln(1-u_j)\right] \tag{5.7.2312}$$

This is one of the closed form of the Anderson-Darling GoF test (especially well known as normality test) and that in the context of a Normal distribution is expressed by tradition in the following form:

$$\boxed{A_n^2 = -n - \frac{1}{n}\sum_{j=1}^{n}\left[(2j-1)\ln(\Phi(Y_j)) + (2(j-n)-1)\ln(1-\Phi(Y_j))\right]} \tag{5.7.2313}$$

But there is another very common simplified expression. To establish it, we start again from the prior-previous expression:

$$W_n^2 = -n - \frac{1}{n}\sum_{j=1}^{n}\left[(2j-1)\ln(u_j) + (2(j-n)-1)\ln(1-u_j)\right] \tag{5.7.2314}$$

By doing the change of variable $j = 1+n-i$ in the last sum, the expression:

$$(2(j-n)-1)\ln(1-u_j) \tag{5.7.2315}$$

becomes:

$$(1-2i)\ln(1-u_{1+n-i}) \tag{5.7.2316}$$

and the bounds of the sum becomes:

$$\begin{aligned} i &= 1+n-j \underset{j=1}{\Rightarrow} i = n \\ i &= 1+n-j \Rightarrow i = 1 \end{aligned} \tag{5.7.2317}$$

Therefore:

$$\sum_{j=1}^{n} = \sum_{i=n}^{1} = \sum_{i=1}^{n} \tag{5.7.2318}$$

Hence:

$$\begin{aligned} \frac{1}{n}W_n^2 &= -1 - \frac{1}{n^2}\sum_{j=1}^{n}(2j-1)\ln(u_j) + \frac{1}{n^2}\sum_{i=1}^{n}(1-2i)\ln(u_{1+n-i}) \\ &= -1 - \frac{1}{n^2}\sum_{j=1}^{n}(2j-1)\ln(u_j) + \frac{1}{n^2}\sum_{j=1}^{n}(1-2j)\ln(u_{1+n-j}) \\ &= -1 - \frac{1}{n^2}\sum_{j=1}^{n}(2j-1)\left[\ln(u_j) + \ln(u_{1+n-j})\right] \end{aligned} \tag{5.7.2319}$$

Finally:

$$\boxed{W_n^2 = \text{AD} = -n - \frac{1}{n}\sum_{j=1}^{n}(2j-1)\left[\ln(u_j) + \ln(u_{1+n-j})\right] = -n - \frac{1}{n}\sum_{j=1}^{n}S_j} \tag{5.7.2320}$$

✍**Example:**

Suppose we have measured the following five values:

$$-1.2, 0.2, -0.6, 0.8, -1.0$$

thus ordered:

$$x_1 = -1.2, x_2 = -1.0, x_3 = -0.6, x_4 = 0.2, x_5 = 0.8$$

We want to test the following null hypothesis:

$$H_0 : \text{CDF}(x_i) = \Phi(x_i) \tag{5.7.2321}$$

where $\Phi(x)$ is for recall the distribution function of the Normal centered reduced distribution $\mathcal{N}(0,1)$.

To implement the calculation of the AD in a spreadsheet software like Microsoft® Excel® 14.0.6123 we first do:

	A	B	C	D	E	F
1	x	j	Normal $\Phi(x_j)$	1-$\Phi(x_j)$	1-$\Phi(x_{n-j+1})$	S_j
2	-1.2	1	0.1151	0.8849	0.2119	-3.71
3	-1	2	0.1587	0.8413	0.4207	-8.12
4	-0.6	3	0.2743	0.7257	0.7257	-8.07
5	0.2	4	0.5793	0.4207	0.8413	-5.03
6	0.8	5	0.7881	0.2119	0.8849	-3.24

Figure 5.219: **Initial values for AD GoF test**

Explicitly:

	A	B	C	D	E	F
1	x	j	Normal $\Phi(x_j)$	1-$\Phi(x_j)$	1-$\Phi(x_{n-j+1})$	S_j
2	-1.2	1	=NORM.S.DIST(A2,1)	=1-C2	=1-INDEX($C$2:$C$6,COUNT($C$2:$C$6)-B2+1)	=(2*B2-1)*(LN(C2)+LN(E2))
3	-1	2	=NORM.S.DIST(A3,1)	=1-C3	=1-INDEX($C$2:$C$6,COUNT($C$2:$C$6)-B3+1)	=(2*B3-1)*(LN(C3)+LN(E3))
4	-0.6	3	=NORM.S.DIST(A4,1)	=1-C4	=1-INDEX($C$2:$C$6,COUNT($C$2:$C$6)-B4+1)	=(2*B4-1)*(LN(C4)+LN(E4))
5	0.2	4	=NORM.S.DIST(A5,1)	=1-C5	=1-INDEX($C$2:$C$6,COUNT($C$2:$C$6)-B5+1)	=(2*B5-1)*(LN(C5)+LN(E5))
6	0.8	5	=NORM.S.DIST(A6,1)	=1-C6	=1-INDEX($C$2:$C$6,COUNT($C$2:$C$6)-B6+1)	=(2*B6-1)*(LN(C6)+LN(E6))
7						
8	ΣS_j	=SUM(F2:F6)				
9	AD	=-COUNT(B2:B6)-(1/COUNT(B2:B6))*B8				

Figure 5.220: **Formulas in previous figure values for AD GoF test**

So we get the same value of the indicator AD that as statistical softwares that allows to choose the law to be compared (and therefore the parameters relating). However, for very small samples statistics software uses the following correction (which we were not able to re-obtain by simulation...):

$$\text{AD}^* = \text{AD}\left(1 + \frac{0.75}{n} + \frac{2.25}{n^2}\right) \tag{5.7.2322}$$

thus in our case AD* is about 0.789 as $\text{AD} = 0.636$.

Then to calculate the p-value we need to investigate a curiosity... Indeed if we determine it by a Monte Carlo simulation as we did during our practical application of the Kolmogorov-Smirnov test by first writing in the column `A` from a new sheet the following formulas:

	A	B
1	*x*	*j*
2	=LARGE($O$2:$O$6,6-B2)	1
3	=LARGE($O$2:$O$6,6-B3)	2
4	=LARGE($O$2:$O$6,6-B4)	3
5	=LARGE($O$2:$O$6,6-B5)	4
6	=LARGE($O$2:$O$6,6-B6)	5
7		

Figure 5.221: **Formulas to sort Monte Carlo simulated values for AD GoF test**

values coming from the column `O` where we have:

	O	P	Q
1	Simulated Values		
2	=NORM.INV(RANDBETWEEN(1,99999)/100000,$Q$10,$Q$11)		
3	=NORM.INV(RANDBETWEEN(1,99999)/100000,$Q$10,$Q$11)		
4	=NORM.INV(RANDBETWEEN(1,99999)/100000,$Q$10,$Q$11)		
5	=NORM.INV(RANDBETWEEN(1,99999)/100000,$Q$10,$Q$11)		
6	=NORM.INV(RANDBETWEEN(1,99999)/100000,$Q$10,$Q$11)		
7			
8	*i*		0
9			
10	Average		0
11	Standard Deviation		1

Figure 5.222: **Monte Carlo simulated formulas values for AD GoF test**

The reader will notice that this is same as comparing the sample with a uniform distribution!!!

Then having prepare the following columns `H`, `I` (see the figure below) that will contain the simulated values reported by the VBA code given a little further and columns `L`, `M` that allow us after to have the distribution of AD and AD values thanks to the calculation of the percentile:

	H	I	J	K	L	M
1	Values AD	Values AD*		Centiles	AD Values	AD* Values
2				0.05	=PERCENTILE(H:H,K2)	=PERCENTILE(I:I,K2)
3				0.1	=PERCENTILE(H:H,K3)	=PERCENTILE(I:I,K3)
4				0.15	=PERCENTILE(H:H,K4)	=PERCENTILE(I:I,K4)
5				0.2	=PERCENTILE(H:H,K5)	=PERCENTILE(I:I,K5)
6				0.25	=PERCENTILE(H:H,K6)	=PERCENTILE(I:I,K6)
7				0.3	=PERCENTILE(H:H,K7)	=PERCENTILE(I:I,K7)
8				0.35	=PERCENTILE(H:H,K8)	=PERCENTILE(I:I,K8)
9				0.4	=PERCENTILE(H:H,K9)	=PERCENTILE(I:I,K9)
10				0.45	=PERCENTILE(H:H,K10)	=PERCENTILE(I:I,K10)
11				0.5	=PERCENTILE(H:H,K11)	=PERCENTILE(I:I,K11)
12				0.55	=PERCENTILE(H:H,K12)	=PERCENTILE(I:I,K12)
13				0.6	=PERCENTILE(H:H,K13)	=PERCENTILE(I:I,K13)
14				0.65	=PERCENTILE(H:H,K14)	=PERCENTILE(I:I,K14)
15				0.7	=PERCENTILE(H:H,K15)	=PERCENTILE(I:I,K15)
16				0.75	=PERCENTILE(H:H,K16)	=PERCENTILE(I:I,K16)
17				0.8	=PERCENTILE(H:H,K17)	=PERCENTILE(I:I,K17)
18				0.85	=PERCENTILE(H:H,K18)	=PERCENTILE(I:I,K18)
19				0.9	=PERCENTILE(H:H,K19)	=PERCENTILE(I:I,K19)
20				0.95	=PERCENTILE(H:H,K20)	=PERCENTILE(I:I,K20)
21				1	=PERCENTILE(H:H,K21)	=PERCENTILE(I:I,K21)

Figure 5.223: Columns for writing the AD/AD* values computed by VBA and the percentiles calculations

with the little VBA code below quickly and dirty made:

Listing 5.1: VBA code of the AD GoF test

```
Sub SimulAndersonDarling()

        Const intSimulations As Integer = 1000
        Dim i As Integer

        For i=1 To intSimulations
                Calculate
                Cells(i+1, 8).Value = Cells(9, 2).Value
                Cells(i+1, 9).Value = Cells(10, 2).Value
                Cells(8, 17).Value = i
        Next i
End Sub
```

we then have with $10,000$ simulations the following distribution of AD and AD* values:

	K	L	M
1	Centiles	AD Values	AD* Values
2	5%	0.28235841	0.3156881
3	10%	0.34331007	0.39023333
4	15%	0.39526256	0.44586877
5	20%	0.4424214	0.49964226
6	25%	0.49337676	0.55801007
7	30%	0.54662189	0.61132471
8	35%	0.59828249	0.66796248
9	40%	0.6526198	0.7274192
10	45%	0.71248569	0.7991897
11	50%	0.77535595	0.87396866
12	55%	0.84854141	0.95459933
13	60%	0.93389709	1.04380898
14	65%	1.02435047	1.14362702
15	70%	1.13045717	1.26941172
16	75%	1.25027483	1.40437671
17	80%	1.41974411	1.58435554
18	85%	1.63511945	1.83133612
19	90%	1.97079527	2.18289416
20	95%	2.57162931	2.83783249
21	100%	8.07906414	9.29234012

Figure 5.224: AD GoF test percentiles

So whether it is for AD or AD* the p-value is in our particular case almost equal to $1-40\%=60\%$ which corresponds to the tabulated values by Peter A.W. Lewis at IBM (11961 according to holocene calendar).

What is curious and that we need to investigate is that the majority of software use the following formulas (R.B. D'Agostino and M.A. Stephens, Eds., 11986 (holocene calendar), Goodness-of-Fit Technology, Marcel Dekker) to avoid Monte Carlo simulations:

$$\begin{aligned}
&\text{AD}^*\geq 0.6\Rightarrow p\text{-values}\cong e^{1.2937-5.709\text{AD}^*+0.0186\text{AD}^{*2}}\\
&0.34\leq\text{AD}^*<0.6\Rightarrow p\text{-values}\cong e^{0.9177-4.279\text{AD}^*-1.38\text{AD}^{*2}}\\
&0.2\leq\text{AD}^*<0.34\Rightarrow p\text{-values}\cong 1-e^{-8.318+42.796\text{AD}^*-59.938\text{AD}^{*2}}\\
&\text{AD}^*\leq 0.2\Rightarrow p\text{-values}\cong 1-e^{-13.436+101.14\text{AD}^*-223.73\text{AD}^{*2}}
\end{aligned}\tag{5.7.2323}$$

and in our case, the application of these formulas give a p-value of about 9% !!! Value actually given by statistical softwares! We will try to find where this difference comes from as our calculation seem subjectively more accurate than this empirical formulas... We asked the support of an American statistical package editor to explain the reason for the difference between the values tabulated by Peter A.W. Lewis and those of R.B D'Augostino and M.A. Stephens but they were not able to answer. We also contacted M.A. Stephens himself so that he can communicate us how he had obtained these formulas but we never get any answers ...

5.7.13.9.6 Cramér–von Mises GoF Test

In statistics the Cramér–von Mises GoF test (considered by many as a nonparametric test) is used for judging the goodness of fit of a cumulative distribution function F^* compared to a given empirical distribution function F_n, or for comparing two empirical distributions (the criterion is named after Harald Cramér and Richard Edler von Mises who first proposed it in 11928–11930 according to holocene calendar). It is also used as a part of other algorithms, such as minimum distance estimation. It is commonly defined as following (as we have already introduced it just earlier above):

$$W^2 = n \int_{-\infty}^{+\infty} (F_n(x) - F^*(x))^2 \, \mathrm{d}F^*(x) \tag{5.7.2324}$$

but should better be written as:

$$W^2 = \int \left(\hat{F}_n(t) - F_0(t)\right)^2 \mathrm{d}F_0(t) \tag{5.7.2325}$$

In one-sample applications F^* is the theoretical distribution and F_n is the empirically observed distribution. Alternatively the two distributions can both be empirically estimated ones; this is named the "two-sample case".

We want to derive the Cramér-von Mises test statistic (said to be with n-degrees of freedom):

$$\boxed{W^2 = \frac{1}{12n} + \sum_{i=1}^{n} \left(U_i - \frac{2i-1}{2n}\right)^2} \tag{5.7.2326}$$

where $U_i = F_0(X_{i:n})$ is the theoretical order statistics from the original (that's why it's a parametric test! We need to estimate the parameters of the original distribution):

$$\frac{W^2}{n} := C_n = \int \left(\hat{F}_n(t) - F_0(t)\right)^2 \mathrm{d}F_0(t) \tag{5.7.2327}$$

Notice that this statistic is tabulated[84] against the null hypothesis H_0 that $\hat{F}_n(t) = F_0(t)$.

Let $X_1, \ldots, X_n$ be a random sample of size n from $f(x)$. The empirical CDF is:

$$\hat{F}_n(x) = \frac{1}{n} \sum_{i=1}^{n} I(X_i \leq x) = \begin{cases} 0 & \text{if } x < X_{1:n} \\ i/n & \text{if } X_{i:n} \leq x < X_{i+1:n} \\ 1 & \text{if} X_{n:n} \leq x \end{cases} \tag{5.7.2328}$$

---

[84] Mainly and sadly only for the Normal distribution also in some of the most important statistical softwares.

Let $U_i=F_0(X_{i:n})$, then (the reader will see that there are some quite clever simplifications):

$$\begin{aligned}
C_n &\triangleq \int \left[\hat{F}_n(x)-F_0(x)\right]^2 \mathrm{d}F_0(x)\\
&=\int\limits_{-\infty}^{X_{1:n}}\left[-F_0(x)\right]^2 \mathrm{d}F_0(x)+\sum_{i=1}^{n-1}\int\limits_{X_{i:n}}^{X_{i+1:n}}\left[\frac{i}{n}-F_0(x)\right]^2 \mathrm{d}F_0(x)+\int\limits_{X_{n:n}}^{+\infty}\left[1-F_0(x)\right]^2 \mathrm{d}F_0(x)\\
&=\frac{1}{3}U_1^3+\frac{1}{3}\sum_{i=1}^{n-1}\left[\left(U_{i+1}-\frac{i}{n}\right)^3-\left(U_i-\frac{i}{n}\right)^3\right]-\frac{1}{3}(U_n-1)^3\\
&=\frac{1}{3}U_1^3+\frac{1}{3}\sum_{i=1}^{n-1}\left[U_{i+1}^3-U_i^3+\frac{3i^2}{n^2}\left(U_{i+1}-U_i\right)-\frac{3i}{n}\left(U_{i+1}^2-U_i^2\right)\right]-\frac{1}{3}(U_n-1)^3
\end{aligned}\tag{5.7.2329}$$

Now we use:

$$\begin{aligned}
\sum_{i=1}^{n-1}i^2(U_{i+1}-U_i)&=\sum_{i=2}^{n}(i-1)^2U_i-\sum_{i=1}^{n-1}i^2U_i=(n-1)^2U_n-U_1-\sum_{i=2}^{n-1}(2i-1)U_i\\
&=n^2U_n-\sum_{i=1}^{n}(2i-1)U_i
\end{aligned}\tag{5.7.2330}$$

Therefore:

$$\begin{aligned}
C_n &\triangleq \frac{1}{3}U_1^3+\frac{1}{3}U_n^3-\frac{1}{3}U_1^3+\left(U_n-\sum_{i=1}^{n}\frac{2i-1}{n^2}U_i\right)-\left(U_n^2-\sum_{i=1}^{n}\frac{1}{n}U_i^2\right)-\frac{1}{3}(U_n-1)^3\\
&=\frac{1}{3}+\frac{1}{n}\sum_{i=1}^{n}\left(U_i^2-\frac{2i-1}{n}U_i\right)=\frac{1}{3}+\frac{1}{n}\sum_{i=1}^{n}\left(U_i-\frac{2i-1}{2n}\right)^2-\frac{1}{n}\sum_{i=1}^{n}\left(\frac{2i-1}{2n}\right)^2\\
&=\frac{1}{3}+\frac{1}{n}\sum_{i=1}^{n}\left(U_i-\frac{2i-1}{2n}\right)^2-\frac{1}{4n^2}\sum_{i=1}^{n}(2i-1)^2\\
&=\frac{1}{3}+\frac{1}{n}\sum_{i=1}^{n}\left(U_i-\frac{2i-1}{2n}\right)^2-\frac{1}{4n^2}\frac{1}{3}n(4n^2-1)\\
&=\frac{1}{12n^2}+\frac{1}{n}\sum_{i=1}^{n}\left(U_i-\frac{2i-1}{2n}\right)^2
\end{aligned}\tag{5.7.2331}$$

Therefore:

$$W^2=nC_n=\frac{1}{12n}+\sum_{i=1}^{n}\left(U_i-\frac{2i-1}{2n}\right)^2\tag{5.7.2332}$$

✍Example:

Consider we have the following parameters from a sample:

$$\bar{X} = 6.4034 \qquad \text{and} \qquad \sigma_X = 3.299319$$

Assuming a Normal distribution $\mathcal{N}(\bar{X}, \sigma_X)$, we get for each of the values:

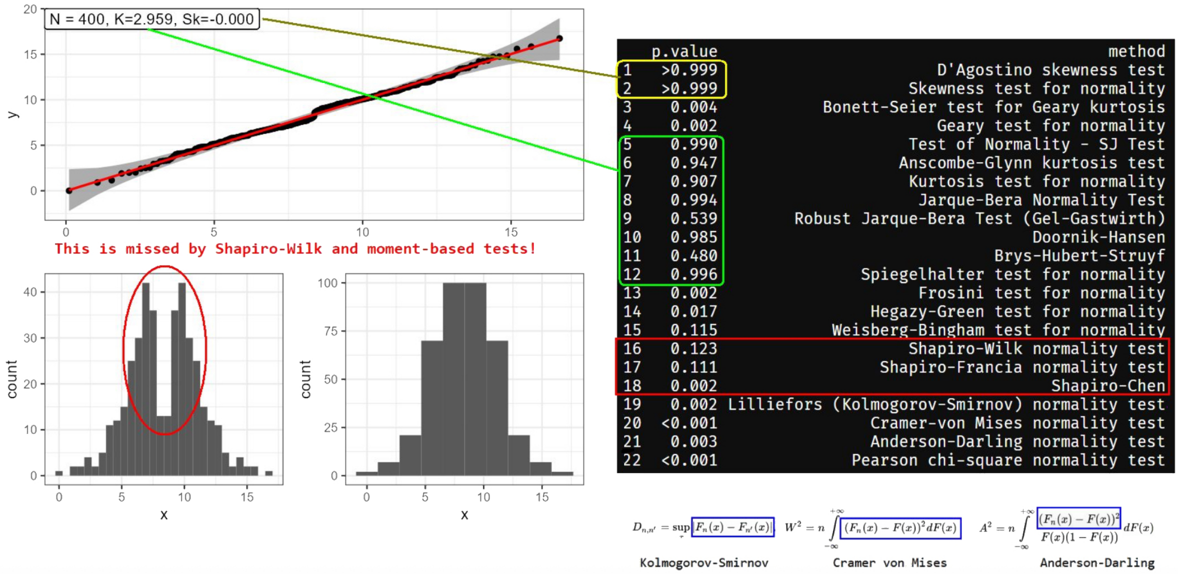
$$F_0(X) = (0.04943849, 0.05925460, 0.06477221, 0.07101753, 0.13526439, 0.25218337, 0.31746223, 0.38651837, 0.48830421, 0.67550752, 0.68425558, 0.69965168, 0.78797818, 0.79458401, 0.79661282, 0.83025028, 0.83051069, 0.83202204, 0.83609969, 0.84033359)$$

Let us calculate now the Cramér-von Mises statistic using:

$$\begin{aligned} W^2 &= \frac{1}{12 \cdot 20} + \sum_{i=1}^{20} \left(\frac{F(x_i) - (2 \cdot i - 1)}{20 \cdot 20} \right)^2 \\ &= \frac{1}{240} + \left(\frac{0.04943849 - (2-1)}{40} \right)^2 + \cdots \left(\frac{0.84033359 - (40-1)}{40} \right)^2 \\ &= \frac{1}{240} + (0.005972399 + 0.0002479177 + 0.003627386 + \cdots + 0.01813504) \\ &= 0.04166667 + 0.1861175 = 0.1902842 \end{aligned} \tag{5.7.2333}$$

We get here $W^2 = 0.1902842$ that we report in the Cramér-von Mises table for 20 degrees of freedom, which gives a p-value of $0.006 < 5\%$. Hence, we reject H_0 and we conclude that the distribution function of X is very likely not drawn from a Normal distribution.

There are almost half a hundred of GoF tests and because all of them have different assumptions they don't lead the same results as illustrated below with a bi-modal quasi-Gaussian distribution:



```
   p.value                                    method
1   >0.999                  D'Agostino skewness test
2   >0.999               Skewness test for normality
3    0.004        Bonett-Seier test for Geary kurtosis
4    0.002                  Geary test for normality
5    0.990               Test of Normality - SJ Test
6    0.947                Anscombe-Glynn kurtosis test
7    0.907               Kurtosis test for normality

17   0.111           Shapiro-Francia normality test
18   0.002                             Shapiro-Chen
19   0.002 Lilliefors (Kolmogorov-Smirnov) normality test
20  <0.001           Cramer-von Mises normality test
21   0.003           Anderson-Darling normality test
22  <0.001          Pearson chi-square normality test
```

$$D_{n,n'} = \sup_x \boxed{|F_n(x) - F_{n'}(x)|} \qquad W^2 = n \int_{-\infty}^{+\infty} \boxed{(F_n(x) - F(x))^2 dF(x)} \qquad A^2 = n \int_{-\infty}^{+\infty} \frac{\boxed{(F_n(x) - F(x))^2}}{F(x)(1 - F(x))} dF(x)$$

Kolmogorov-Smirnov Cramer von Mises Anderson-Darling

5.7.13.10 Kernel density estimation

In statistics, "kernel density estimation" (KDE) or "kernel smoothing" is a nonparametric way to estimate the probability density function of a random variable, but also to do some special regressions (see section Numerical Methods page 6447). Kernel density estimation is a fundamental data smoothing problem in business and science where inferences about the population are made, based on a finite data sample. In some fields such as signal processing and econometrics it is also termed the "Parzen–Rosenblatt window method", after Emanuel Parzen and Murray Rosenblatt, who are usually credited with independently creating it in its current form.

The nonparametric estimation of a probability density function is very important in all domains using statistics! We already know that the technique making use of histograms is very delicate and questionable because it is necessary to choose the right interval width for each of the bars, which is very subjective and the Sturges rule that we have seen earlier can be discussed!

To introduce the subject we first recall that we have in the univariate case:

$$F(x-h<X<x+h)=P(x-h<X<x+h)=\int\limits_{x-h}^{x+h} f(t)\mathrm{d}t \qquad (5.7.2334)$$

Or what is sometimes written more elegantly:

$$F(x\in I_j)=P(x\in I_j)=\int\limits_{I_j} f(t)\mathrm{d}t \qquad (5.7.2335)$$

Based on the method of numerical integration with rectangles (see section Numerical Methods page 6623) we can write:

$$P(x-h<X<x+h)=\int\limits_{x-h}^{x+h} f(t)\mathrm{d}t\cong 2hf(x) \qquad (5.7.2336)$$

Therefore, we have:

$$f(x)\cong\frac{1}{2h}P(x-h<X<x+h) \qquad (5.7.2337)$$

The above probability can be estimated by the relative frequency of observations:

$$\hat{f}(x)=\frac{1}{2h}\frac{\#\text{ observations in the interval }]x-h,x+h[}{n} \qquad (5.7.2338)$$

What is sometimes written:

$$\hat{f}(x)=\frac{1}{2h}\frac{\#\{x_i\in I_j\}}{n} \qquad (5.7.2339)$$

An alternative non-trivial writing (and equal in numerical value!) is:

$$\hat{f}(x)=\frac{1}{n}\sum_{i=1}^{n}w(x-x_i)=\frac{1}{n}\sum_{i=1}^{n}w(t,h) \qquad (5.7.2340)$$

where $x_1, x_2, \ldots, x_n$ are the observed values and:

$$w(x-x_i,h)=w(t,h)=\begin{cases}\dfrac{1}{2h} & |t|<h \\ 0 & \text{otherwise}\end{cases} \qquad (5.7.2341)$$

is named the "weight of the kernel" function or "univariate Rosenblatt kernel function". The later relation is also often denoted:

$$\hat{f}(x)=\frac{1}{nh}\sum_{i=1}^{n}K\left(\frac{x-x_i}{h}\right) \qquad (5.7.2342)$$

With (notation a little unfortunate in my point of view...):

$$K(x)=K\left(\frac{x-x_i}{h}\right)=\begin{cases}\dfrac{1}{2} & |x-x_i|<h \\ 0 & \text{otherwise}\end{cases} \qquad (5.7.2343)$$

and where h is named the "bandwidth".

In general, a "kernel function" $K(x)$ is a function that must satisfy the following properties:

P1. The kernel function is greater than or equal to zero $K(x)\geq 0$

P2. The kernel function is maximum in $x=0$

P3. The kernel function is symmetric with respect to the vertical axis passing through $x=0$

P4. The kernel function tends to zero away from $x=0$ such that $\lim_{|x|\to+\infty}K(x)=0$

P5. The kernel function is a probability density function

The property P1 is obvious to control and it does not require any proof even in more complicated cases than the kernel function taken as an example previously.

The property P2 is more an implementation constraint rather than a property. To be satisfied, we must simply center the values (measurements) with the which we work and assume that the distribution is unimodal.

The property P3 is also more an implementation constraint than a property. It will be useful to us to simplify certain calculations such as the bias of the expected mean or of the standard deviation (see below).

The property P4 applies by common sense and derives from the property P2. In the case of unimodal probability density functions (reason why this property is often omitted from the statements).

To check property P5 it is sufficient to show that the cumulative probability is unitary.

Proof 5.48.7. We know by construction of the previous kernel function that on each point is placed a rectangle of height $1/2h$ and of width $2h$. Then, the idea is simply to write:

$$\begin{aligned}\sum_i \hat{f}(x_i)2h &= \sum_i \left[\frac{1}{nh}K\left(\frac{x-x_i}{h}\right)\right]2h = \sum_i \frac{1}{2h}\frac{\#\{x_i \in [x_i-h, x_i+h]\}}{n}2h\\ &= \sum_i \frac{\#\{x_i \in [x_i-h, x_i+h]\}}{n} = \sum_{i=1}^{n}\frac{1}{n} = n\frac{1}{n} = 1\end{aligned} \quad (5.7.2344)$$

■ Q.E.D.

Some examples of kernel functions that satisfy these properties are (the most important ones have already been dissected in the previous subsections) to a given normalization constant:

- The Gaussian kernel:

$$K(x) = \frac{1}{\sqrt{2\pi}}e^{-\frac{1}{2}x^2} \quad (5.7.2345)$$

- The Cauchy kernel:

$$K(x) = \frac{1}{\pi(1+x^2)} \quad (5.7.2346)$$

- The Picard kernel:

$$K(x) = \frac{1}{2}e^{-|x|} \quad (5.7.2347)$$

- The Epanechnikov kernel:

$$K(x) = \begin{cases}\frac{3}{4}(1-x^2) & \text{when } t \in [-1,1]\\ 0 & \text{otherwise}\end{cases} \quad (5.7.2348)$$

Let us now consider some important properties of the empirical density function.

Let us calculate its expected mean (as it is a matter of calculating the expected mean of the density function itself, this will ultimately give us the bias of the expected mean):

$$\text{E}(x) = \text{E}\left(\sum_{i=1}^{n}\frac{1}{nh}K\left(\frac{x-x_i}{h}\right)\right) = \frac{1}{nh}\sum_{i=1}^{n}\text{E}\left(K\left(\frac{x-x_i}{h}\right)\right) \quad (5.7.2349)$$

For example, for a Gaussian kernel we have:

$$\begin{aligned}\text{E}(X) &= \int x\hat{f}(x)\mathrm{d}x = \int \frac{x}{n}\sum_{i=1}^{n}\frac{1}{h}K\left(\frac{x-x_i}{h}\right)\mathrm{d}x\\ &= \int \sum_{i=1}^{n}\frac{x}{nh}K\left(\frac{x-x_i}{h}\right)\mathrm{d}x = \int \sum_{i=1}^{n}\frac{x}{nh\sqrt{2\pi}}e^{-\frac{1}{2}\left(\frac{x-x_i}{h}\right)^2}\mathrm{d}x\end{aligned} \quad (5.7.2350)$$

From this point on, the variable of which we take the expectation, that is:

$$\mathrm{E}\left(K\left(\frac{x-x_i}{h}\right)\right) \tag{5.7.2351}$$

is no longer a probability density function but a simple transformed random variable. We will therefore extend to the continuous case and multiply it by its true probability. The very clever idea being that if the bias is zero we should find:

$$\mathrm{E}(\hat{f}(x))=\mathrm{E}(f(x))=f(x) \tag{5.7.2352}$$

and if we don't fall back on this result. The difference will give us the bias we are looking for!

Let us check that:

$$\begin{aligned}\mathrm{E}(\hat{f}(x))&=\int\limits_{-\infty}^{+\infty}\frac{1}{nh}\sum_{i=1}^{n}\mathrm{E}\left(K\left(\frac{x-t}{h}\right)\right)f(t)\mathrm{d}t=\frac{1}{nh}\int\limits_{-\infty}^{+\infty}K\left(\frac{x-t}{h}\right)f(t)\mathrm{d}t\\&=\frac{1}{nh}n\int\limits_{-\infty}^{+\infty}K\left(\frac{x-t}{h}\right)f(t)\mathrm{d}t=\frac{1}{h}\int\limits_{-\infty}^{+\infty}K\left(\frac{x-t}{h}\right)f(t)\mathrm{d}t\end{aligned} \tag{5.7.2353}$$

Let us put to simplify the further developments:

$$z=\frac{x-t}{h}\Leftrightarrow t=x-hz\Rightarrow\frac{\mathrm{d}z}{\mathrm{d}t}=-\frac{1}{h} \tag{5.7.2354}$$

and therefore:

$$\mathrm{E}(\hat{f}(x))=\frac{1}{h}\int\limits_{-\infty}^{+\infty}K(z)f(x-hz)(-h)\mathrm{d}z=-\int\limits_{-\infty}^{+\infty}K(z)f(x-hz)\mathrm{d}z \tag{5.7.2355}$$

Let us develop the function $f(x-hz)$ as a Taylor series development (see section Sequences and Series page 1696) on $z=0$:

$$\begin{aligned}f(x-hz)&\cong f(x)+\frac{1}{1!}f'(x)\left((x-hz)-x\right)+\frac{1}{2!}f'(x)\left((x-hz)-x\right)^2+\mathcal{O}(h^2)\\&=f(x)+f'(x)(-hz)+\frac{1}{2!}f''(x)(-hz)^2+\mathcal{O}(h^2)\\&=f(x)-hzf'(x)+\frac{1}{2!}(hz)^2f''(x)+\mathcal{O}(h^2)\end{aligned} \tag{5.7.2356}$$

Then we have:

$$\begin{aligned}\mathrm{E}(\hat{f}(x))&=-\int\limits_{-\infty}^{+\infty}K(z)f(x-hz)\mathrm{d}z\cong-\int\limits_{-\infty}^{+\infty}\left[f(x)+hzf'(x)+\frac{(hz)^2}{2}f''(x)\right]\mathrm{d}z\\&=-f(x)\int\limits_{-\infty}^{+\infty}K(z)\mathrm{d}z+hf'(x)\int\limits_{-\infty}^{+\infty}zK(z)\mathrm{d}z+\frac{h^2}{2}f''(x)\int\limits_{-\infty}^{+\infty}z^2K(z)\mathrm{d}z\end{aligned} \tag{5.7.2357}$$

But, we know that if the kernel function is symmetric and maximal at zero (unimodal) then we can invert the sign of the first integral:

$$\mathrm{E}(\hat{f}(x))=f(x)\int\limits_{+\infty}^{-\infty}K(z)\mathrm{d}z+hf'(x)\int\limits_{-\infty}^{+\infty}zK(z)\mathrm{d}z+\frac{h^2}{2}f''(x)\int\limits_{-\infty}^{+\infty}z^2K(z)\mathrm{d}z \qquad (5.7.2358)$$

The first integral is equal to 1 since the kernel function is a probability density function. Then it remains:

$$\mathrm{E}(\hat{f}(x))=f(x)+hf'(x)\int\limits_{-\infty}^{+\infty}zK(z)\mathrm{d}z+\frac{h^2}{2}f''(x)\int\limits_{-\infty}^{+\infty}z^2K(z)\mathrm{d}z \qquad (5.7.2359)$$

The second integral calculates the expected mean. Now, since the kernel function is supposed to be symmetric and maximal in zero, it follows that its expected mean is zero and therefore it remains:

$$\mathrm{E}(\hat{f}(x))=f(x)+\frac{h^2}{2}f''(x)\int\limits_{-\infty}^{+\infty}z^2K(z)\mathrm{d}z=f(x)+\frac{h^2}{2}f''(x)\sigma^2 \qquad (5.7.2360)$$

And therefore the bias of the expected mean is:

$$\text{Bias}\left(\mathrm{E}(\hat{f}(x))\right)\cong\frac{h^2}{2}f''(x)\sigma^2 \qquad (5.7.2361)$$

Thus the bias decreases if we decrease h (but we will immediately show that it is the opposite for the variance).

Now therefore let us calculate the variance:

$$\mathrm{V}\left(\hat{f}(x)\right)=\mathrm{V}\left(\sum_{i=1}^{n}\frac{1}{nh}K\left(\frac{x-x_i}{h}\right)\right)=\frac{1}{n^2h^2}\sum_{i=1}^{n}\mathrm{V}\left(K\left(\frac{x-x_i}{h}\right)\right) \qquad (5.7.2362)$$

Because the x_i, $i=1,2,\ldots,n$, are independently distributed. Now using Huygens Theorem:

$$\begin{aligned}\mathrm{V}\left(K\left(\frac{x-x_i}{h}\right)\right)&=\mathrm{E}\left(K\left(\frac{x-x_i}{h}\right)^2\right)-\left(\mathrm{E}\left(\frac{x-x_i}{h}\right)\right)^2\\&=\int K\left(\frac{x-t}{h}\right)^2f(t)\mathrm{d}t-\left(\int K\left(\frac{x-t}{h}\right)f(t)\mathrm{d}t\right)\end{aligned} \qquad (5.7.2363)$$

Therefore:

$$\begin{aligned}\mathrm{V}(\hat{f}(x))&=\frac{1}{n}\int\frac{1}{h^2}K\left(\frac{x-t}{h}\right)^2f(t)\mathrm{d}t-\frac{1}{n}\left(\frac{1}{h}\int K\left(\frac{x-t}{h}\right)f(t)\mathrm{d}t\right)^2\\&=\frac{1}{n}\int\frac{1}{h^2}K\left(\frac{x-t}{h}\right)^2f(t)\mathrm{d}t-\frac{1}{n}\left(f(x)+\text{Bias}\left(\hat{f}(x)\right)\right)\end{aligned} \qquad (5.7.2364)$$

Substituting $z=(x-t)/h$ we get:

$$\mathrm{V}(\hat{f}(x))=\frac{1}{nh}\int K(z)^2f(x-hz)\mathrm{d}z-\frac{1}{n}\left(f(x)+\mathcal{O}(h^2)\right) \qquad (5.7.2365)$$

Applying again a Taylor approximation yields:

$$\mathrm{V}(\hat{f}(x)) \cong \frac{1}{nh}\int K(z)^2\left(f(x)-hzf'(x)+\mathcal{O}(h)\right)-\frac{1}{n}\left(f(x)+\mathcal{O}(h^2)\right)^2 \tag{5.7.2366}$$

Notice that if n becomes large and h becomes small then the above expression become approximately:

$$\mathrm{V}(\hat{f}(x)) \cong \frac{1}{nh}f(x)\int K^2(z)\mathrm{d}z \tag{5.7.2367}$$

we notice that the variance decreases as h increases.

Selection of the bandwidth h of kernel estimator is a subject of considerable research. There exist more than one heuristic popular method but at least they are all more robust than the Sturge rule!

Here are some examples without the script of some Kernel smoothing:

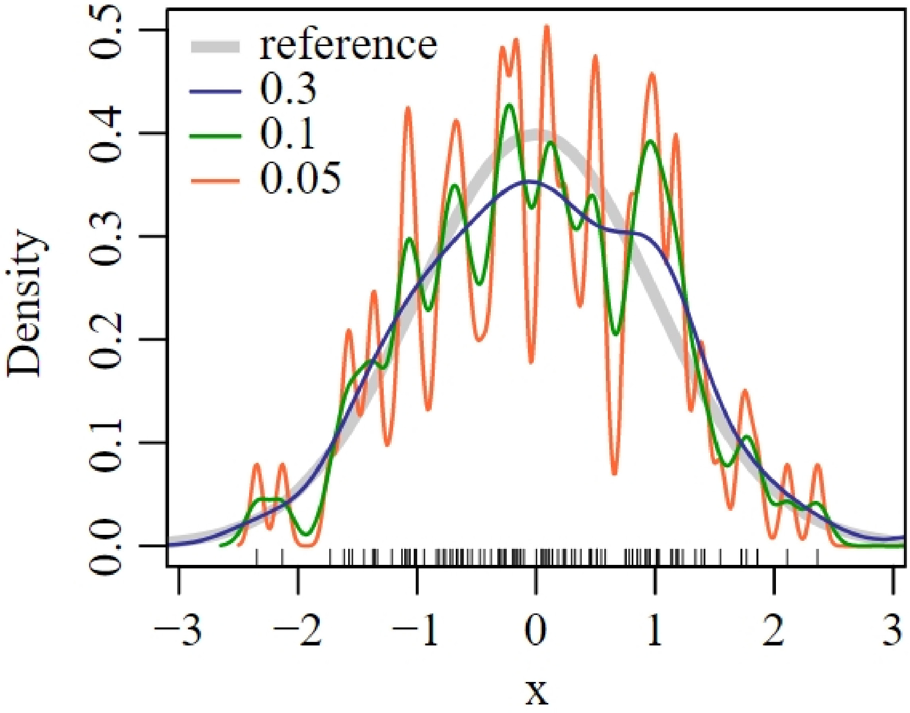

Figure 5.225: **Kernel density estimation of 100 normally distributed random numbers using different smoothing bandwidths (source: Wikipedia)**

and a comparison between a histogram and a Kernel smoothing:

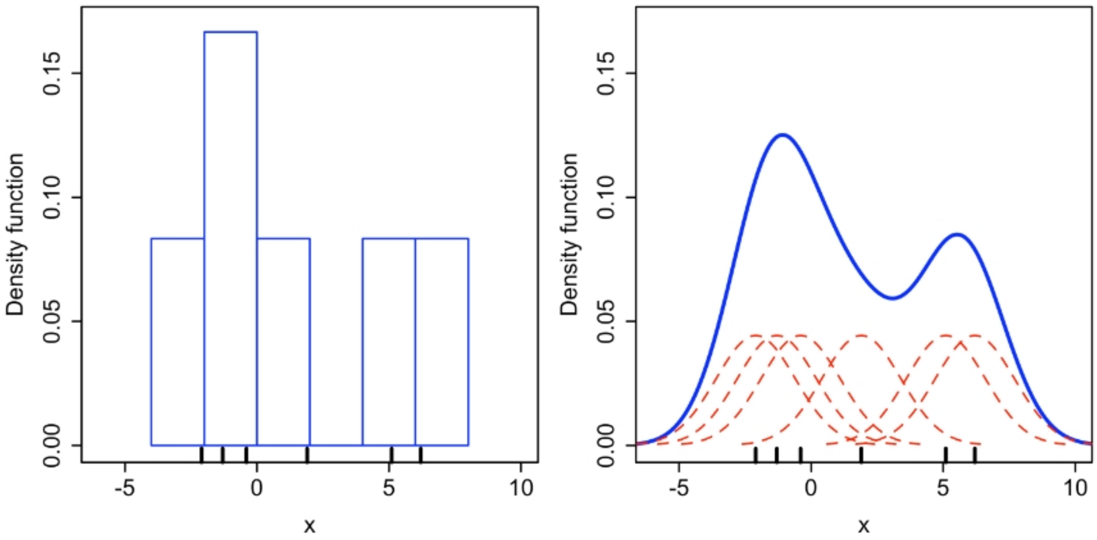

Figure 5.226: Comparison of histogram (left) and kernel density estimate (right) constructed from the same data. The individual 6 kernels are the red dotted curves, the density of the kernel estimates the blue curve. The data points are the small vertical lines the horizontal axis (source: Wikipedia)

And another interesting figure highlighting the issue of histograms [601]:

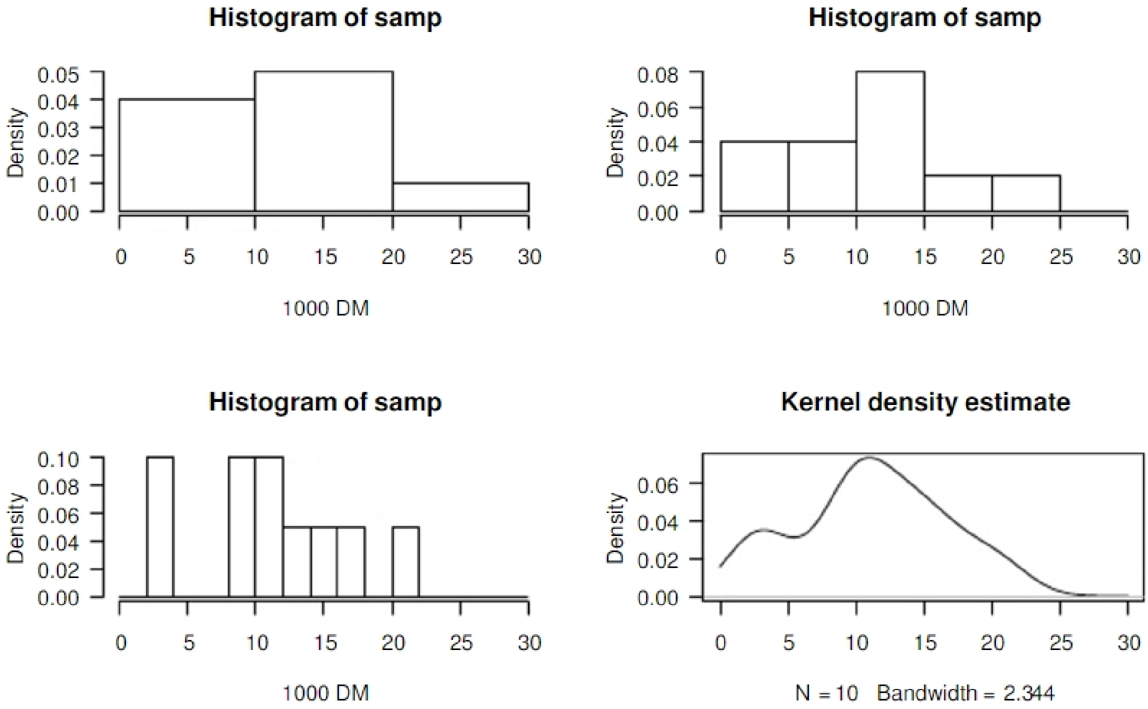

Figure 5.227: Histograms with different bin widths and a kernel estimate of $f(x)$ for the same sample

The reader interested can see our R and MATLAB® companion books to get the details on how to run Kernel smoothing on scientific softwares.

5.7.13.11 Likelihood-ratio Tests

Many statistics software returns, in complementary of classical statistical results, an output that is sometimes named "maximum likelihood test" or "maximum likelihood ratio test" (LRT) for a test whose result is already given. This maximum likelihood test is also sometimes the unique output as classical methods does not provide a computable or accurate output (this is the case of the G-test and Poisson test of means). As we will see just below, the principle is basically ... extremely simple!

Let us recall that we have proved that for a Normal law during our study of likelihood estimators that:

$$\ln\left(L(\mu,\sigma^2)\right)=-\frac{n}{2}\ln(2\pi)-n\ln(\sigma)-\frac{1}{2\sigma^2}\sum_{i=1}^{n}(x_i-\mu)^2 \tag{5.7.2368}$$

For example, if we know the standard deviation but we try to estimate the mean then this last relation can be written:

$$\ln\left(L(\hat{\mu})\right)=\left(-\frac{1}{2}\sum_{i=1}^{n}\frac{(x_i-\hat{\mu})^2}{\sigma^2}\right)+c^{te} \tag{5.7.2369}$$

Then nothing prevents us from writing:

$$\ln\left(L(\mu)\right)-\ln\left(L(\hat{\mu})\right)=\left[\left(-\frac{1}{2}\sum_{i=1}^{n}\frac{(x_i-\mu)^2}{\sigma^2}\right)+c^{te}\right]-\left[\left(-\frac{1}{2}\sum_{i=1}^{n}\frac{(x_i-\hat{\mu})^2}{\sigma^2}\right)+c^{te}\right] \tag{5.7.2370}$$

Therefore after some very small elementary algebra and arithmetic manipulations:

$$-2\ln\left(\frac{L(\mu)}{L(\hat{\mu})}\right)=\sum_{i=1}^{n}\frac{(x_i-\mu)^2}{\sigma^2}-\sum_{i=1}^{n}\frac{(x_i-\hat{\mu})^2}{\sigma^2}=\sum_{i=1}^{n}\frac{(x_i-\hat{\mu})^2-(x_i-\mu)^2}{\sigma^2} \tag{5.7.2371}$$

In the case of following hypothesis (two sided Student T-test) with the assumption of homoscedasticity:

$$\begin{aligned}H_0&:\ \mu=\hat{\mu}\\ H_1&:\ \mu\neq\hat{\mu}\end{aligned} \tag{5.7.2372}$$

We have:

$$\frac{(x_i-\hat{\mu})^2-(x_i-\mu)^2}{\sigma^2}=(\mathcal{N}(0,1))^2 \tag{5.7.2373}$$

Therefore under the null hypothesis:

$$-2\ln\left(\frac{L(\mu)}{L(\hat{\mu})}\right)=\sum_{i=1}^{n}\frac{(x_i-\hat{\mu})^2-(x_i-\mu)^2}{\sigma^2}=\sum_{i=1}^{n}Z_i^2=\chi^2_{n-1} \tag{5.7.2374}$$

That is often denoted:

$$\boxed{\Lambda=-2\ln\left(\frac{L(\mu)}{L(\hat{\mu})}\right)=-2\left(\ln(\vec{\theta})-\ln(\hat{\vec{\theta}})\right)=\chi^2_{n-1}} \tag{5.7.2375}$$

and is the "likelihood ratio test for the comparison of the means from a Normal law" or "maximum likelihood goodness-of-test for normality".

Remark

Some softwares use for reasons I was mathematically not able to prove a chi-square distribution χ^2_{n-d-1}, where d is the number of parameters of the implicit assumed distribution law ($d=1$ for a Poisson law or $d=2$ for a Normal distribution, etc.).

Therefore we see already, before continuing, that a likelihood ratio test is a statistical test used for comparing the goodness of fit of two models, one of which (the null model) is a special case of the other (the alternative model). The test is based on the likelihood ratio, which expresses how many times more likely the data are under one model than the other. This likelihood ratio, or equivalently its logarithm, can then be used obviously to compute a p-value, or compared to a critical value to decide whether to reject the null model in favour of the alternative model. When the logarithm of the likelihood ratio is used, the statistic is known as a "log-likelihood ratio statistic", and the probability distribution of this test statistic, assuming that the null model is true, can be approximated using "Wilks' theorem" (approximation by a chi-squared distribution).

Remark

In the case of distinguishing between two models, each of which has no unknown parameters, use of the likelihood ratio test can be justified by the Neyman–Pearson lemma, which demonstrates that such a test has the highest power among all competitors. But this is out of the scope of this textbook (at least actually...).

In practice we find more often the test of the ratio of maximum likelihood with the Poisson's law. We recall that for the latter we have also proved during our study of likelihood estimators:

$$\ln\left(L(\mu)\right)=\ln(\mu)\sum_{i=1}^n x_i-\sum_{i=1}^n \ln(x_i!)-\mu n \tag{5.7.2376}$$

Therefore:

$$\ln\left(L(\mu)\right)=\sum_{i=1}^n \left(x_i\ln(\mu)-\mu\right)+c^{te} \tag{5.7.2377}$$

As for the case with the Normal law, we can write:

$$\ln\left(L(\mu)\right)-\ln\left(L(\hat{\mu})\right)=\left[\sum_{i=1}^n \left(x_i\ln(\mu)-\mu\right)+c^{te}\right]-\left[\sum_{i=1}^n \left(x_i\ln(\hat{\mu})-\hat{\mu}\right)+c^{te}\right] \tag{5.7.2378}$$

Therefore:

$$\ln\left(\frac{L(\mu)}{L(\hat{\mu})}\right)=\sum_{i=1}^n\left[x_i\ln\left(\frac{\mu}{\hat{\mu}}\right)-\mu+\hat{\mu}\right] \tag{5.7.2379}$$

What it is customary to write:

$$-2\ln\left(\frac{L(\mu)}{L(\hat{\mu})}\right)=-2\sum_{i=1}^n\left[n_i\ln\left(\frac{\mu}{\hat{\mu}}\right)-\mu+\hat{\mu}\right] \tag{5.7.2380}$$

Suppose we want to test the fact that our measurements do not deviate too much from the true expectation, that is to say:

$$\begin{aligned} H_0 &: \mu = \hat{\mu} \\ H_1 &: \mu \neq \hat{\mu} \end{aligned} \tag{5.7.2381}$$

We have the under the null hypothesis:

$$\boxed{\Lambda = -2\ln\left(\frac{L(\mu)}{L(\hat{\mu})}\right) = 0} \tag{5.7.2382}$$

So.... arrrrgh. We cannot make inference on such a result. So it's very annoying to deal with such a likelihood ratio ... Fortunately we know that in the case where:

$$\sigma^2 = \mu \qquad \mu \rightarrow +\infty \tag{5.7.2383}$$

the Poisson's law tends to a Normal law (if μ is greater than about 10, then the Normal distribution is a good approximation if an appropriate continuity correction is performed). Then in these conditions we use the previous result of the Normal law!

More generally we can (sadly) found the above final relations in the following forms in various textbooks:

$$\boxed{\Lambda(x) = \frac{L(\theta_0 \,|\, x)}{L(\theta_1 \,|\, x)} = \frac{f(\bigcup_i x_i \,|\, \theta_0)}{f(\bigcup_i x_i \,|\, \theta_1)} = \frac{L(\theta_0 \,|\, x)}{\sup\{\, L(\theta \,|\, x) : \theta \in \{\theta_0, \theta_1\}\}}} \tag{5.7.2384}$$

So many common test statistics such as the Z-test, the F-test, the T-test, the Pearson's chi-squared test and the G-test are tests for nested models and can be phrased as log-likelihood ratios or approximations thereof.

Remark

Some softwares propose another adequation test for discrete distribution, named the "minimum chi-square estimation goodness-of-fit". The idea is quite simple and we will illustrate it with a Poisson distribution. Consider the following sample ($n = 8$ for a total sample size equal to 20):

Value	**Frequency**
0	1
1	2
2	4
3	5
4	3
5	3
6	1
7	0
8	1

The minimum chi-square estimate of the population of parameter λ, is the λ value that minimize:

$$\sum_{k=0}^{n}\frac{(\text{Observed}-\text{Expected})^2}{\text{Expected}}=\sum_{k=0}^{8}\frac{\left((\text{count in cell } k)-20\left(\frac{\lambda^k e^{-\lambda}}{k!}\right)\right)^2}{20\left(\frac{\lambda^k e^{-\lambda}}{k!}\right)} \quad (5.7.2385)$$

Numerical computation shows that the value of λ that minimizes the chi-square statistic is about 3.5242. That is the minimum chi-square estimate of λ. For that value of λ, the chi-square statistic is about 3.062764. There are 10 cells. If the null hypothesis had specified a single distribution, rather than requiring λ to be estimated, then the null distribution of the test statistic would be a chi-square distribution with $10-1=9$ degrees of freedom.

5.7.14 Robustness and Nonparametric Statistics

In the area of inferential statistics and hypothesis testing, robustness is a recurring concept (the banks are compelled to stress testing / crash testing of their risk models for example). We have already mentioned this fact previously.

Definitions (#5.7.153):

D1. A test is named "robust test" if it remains valid while the assumptions for the application are not all met. This can be a somewhat low sample size or a probability distribution (Normal distribution for parametric tests) that is not very well satisfied, or the outliers that influence too much the result of the test. For example, ANOVA is robust with respect to the Normality assumption but not compared to that of homoscedasticity.

D2. An indicator is named "robust indicator" if it is not very sensitive to the presence of outliers (the correlation coefficient or the average, for examples, are not very robust indicators).

D3. More generally, a model is named "robust model" when it allows an extension of the results (in time or for a population). The robustness is equally applicable to a multiple regression, statistical tests or to a scorecard, or project planning.

Therefore, unless to be only descriptive, your studies will have to respect some rules so that their findings are generalisable.

First condition of a good robustness: the data! Intuitively, we all know that we do not transform a special case in generality (which would not fall in the field of statistics but to countertop discussions). Sufficient data builds reliable and solid models. For example, forecasts derived from a time series showing seasonality require at least three or four years of history.

However, the amount is not enough, we need quality (for most manager Quality is a very difficult concept)!! Indeed, it is best to avoid doing a study on unreliable information that can lead to costly decisions. Furthermore, it is recommended to be very careful with the manipulation of outliers. If this is not possible, we turn to more appropriate methods, such as those that using the median rather than the mean, ranks rather than values, or filtering techniques.

Definition (#5.7.154): "Nonparametric statistics" is the branch of statistics that is not based solely on parametrized families of probability distributions (common examples of parameters are the mean and variance).

The term "nonparametric statistics" has been imprecisely defined in the following two ways (among others...):

1. They do not rely on assumptions that the data are drawn from a given probability distribution. We then say that they are "distribution free methods".
2. They do not rely on any arithmetical operation of all the individual data (like "ranks" or "ranges" for example!)

As we will see further below and as we have also already seen some special cases earlier above, there is quite a lot of nonparametric statistics and nonparametric tests (keep in mind that even if their are not based on parametrized families of distributions, they have however other assumptions that are visible only when your study their mathematical proof!!!). Rather than listing them all here, we rather want to answer the most common question from many practitioners that is a non-exhaustive list of the equivalent nonparametric to some parametric tests and statistics. So here is a table that summarize for the most important one that question request:

Parametric Tests	Nonparametric Tests	Main characteristics
1-sample T or Z test	1-sample sign test	Test on the median for data from a nonsymmetric distribution
	1-sample Wilcoxon test	Test on the median for data from a symmetric distribution
2-sample T-test	Mann-Whithney test	Test on two medians using ranks of the sample data
One-Way ANOVA	Kruskal-Wallis test	Test on the equality of medians from two or more populations. More powerful than Mood's median test, but less robust to outliers
	Mood's median test	Test on the equality of medians from two or more populations. More robust to outliers than the Kruskal-Wallis test, but less powerful.
Two-Way Randomized Block ANOVA	Friedman test	Test on medians, using randomized block experiments
Pearson's Correlation Coefficient	Spearman's rank correlation coefficient	Measures statistical dependence between two variables using ranks
Anderson-Darling, Shapiro-Wilk, Kolmogorov-Smirnov GoF	Mann–Whitney U or Wilcoxon rank sum test	Tests whether two samples are drawn from the same distribution, as compared to a given alternative hypothesis.

Table 5.76: **Summary of some naive parametric tests/statistics and their nonparametric equivalent**

For a much more exhaustive list of parametric and non-parametric tests, the reader has to refer to the Data Science mind map at page 6770 or to the both excellent textbooks [304] and [430].

5.7.14.1 Rank Statistics

Definition (#5.7.155): The Rank Statistics, also named "Order Statistics" are defined as all the techniques of statistical calculations and statistical inference that have for main objective of getting rid of the knowledge of a parametric distribution and for using it ranks only (order) of the measurements. This is a very powerful and practically used tool for nonparametric statistics!

As we have already mentioned, we are talking about parametric tests when we stipulate that the data are from a given known distribution. In this case, the characteristics of the data can be summarized using the parameters estimated on the sample, the subsequent test procedure then only focus on these parameters.

Remark

The reader interested to learn more but without detailed is referred to the excellent book of Gopal K. Kanji which contains a summary presentation of the most used 100 parametric and nonparametric test with for each a small practical example. Sadly this textbook should be published in a new edition with the 200 most used statistical tests to be almost complete and perfect.

Nonparametric tests (such as the chi-square tests already seen) eliminate the necessary step consisting to estimate the parameters of the distribution prior to doing the hypothesis test. In general, conclusions drawn from nonparametric tests are not as powerful as the parametric ones. However, as nonparametric tests make fewer assumptions, they are more flexible, more robust, and applicable to non-quantitative data.

When the data are quantitative, most common nonparametric tests transforms values into ranks. The name "ranks test" is then often encountered. When the data are qualitative, only the nonparametric can be used.

5.7.14.1.1 L-Statistics

Before addressing nonparametric distributions and tests, let us give some definitions that the reader may have seen be in the hyperspecialized literature and that we avoided to use so far...

The median, mean and range suggest the use of linear combinations of the components of the order statistics vector.

Definition (#5.7.156): Thus, let us denote by $X_{(1)} \geq X_{(2)}, \ldots, \geq X_{(n)}$, the order statistics (values ordered in descending order by their rank and numbered). We define then the "L-statistic" by:

$$\boxed{L = \sum_{i=1}^{n} a_{i,n} X_{(i)}} \quad (5.7.2386)$$

The first most known "L-estimator" is the arithmetic mean for which:

$$a_{i,n} = \frac{1}{n} \quad (5.7.2387)$$

The second most known L-estimator is the median for which we have when n is odd:

$$a_{i,n}=\begin{cases}1 & i=\dfrac{n+1}{2}\\ 0 & i\neq\dfrac{n+1}{2}\end{cases} \tag{5.7.2388}$$

and when n is even:

$$a_{i,n}=\begin{cases}1 & i=\dfrac{n}{2},\dfrac{n}{2}+1\\ 0 & \text{otherwise}\end{cases} \tag{5.7.2389}$$

The third best L-estimator known is the range for which we have:

$$a_{i,n}=\begin{cases}+1 & i=1\\ -1 & i=n\\ 0 & \text{otherwise}\end{cases} \tag{5.7.2390}$$

There are other empirical L-estimators but we will stop here because the list is quite long.

5.7.14.1.2 Ranks Distribution law

The k-th order statistic is the kth smallest value in sample of n from a random distribution $F(x)$. Let the random variables $X_1,X_2,\ldots,X_n$ be independent and identically distributed. Label the smallest value $X_{(1)}$, the next smallest $X_{(2)}$ and so on up to $X_{(n)}$. Then the value of the kth order statistic is $X_(k)$, for $1\leq k\leq n$.

Let $F(x)$ denote the distribution function of the X_i's and $f(x)$ the density function. Let us first determine the distribution of the kth order statistic, that is:

$$P(X_{(k)}\leq x) \tag{5.7.2391}$$

To have $X_{(k)}\leq x$ we need to have at least k of the n X_i's less than or equal to x. Each of the n independent trials has probability $F(x)$ of being less than or equal to x, thus the number of trials less than or equal to x has a Binomial distribution with n trials and probability $F(x)$. That is:

$$\begin{aligned}P(X_{(k)}\leq x)&=P\left(\text{at least } k \text{ success from a } \mathcal{B}(n,F(x)) \text{ distribution}\right)\\&=\sum_{j=1}^{n}P(j\text{ sucesses})\\&=\sum_{j=1}^{n}\binom{n}{j}\left(F(x)\right)^j\left(1-F(x)\right)^{n-j}\end{aligned} \tag{5.7.2392}$$

To find the density function we take the derivative with respect to x:

$$
\begin{aligned}
&\frac{\mathrm{d}}{\mathrm{d}x}P(X_{(k)}\leq x)\\
&=\frac{\mathrm{d}}{\mathrm{d}x}\left(\sum_{j=1}^{n}\binom{n}{j}(F(x))^j(1-F(x))^{n-j}\right)\\
&=\sum_{j=k}^{n-1}\binom{n}{j}\left[j(F(x))^{j-1}f(x)(1-F(x))^{n-1}-(n-j)(F(x))^j(1-F(x))^{n-j-1}f(x)\right]\\
&+nf(x)(F(x))^{n-1}\\
&=nf(x)\sum_{j=k}^{n-1}\left[\binom{n-1}{j-1}(F(x))^{j-1}(1-F(x))^{n-1}-\binom{n-1}{j}(F(x))^j(1-F(x))^{n-j-1}\right]\\
&+nf(x)(F(x))^{n-1}\\
&=nf(x)\left(\sum_{j=k-1}^{n-2}\binom{n-1}{j}(F(x))^j(1-F(x))^{n-j-1}-\sum_{j=k}^{n-1}(F(x))^j(1-F(x))^{n-j-1}\right)\\
&+nf(x)(F(x))^{n-1}\\
&=nf(x)\binom{n-1}{k-1}(F(x))^{k-1}(1-F(x))^{n-(k-1)-1}-nf(x)\binom{n-1}{n-1}(F(x))^{n-1}(1-F(x))^{n-(n-1)-1}\\
&+nf(x)(F(x))^{n-1}\\
&=nf(x)\binom{n-1}{k-1}(F(x))^{k-1}(1-F(x))^{n-(k-1)-1}-nf(x)(F(x))^{n-1}+nf(x)(F(x))^{n-1}\\
&=nf(x)\binom{n-1}{k-1}(F(x))^{k-1}(1-F(x))^{n-(k-1)-1}
\end{aligned}
\tag{5.7.2393}
$$

Written in this form, it is obvious that the majority of terms will cancel. This leaves:

$$\frac{\mathrm{d}}{\mathrm{d}x}P(X_{(k)}\leq x)=\frac{n!}{(n-k)!(k-1)!}f(x)(F(x))^{k-1}(1-F(x))^{n-k}\tag{5.7.2394}$$

5.7.14.1.3 Distribution free confidence intervals for percentiles

Earlier we learned (among a lot of others stuff) how to calculate a sample percentile as a point estimate of a population (or distribution) percentile. Just as it is a good idea to calculate confidence intervals for other population parameters, such as means and variances, it would be a good idea to learn how to calculate a confidence interval for percentiles of a population. That's what we'll work on just below. As the title of the subject suggests it, we won't make any assumptions about the distribution of the data, that is, other than it being continuous!

As is generally the case, let's motivate the method for calculating a confidence interval for a population median M_e by way of a concrete example[85]. Suppose $Y_1<Y_2<Y_3<Y_4<Y_5$ are the order statistics of a random sample of size $n=5$ from a continuous distribution. Our previous work tells us that Y_3 serves as a good point estimator of the median M_e. Let's see what we

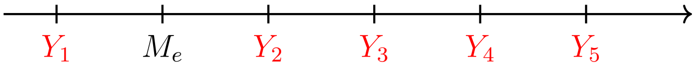
---

[85] It's a well knows example that you can find in numerous textbooks and websites which original author seems impossible to determine.

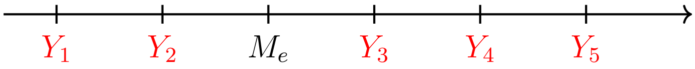
can come up with for a confidence interval given we have these order statistics at our disposal. Well, suppose we suggested that the interval constrained by the first and fifth order statistics, that is, $[Y_1, Y_5]$ would serve as a good interval. How confident can we be that the interval $[Y_1, Y_5]$ would contain the unknown population median M_e? To answer that question, we simply need to calculate the following probability:

$$P(Y_1 < M_e < Y_5) \tag{5.7.2395}$$

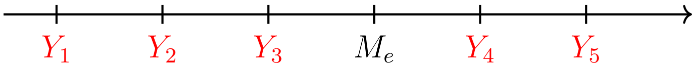
Calculating the probability reduces to a simple binomial calculation once we figure out all the ways in which the population median M_e is sandwiched between Y_1 and Y_5. Well, the population median M_e is sandwiched between Y_1 and Y_5, if the first order statistic is the only order statistic less than the median M_e:



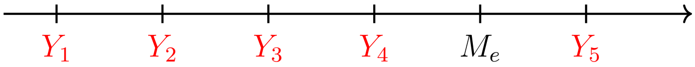
The population median M_e is sandwiched between Y_1 and Y_5, if the first two order statistics are the only order statistics less than the median M_e:



The population median M_e is sandwiched between Y_1 and Y_5, if the first three order statistics are less than the median M_e, and the fourth and fifth order statistics are greater than M_e:



And, the population median M_e is sandwiched between Y_1 and Y_5, if the fifth order statistic is the only order statistic greater than the median M_e:



This means that in order to calculate the probability $P(Y_1 \leq M_e \leq Y_5)$, we need to calculate the probability of each of the above events. Now, if we let W denote the number of $X_i < M_e$, then W is a binomial random variable with n mutually independent trials and probability of success $p = P(X_i < M_e) = 0.5$. And, reviewing the events as depicted above, the desired probability is calculated as:

$$P(Y_1 \leq M_e \leq Y_5) = P(W=1) + P(W=2) + P(W=3) + P(W=4) \tag{5.7.2396}$$

The binomial probability mass function (or, alternatively, the binomial table) makes the calculation straightforward:

$$P(Y_1 \leq M_e \leq Y_5) = \sum_{k=1}^{4} P(W=k) = \sum_{k=1}^{4} \binom{5}{k} (0.5)^k (0.5)^{5-k} = 0.9376 \tag{5.7.2397}$$

So, the probability that the random interval $[Y1, Y5]$ contains the median M_e is 0.9376. We aren't always so lucky with arriving at a decent confidence coefficient on our first try. Sometimes we have to try again aiming to get a confidence coefficient that it as least 90%, but as close to 95% as possible. In this case, the confidence coefficient for the interval $[Y2, Y4]$ is:

$$P(Y_2 \leq M_e \leq Y_4) = \sum_{k=2}^{3} P(W=k) = \sum_{k=2}^{3} \binom{5}{k} (0.5)^k (0.5)^{5-k} = 0.6250 \qquad (5.7.2398)$$

Clearly, we would be better served to stick with the interval $[Y_1, Y_5]$ in this case.

Notice that in general we then have:

$$\boxed{P(Y_i \leq M_e \leq Y_j) = \sum_{k=i}^{j-1} P(W=k) = \sum_{k=i}^{j-1} \binom{n}{k} (0.5)^k (0.5)^{n-k}} \qquad (5.7.2399)$$

The method that we learned for finding a confidence interval for the median of a continuous distribution can be easily extended so that we can find a confidence interval for any percentile π_p. The only thing we have to change is the probability of a success, that is, that X_i is less than π_p:

$$p = P(X_i < \pi_p) \qquad (5.7.2400)$$

Then, the exact confidence coefficient is calculated just as before using the binomial distribution with parameters n and p:

$$\boxed{P(Y_i \leq \pi_p \leq Y_j) = \sum_{k=i}^{j-1} \binom{n}{k} p^k (1-p)^{n-k}} \qquad (5.7.2401)$$

5.7.14.1.4 Wilcoxon Rank Sum Test

The idea of the "Wilcoxon rank sum test" is the following: if we collect two samples of measurement, and that we store the values in order, the alternance of the X_i (of size n_x) and Y_i (of size n_y) should be fairly steady if both samples distribution law F and G respectively follow the same probability distribution. It is therefore like a "fit check".

This is in fact equivalent as saying that the null hypothesis is: «*The distribution of the ranks in the two groups are equal*».

Formally:

$$H_0 : P(X_A > X_B) = 0.5; H_A : P(X_A > X_B) \neq 0.5 \qquad (5.7.2402)$$

In plain language the null hypothesis is that the probability of a random observation from group A exceeding the paired observation drawn from group B is one half (i.e. a random observation in group A has just as much probability of being greater than, as being less than its paired observation in group B).

The practical value of this is hard to see, and thus in many places, including textbooks, the null hypothesis is presented as the “two populations have equal medians”. The actual null hypothesis can be expressed as the latter median hypothesis, but only under the additional assumption that the shapes of the distributions are identical in each group!

In other words, our interpretation of the test as comparing the medians of the distributions requires the location-shift-only alternative to be the case. Since this is rarely true, and never assessed, we should probably use extreme caution in using, and especially in interpreting, the Wilcoxon rank-sum test.

It is therefore not such as Chi-square adequation test to compare measurements at a theoretical law, but to other measurement of a hypothesized same law.

Remark

The Wilcoxon rank sum test is a nonparametric test, used therefore for "Nonparametric Null Hypothesis Significance Tests" (NNHST), because we have no need of use of any measure of dispersion or position of the random variables. Moreover, it is a test say to be "robust" in the sense that it does not assume the Normality of the data.

Let us take an example before tackling the theoretical aspect. Here are two samples of size 10 ($n_x = n_y$) of quantitative variables:

$$\begin{gathered}5.7, 3.2, 8.4, 4.1, 6.9, 5.3, 1.7, 3.2, 2.5, 7.4\\ 8.1, 5.5, 3.4, 7.9, 4.6, 1.6, 8.5, 7.1, 8.7, 5.7\end{gathered} \tag{5.7.2403}$$

Remark

The Wilcoxon rank sum test may well be used for ordinal variables (but only as long as they are in an acceptable number). Typically, the Wilcoxon rank sum test is also used to analyse the response to business surveys using a Likert scales of 7 points.

Here are the order statistics of the sample of size 20 ($N = n_x + n_y$) regrouped and ordered (the 10 values of the first sample are underlined):

$$1.6, \underline{1.7}, \underline{2.5}, \underline{3.2}, \underline{3.2}, 3.4, \underline{4.1}, 4.6, \underline{5.3}, 5.5, \underline{5.7}, 5.7, \underline{6.9}, 7.1, \underline{7.4}, 7.9, 8.1, \underline{8.4}, 8.5, 8.7 \tag{5.7.2404}$$

The values of the first sample X (named "treatment values") in this example looks like to be smaller than those of the second sample Y (named "control values") that we often represent in a diagram as the following (by cheating a bit with Microsoft® Excel® 11.8346):

	A	B
1	X/Y	Niveau
2	5.7	1
3	3.2	1
4	8.4	1
5	4.1	1
6	6.9	1
7	5.3	1
8	1.7	1
9	3.2	1
10	2.5	1
11	7.4	1
12	8.1	2
13	5.5	2
14	3.4	2
15	7.9	2
16	4.6	2
17	1.6	2
18	8.5	2
19	7.1	2
20	8.7	2
21	5.7	2

Figure 5.229: **Comparing ordered values of two samples in Microsoft® Excel® 11.8346**

Remark

You must be careful about the Wilcoxon test we are studying here and the Kruskal-Wallis test that we will see later. Indeed, many people think that because they are nonparametric they don't have any assumptions... However as we know this is wrong!!! A nonparametric test is indeed independent of distribution parameters but there may have other assumptions. In the case of the Wilcoxon and the Kruskal-Wallis test, the assumption is (quite obviously...) that the scale parameters between the both samples are equal (otherwise it would be a non-sense to compare two things that we already know as being not comparable!).

The idea is then to find out if this trend is statistically significant? That is to say, whether we have a difference of the kind $F < G$ between their respective distributions laws:

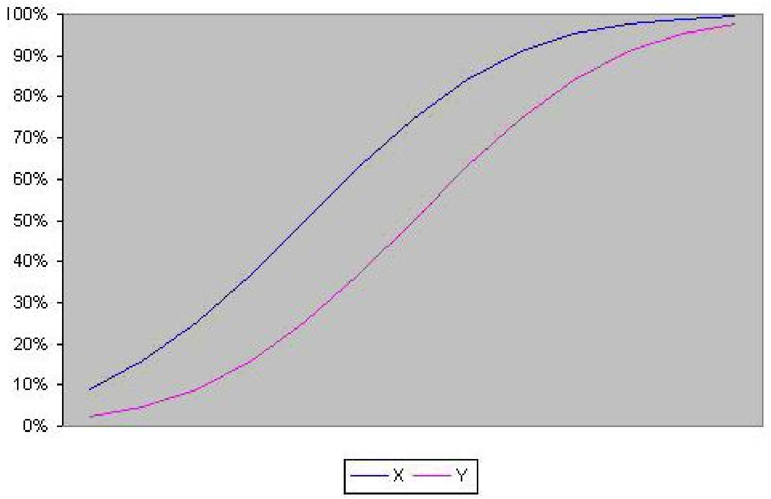


Figure 5.230: **Generic example of the comparison of two distributions in Microsoft® Excel® 11.8346**

or whether they can be considered as identical. For this, we must examine the concept of "rank":

Definition (#5.7.157): Given a random n-sample $X_1, X_2, \ldots, X_n$ of any continuous statistical law, we denote by R_i the rank of the X_i ordered in a sample population. The rank i is a non-zero integer strictly positive and between 1 and n.

✍**Example:**

In:

$$1.6, \underline{1.7}, \underline{2.5}, \underline{3.2}, \underline{3.2}, 3.4, \underline{4.1}, 4.6, \underline{5.3}, 5.5, \underline{5.7}, 5.7, \underline{6.9}, 7.1, \underline{7.4}, 7.9, 8.1, \underline{8.4}, 8.5, 8.7$$

We have respectively the following "order statistics":

$$X: R_2 = 1.7, R_3 = 2.5, R_4 = 3.2, R_5 = 3.2, R_7 = 4.1, \ldots \tag{5.7.2405}$$

$$Y: R_1 = 1.6, R_6 = 3.4, R_8 = 4.6, R_{10} = 5.5, R_{11} = 5.7, \ldots \tag{5.7.2406}$$

Once the concept of "rank" defined and calculated, let us look at the sum in the context of our example with two samples:

$$1.6, \underline{1.7}, \underline{2.5}, \underline{3.2}, \underline{3.2}, 3.4, \underline{4.1}, 4.6, \underline{5.3}, 5.5, \underline{5.7}, 5.7, \underline{6.9}, 7.1, \underline{7.4}, 7.9, 8.1, \underline{8.4}, 8.5, 8.7$$

The sum rank denoted traditionally W_x (W for Wilcoxon) for the first sample is thus:

$$W_x = 2+3+4+5+7+9+12+13+15+18 = 88 \tag{5.7.2407}$$

and for the second sample:

$$W_y = 1+6+8+10+11+14+16+17+19+20 = 122 \tag{5.7.2408}$$

The values W_x, W_y are named "Wilcoxon Statistics".

We can therefore already see that there is indeed a difference that seems a priori significant in terms of ranking between both samples. The problem remains to build a rigorous mathematical tool to infer a fact with some certainty.

For this, let us first introduce the average of the ranks using the result shown in the section of Sequences and Series by considering only one sample:

$$\bar{R} = \frac{1}{n}\sum_{i=1}^{n} R_i = \frac{1}{n}\sum_{i=1}^{n} i = \frac{1}{n}\frac{n+1}{2} \tag{5.7.2409}$$

By calculating this, we notice quickly that this is the expected mean of the uniform discrete distribution study earlier in this section for a discrete random variable with values between 1 and n, which is exactly the definition of rank! Thus, we have the rank that will have for mean and variance for the entire population:

$$\begin{aligned} \mu = \bar{R} &= \frac{n+1}{2} \\ \mathrm{V}(R) &= \frac{n^2-1}{12} \end{aligned} \tag{5.7.2410}$$

For those who find this analogy questionable we give just right below the proof of the variance using the Huygens relation and the sum of squares of positive integers proved in the section of

Sequences and Series:

$$\begin{aligned}\mathrm{V}(R)&=\mathrm{E}(R^2)-\mathrm{E}(R)^2=\sum_{i=1}^{n}p(R_i)R_i^2-\left(\frac{n+1}{2}\right)^2\\&=\frac{1}{n}\frac{n(2n+1)(n+1)}{6}-\frac{(n+1)^2}{4}=\frac{2(2n+1)(n+1)-3(n^2+n+1)}{12}\\&=\frac{2(2n^2+2n+n+1)-3n^2-6n-3}{12}=\frac{4n^2+4n+2n+2-3n^2-6n-3}{12}=\frac{n^2-1}{12}\end{aligned}\tag{5.7.2411}$$

But obviously for a single sample this has no interest! Let us take again our two series X_i, Y_i respectively of equal size $n_x=10, n_y=10$ without distinction:

$$1.6, 1.7, 2.5, 3.2, 3.2, 3.4, 4.1, 4.6, 5.3, 5.5, 5.7, 5.7, 6.9, 7.1, 7.4, 7.9, 8.1, 8.4, 8.5, 8.7\tag{5.7.2412}$$

We then have the statistical indicators of ranks without distinction (you must remember that we still do not know at this level of the mathematical development if this will be helpful or not):

$$\begin{aligned}W_{x,y}&=\sum_{i=1}^{n_x+n_y}R_i=\sum_{i=1}^{n_x+n_y}i=\frac{(n_x+n_y)(n_x+n_y+1)}{2}=210\\\mu_{x,y}&=\bar{R}_{x,y}=\frac{(n_x+n_y)+1}{2}=10.5\\\mathrm{V}(R_{x,y})&=\frac{(n_x+n_y)^2-1}{12}=33.25\end{aligned}\tag{5.7.2413}$$

and the statistical indicators of ranks but this time with distinction:

$$1.6, \underline{1.7}, \underline{2.5}, \underline{3.2}, \underline{3.2}, 3.4, \underline{4.1}, 4.6, \underline{5.3}, 5.5, \underline{5.7}, 5.7, \underline{6.9}, 7.1, \underline{7.4}, 7.9, 8.1, \underline{8.4}, 8.5, 8.7$$

We then have the following local statistical indicators:

$$\begin{aligned}W_x&=\sum R_{x,i}=2+3+4+5+7+9+12+13+15+18=88\\W_y&=\sum R_{y,i}=1+6+8+10+11+14+16+17+19+20=122\\\bar{R}_x&=\frac{1}{n}\sum R_{x,i}=\frac{2+3+4+5+7+9+12+13+15+18}{10}=8.8\\\bar{R}_y&=\frac{1}{n}\sum R_{y,i}=\frac{1+6+8+10+11+14+16+17+19+20}{10}=12.2\\\mathrm{V}(R_x)&=\frac{1}{n_x}\sum(R_{x,i}-\bar{R}_x)^2=27.16\\\mathrm{V}(R_x)&=\frac{1}{n_y}\sum(R_{y,i}-\bar{R}_y)^2=33.56\end{aligned}\tag{5.7.2414}$$

These calculations now done, we have nothing concretely yet rigorous regarding the Wilcoxon's rank sum test which purpose is for reminder to check whether the two samples follow the same law or not (and therefore have the same moments as the expected mean, variance, median, etc.).

To move forward, let us consider the n_x values of the sample X. We know (see section Probabilities page 528) then that there is:

$$C_{n_x}^{n_x+n_y}=\binom{n_x+n_y}{n_x}=\frac{(n_x+n_y)!}{n_x!((n_x+n_y)-n_x)!}=\frac{(n_x+n_y)!}{n_x!n_y!}\tag{5.7.2415}$$

number of possible arrangements of the X_i in the population of the samples and if the Wilcoxon's rank sum test is verified (that is to say, the probability laws are the same for both samples), the various arrangements should be equally likely.

For example, if we take 2 samples with respectively each 2 measures (2 random variables of treatment and 2 control random variables), we have:

$$(n_x+n_y)!=4!=24 \tag{5.7.2416}$$

arrangements all different:

$$\begin{matrix} (1,2,3,4) & (2,1,3,4) & (3,1,2,4) & (4,1,2,3) \\ (1,2,4,3) & (2,1,4,3) & (3,1,4,2) & (4,1,3,2) \\ (1,3,2,4) & (2,3,1,4) & (3,2,1,4) & (4,2,1,3) \\ (1,3,4,2) & (2,3,4,1) & (3,2,4,1) & (4,2,3,1) \\ (1,4,2,3) & (2,4,1,3) & (3,4,1,2) & (4,3,1,2) \\ (1,4,3,2) & (2,4,3,1) & (3,4,2,1) & (4,3,2,1) \end{matrix} \tag{5.7.2417}$$

But... sadly... this is not what we want in our case because we would like already to be able to distinguish the two samples and also do not take into account the arrangements that consist only of a permutation of the variables of the same sample. We then have (see section Probabilities page 528):

$$C_{n_x}^{n_x+n_y}=\binom{n_x+n_y}{n_x}=\frac{4!}{2!2!}=6 \tag{5.7.2418}$$

possible combinations! Effectively with two samples having two treatment variables (X) and two control variables (Y), we have (W_S is the sum of ranks of last column):

Possible ranks (Controls)	**Possible ranks (Treatments)**	W_S
$1,2$	$3,4$	7
$1,3$	$2,4$	6
$1,4$	$2,3$	5
$2,3$	$1,4$	4
$2,4$	$1,3$	4
$3,4$	$1,2$	3

Table 5.77: **Ranks representation of 2 variables of treatment and of control**

If the null hypothesis of the Wilcoxon's sum test rank is not rejected, the 6 rankings are equally likely. We conclude the following table:

Value of W_S	3	4	5	6	7
Probability	$\frac{1}{6}$	$\frac{1}{6}$	$\frac{2}{6}$	$\frac{1}{6}$	$\frac{1}{6}$
Cumulative	$\frac{1}{6}$	$\frac{2}{6}$	$\frac{4}{6}$	$\frac{5}{6}$	$\frac{6}{6}$

Table 5.78: **Probabilities associated to the Wilcoxon's rank sum test**

This table being constructed, suppose that we observe for the sum of rank of treatment variables: $W_S = 7$. The threshold of a one-sided test would then give in conformity with the table above:

$$P(W_S \geq 7) = \frac{1}{6} \cong 17\% \qquad (5.7.2419)$$

or if we get $W_S = 3$:

$$P(W_S \geq 3) = \frac{5}{6} \cong 83\% \qquad (5.7.2420)$$

So we would reject the null hypothesis of an identical distribution between the two samples at any upper limit (or lower, respectively) fixed in advance by laboratory policy ... in unilateral or bilateral test (reason why some statistical softwares give unilateral test values + bilateral test values at the same time).

Two very important things you need to notice for what will follow is that:

1. First in the construction of the above table (where we take again the first part here):

Value of W_S	3	4	5	6	7
Probability	$\frac{1}{6}$	$\frac{1}{6}$	$\frac{2}{6}$	$\frac{1}{6}$	$\frac{1}{6}$

   we see there is a symmetry at the value 5, which means that the law W_S is symmetrical in this particular case. But if we take another example with two samples respectively including two control variables and three of treatments (two random variables) we would have:

Value of W_S	6	7	8	9	10	11	12
Probability	$\frac{1}{10}$	$\frac{1}{10}$	$\frac{2}{10}$	$\frac{2}{10}$	$\frac{2}{10}$	$\frac{1}{10}$	$\frac{1}{10}$

   the reader can check that whatever the number of samples and the number of variables and control treatment, the probability table above is always balanced (well there is a mathematical proof of this but I find it inelegant). But in fact it is pretty intuitive, like combinations $C_{n_x}^{n_x+n_y}$ are independent of the fact that the ranks are sorted in ascending or descending order, it is therefore necessary that there is a symmetry.

2. Secondly the values of the measured variables do not come into account in this parametric statistics but only the tabulated values of the ranks with their associated probabilities. Indeed, as you may have noticed, we did not need explicit values of the random variables to build the table above!

Now, knowing that the law W_S is symmetrical and discreet we would like to calculate its expected mean.

The smallest possible value of W_S is assuming it is in the sample X (computer algorithms automatically determine in which sample but anyway in practice, samples almost always have the same size):

$$W_{S,\min}=1+\ldots+n_x=\frac{1}{2}n_x(n_x+1) \tag{5.7.2421}$$

The largest possible value is naturally (remember that $N=n_x+n_y$):

$$W_{S,\max}=\frac{1}{2}N(N+1)-\frac{1}{2}n_y(n_y+1) \tag{5.7.2422}$$

The expected mean of the sum of the ranks of one of the two samples is then:

$$\begin{aligned}
\mathrm{E}(W_S)&=W_{S,\min}+\frac{W_{S,\max}-W_{S,\min}}{2}=W_{S,\max}-\frac{W_{S,\max}-W_{S,\min}}{2}\\
&=\frac{1}{2}n_x(n_x+1)+\frac{\frac{1}{2}N(N+1)-\frac{1}{2}n_y(n_y+1)-\frac{1}{2}n_x(n_x+1)}{2}\\
&=\frac{2n_x(n_x+1)+N(N+1)-n_y(n_y+1)-n_x(n_x+1)}{4}\\
&=\frac{n_x(n_x+1)+N(N+1)-n_y(n_y+1)}{4}=\frac{n_x^2+n_x+N^2+N-n_y^2-n_y}{4}\\
&=\frac{n_x^2+n_x+N^2+N-n_y^2-(N-n_x)}{4}=\frac{n_x^2+2n_x+N^2-(N-n_x)^2}{4}\\
&=\frac{n_x^2+2n_x+N^2-(N^2-2Nn_x+n_x^2)}{4}=\frac{2n_x+2Nn_x}{4}=\frac{n_x+Nn_x}{2}\\
&=\frac{1}{2}n_x(N+1)
\end{aligned} \tag{5.7.2423}$$

Then finally:

$$\mathrm{E}(W_S)=\frac{1}{2}n_x(N+1) \tag{5.7.2424}$$

To calculate the variance, which will be useful to us to make if necessary an approximation that we will see further below, appears (unfortunately) the covariance because knowledge of the ranks give partial information about other ranks. So we have:

$$\mathrm{V}(W_S)=\mathrm{V}\left(\sum_{i=1}^{n_x}R_i\right)=\sum_{i=1}^{n_x}\mathrm{V}(R_i)+\sum_i\sum_{i\neq j}\mathrm{cov}(R_i,R_j) \tag{5.7.2425}$$

We already know with what we have just proved above that:

$$\sum_{i=1}^{n_x}\mathrm{V}(R_i)=\sum_{i=1}^{n_x}\frac{N^2-1}{12}=\frac{n_x(N^2-1)}{12}=\frac{n_x\left((n_x+n_y)^2-1\right)}{12} \tag{5.7.2426}$$

The problem remains the term with covariance. For its calculation there are rigorous techniques into several pages and... a tip that is much shorter. The trick is to use the global ranking variable which we denote T_i with $i=1\ldots n+m$. As the sum of the T_i is a constant, then we have:

$$\begin{aligned}\mathrm{V}\left(\sum_{i=1}^{n_x+n_y} T_i\right)&=\mathrm{V}\left(\frac{N(N+1)}{2}\right)=\mathrm{V}\left(\frac{(n_x+n_y)(n_x+n_y+1)}{2}\right)\\&=0=\sum_{i=1}^{n_x+n_y}\mathrm{V}(T_i)+\sum_{i=1}^{n_x+n_y}\sum_{i=1,j\neq i}^{n_x+n_y}\mathrm{cov}(T_i,T_j)\\&=(n_x+n_y)\frac{(n_x+n_y)^2-1}{12}+(n_x+n_y)(n_x+n_y-1)\mathrm{cov}(T_i,T_j)\end{aligned}\tag{5.7.2427}$$

It comes then:

$$\mathrm{cov}(T_i,T_j)=-\frac{(n_x+n_y)^2-1}{12(n_x+n_y-1)}=-\frac{n_x+n_y+1}{12}\tag{5.7.2428}$$

We can then take back the initial calculation by replacing the covariances by their expression, the last relation obtained for the covariances calculated on the T_i applying also (which is not necessarily intuitive ... but the trick works) to the R_i:

$$\begin{aligned}\mathrm{V}\left(\sum_{i=1}^{n_x} R_i\right)&=\frac{n_x((n_x+n_y)^2-1)}{12}+n_x(n_x-1)\left(-\frac{n_x+n_y+1}{12}\right)\\&=\frac{1}{12}\left[n_x((n_x+n_y)^2-1)-n_x(n_x-1)(n_x+n_y+1)\right]\\&=\frac{1}{12}\left[n_x(n_x^2+2n_xn_y+n_y^2-1)-(n_x^2-n_x)(n_x+n_y+1)\right]\\&=\frac{1}{12}\left[n_x^3+2n_x^2n_y+n_xn_y^2-n_x-n_x^2(n_x+n_y+1)+n_x(n_x+n_y+1)\right]\\&=\frac{1}{12}\left[n_x^3+2n_x^2n_y+n_xn_y^2-n_x-n_x^3-n_x^2n_y-n_x^2+n_x^2+n_xn_y+n_x\right]\\&=\frac{1}{12}\left(n_x^2n_y+n_xn_y^2+n_xn_y\right)=\frac{n_xn_y(n_x+n_y+1)}{12}\end{aligned}\tag{5.7.2429}$$

Finally:

$$\mathrm{V}\left(\sum_{i=1}^{n_x} R_i\right)=\frac{n_xn_y(n_x+n_y+1)}{12}\tag{5.7.2430}$$

This is the same result as the rigorous methodology that can be found in some rare references.

✍**Example:**

Let us turn to a practical case for the exact case. So consider 2 samples having 2 treatments variables (X) and 2 control variables (Y) (it is a bit simplistic and absurd as an example but it facilitates the educational aspect ...) we have:

$$\begin{gathered}X:5.7,3.2\\Y:8.1,5.5\end{gathered}$$

Thus (the treatment variable therefore has the ranks 1 and 3 which makes a sum of rank of 4):

$$\underline{3.2}, 5.5, \underline{5.7}, 8.1$$

Therefore:

$$\begin{gathered}X: R_1 = 3.2, R_3 = 5.7\\ Y: R_2 = 5.5, R_4 = 8.1\end{gathered}$$

We have the following table as we have shown above:

Value of W_S	3	4	5	6	7
Probability	$\dfrac{1}{6}$	$\dfrac{1}{6}$	$\dfrac{2}{6}$	$\dfrac{1}{6}$	$\dfrac{1}{6}$

with in this case:

$$W_S = 1+3 = 4 \tag{5.7.2431}$$

$$\text{E}(W_S) = \frac{1}{2}n_x(N+1) = \frac{1}{2}2(4+1) = 5 \tag{5.7.2432}$$

If we choose the traditional bilateral confidence threshold level to 5% we have according to the table above that:

$$\begin{gathered}P(W_S \geq 7) = \frac{1}{6} \cong 17\%\\ P(W_S \leq 3) = \frac{1}{6} \cong 17\%\end{gathered} \tag{5.7.2433}$$

So in other words we see that there is:

$$100\% - 2\frac{1}{6} = 66.\bar{6}\% \tag{5.7.2434}$$

of cumulative probability that W_S is between 3 and 7 (the bar above the 6 means for reminder that this digit is repeated to infinity). So 4 is necessarily included in the bilateral range of 95% ... and we do not the reject the null hypothesis as what the two samples are not different. The corresponding p-value in bilateral is then the half of $33.\bar{3}\%$.

Remark

In fact if we wanted to make an interesting computational example by playing with a bilateral threshold of 5% (or 2.5% on either side) we should have at least 2 samples with 4 random variables, that is to say 70 possible combinations of ranks. Below 4 random variables per sample, it is clear that the two-tailed test at a level of 95% will be such that we will almost never reject the null hypothesis of equality...

If the size of the two samples is large enough (most practitioners consider that each sample must be at least 20 individuals), it has been shown by simulations that we can make the following approximation (used by many statistical software):

$$\mathcal{N}(0,1) \cong \frac{W_S - \frac{1}{2}n_x(N+1)}{\sqrt{\frac{n_x n_y(N+1)}{12}}} \tag{5.7.2435}$$

obviously always determining the p-value in bilateral. With the previous example (with only 4 measurement in total), we have therefore:

$$\mathcal{N}(0,1) \cong \frac{W_S - \frac{1}{2}n_x(N+1)}{\sqrt{\frac{n_x n_y(N+1)}{12}}} = \frac{4-5}{\sqrt{1.291}} \cong -0.7746 \tag{5.7.2436}$$

Which corresponds to a cumulative probability of 21.93%. So the corresponding bilateral p-value is about $(1-22\%)/2 \cong 34\%$ (compared to the value of about 33% with the exact case).

5.7.14.1.5 Mann-Whitney Rank Sum Test

The "Mann-Whitney rank sum test" is also a nonparametric adequation test (see [369]) which can be deduced from the Wilcoxon rank sum test (hence based on the same assumption of identically distributed samples with same variances). Furthermore it is inspired to the point that we sometimes name it in the industry "Wilcoxon-Mann-Whitney test" or "Wilcoxon-Mann-Whitney adequation test" or "MWW test" (without specifying each time in the name that it is based on the sum of ranks).

The purpose of this test, as for the Wilcoxon rank sum test, is to find a way to verify that two independent samples not necessarily of the same size are from the same law or not (verbatim come from a same population or not) but with a different approach!

Remark

Just as the Wilcoxon rank sum test, the Mann-Whitney rank sum test may well be used for ordinal variables (categorical but so long as they are in an acceptable number).

Some softwares also generate confusion because they propose the Wilcoxon rank sum test under the name of Mann-Whitney test... and vice-versa ... and most do not indicate or do not offer always the choice between the exact or approximate version... And furthermore the Wilcoxon rank sum test and that of the Signed rank test that we will see further below are not differentiated .... so be careful! This is typically a problem whose source is the absence of an ISO standard to define the terminology and options that should be available in scientific softwares...

To see what is this test, let us build the rank table using two samples including two control variables and three measurement variables, then we have:

Possible ranks (Controls)	Possible ranks (Treatments)	W_S
$1,2$	$3,4,5$	12
$1,3$	$2,4,5$	11
$1,4$	$2,3,5$	10
$1,5$	$2,3,4$	9
$2,3$	$1,4,5$	10
$2,4$	$1,3,5$	9
$2,5$	$1,3,4$	8
$3,4$	$1,2,5$	8
$3,5$	$1,2,4$	7
$4,5$	$1,2,3$	6

Table 5.79: **Representation of ranks 2 control variables and 3 treatment variables**

from which we deduce the following table:

Value of W_S	6	7	8	9	10	11	12
Probability	$\dfrac{1}{10}$	$\dfrac{1}{10}$	$\dfrac{2}{10}$	$\dfrac{2}{10}$	$\dfrac{2}{10}$	$\dfrac{1}{10}$	$\dfrac{1}{10}$

Now imagine that we have another experience to be analysed using two samples having 3 control variables and 2 treatment variables (therefore the symmetric or the previous case!!!), then we have:

Possible ranks (Controls)	Possible ranks (Treatments)	W_S
$3,4,5$	$1,2$	3
$2,4,5$	$1,3$	4
$2,3,5$	$1,4$	5
$2,3,4$	$1,5$	6
$1,4,5$	$2,3$	5
$1,3,5$	$2,4$	6
$1,3,4$	$2,5$	7
$1,2,5$	$3,4$	7
$1,2,4$	$3,5$	8
$1,2,3$	$4,5$	9

Table 5.80: **Representation of ranks 3 control variables and 2 treatment variables**

from which we deduce the following table (the reader will notice that this is exactly the same table as the previous regarding the probabilities!!):

Value of W_S	3	4	5	6	7	8	9
Probability	$\dfrac{1}{10}$	$\dfrac{1}{10}$	$\dfrac{2}{10}$	$\dfrac{2}{10}$	$\dfrac{2}{10}$	$\dfrac{1}{10}$	$\dfrac{1}{10}$

Well the idea of the Mann-Whitney rank sum test is quite simple. Indeed, rather than tabulate symmetric situations, it is enough to simply subtract at each value W_S, the value $W_{S,\min}$ so that each table is identical and only one of the two is helpful. Let us see this with the first table:

Possible ranks (Controls)	**Possible ranks (Treatments)**	$W_s - \frac{1}{2}n_x(n_x+1)$
$1,2$	$3,4,5$	6
$1,3$	$2,4,5$	5
$1,4$	$2,3,5$	4
$1,5$	$2,3,4$	3
$2,3$	$1,4,5$	4
$2,4$	$1,3,5$	3
$2,5$	$1,3,4$	2
$3,4$	$1,2,5$	2
$3,5$	$1,2,4$	1
$4,5$	$1,2,3$	0

Table 5.81: **Symmetrization (2 control/3 treatments)**

We deduce the following table:

Value of W_{XY}	0	1	2	3	4	5	6
Probability	$\frac{1}{10}$	$\frac{1}{10}$	$\frac{2}{10}$	$\frac{2}{10}$	$\frac{2}{10}$	$\frac{1}{10}$	$\frac{1}{10}$

Now imagine that we have another experiment to analyse using two sample having 3 control variables and 2 treatments variables, we have therefore using the same idea:

Possible ranks (Controls)	**Possible ranks (Treatments)**	$W_s - \frac{1}{2}n_x(n_x+1)$
$3,4,5$	$1,2$	0
$2,4,5$	$1,3$	1
$2,3,5$	$1,4$	2
$2,3,4$	$1,5$	3
$1,4,5$	$2,3$	2
$1,3,5$	$2,4$	3
$1,3,4$	$2,5$	4
$1,2,5$	$3,4$	4
$1,2,4$	$3,5$	5
$1,2,3$	$4,5$	6

Table 5.82: **Symmetrization (3 control/2 treatments)**

From which we deduce this time again exactly the same table as before:

Value of W_{YX}	0	1	2	3	4	5	6
Probability	$\frac{1}{10}$	$\frac{1}{10}$	$\frac{2}{10}$	$\frac{2}{10}$	$\frac{2}{10}$	$\frac{1}{10}$	$\frac{1}{10}$

this is why the literature mention that we can take whatever we want!

So to summarize, the Mann-Whitney variant (in the specific case here it is the variant named "exact Mann-Whitney variant") consists to tabulate for symmetrical situations a variable denoted by W_{XY} naturally defined by:

$$\boxed{W_{XY}=W_S-\frac{1}{2}n_x(n_x+1)} \tag{5.7.2437}$$

Denoted also often in the literature by:

$$U_1=R_1-\frac{1}{2}n_1(n_1+1) \tag{5.7.2438}$$

since $W_{XY}\in\{0,1,2,\ldots\}$ and therefore:

$$P(W_{XY}=k|n_x,n_y)=P(W_{XY}=k|n_y,n_x) \tag{5.7.2439}$$

In the tables that we can find in books, the probabilities are given with the normalized value of U. Thus, if we take our previous example, but with the usual notations in practice (U instead of W_{YX}):

Value of U	0	1	2	3	4	5	6
Probability	$\frac{1}{10}$	$\frac{1}{10}$	$\frac{2}{10}$	$\frac{2}{10}$	$\frac{2}{10}$	$\frac{1}{10}$	$\frac{1}{10}$

We see that the cumulative probability that $U=2$ is of 0.4. The above table is sometimes given in literature as follows:

Factor $n_2=3$			
U/n_1	1	2	3
0	0.250	0.100	0.050
1	0.500	0.200	0.100
2	0.750	**0.400**	0.200
3	1	0.600	0.350
4		0.800	0.500
5		0.900	0.650
6		1	...

Table 5.83: **Classic representation of the Mann-Whitney test**

where we have put in bold the value corresponding to our example ($U=2,n_1=2,n_2=3$).

Then the practitioner has to choose what he wants to do with these tables if he wishes to make a bilateral or unilateral test.

Remarks

R1. It is important to remember that we have showed with an example that we can also take:

$$W_{XY}=W_S-\frac{1}{2}n_x(n_x+1) \quad (5.7.2440)$$

than:

$$W_{YY}=W_S-\frac{1}{2}n_y(n_y+1) \quad (5.7.2441)$$

as they generate the same tables!

R2. W_{XY} is traditionally denoted U by practitioners as we already have seen it, this is why in some books this test is given under the name "Mann-Whitney U test" with the associated tables under the same name. But take care not to make confusion with the "Wilcoxon U test" sometimes named "Wilcoxon inversion text" which is base on the alternation of sample values when grouped (this test will not be developed in this textbook).

To see the approximate version (asymptotic) of the Mann-Whitney U test we need the expression of the expected mean and variance. For this, remember that we have seen that the sum of normalized ranks was given by:

$$U_1=R_1-\frac{1}{2}n_1(n_1+1) \quad (5.7.2442)$$

But we can also use as we saw:

$$U_2=R_2-\frac{1}{2}n_2(n_2+1) \quad (5.7.2443)$$

and as:

$$R_1+R_2=\frac{N(N+1)}{2} \quad (5.7.2444)$$

with for reminder:

$$N=n_1+n_2 \quad (5.7.2445)$$

We therefore have:

$$\begin{aligned}U_1+U_2&=\left(R_1-\frac{n_1(n_1+1)}{2}\right)+\left(R_2-\frac{n_2(n_2+1)}{2}\right)\\&=\frac{N(N+1)}{2}-\frac{n_1(n_1+1)}{2}-\frac{n_2(n_2+1)}{2}=\frac{(n_1+n_2)(N+1)}{2}-\frac{n_1(n_1+1)}{2}-\frac{n_2(n_2+1)}{2}\\&=\frac{n_1(n_1+n_2+1)}{2}+\frac{n_2(n_1+n_2+1)}{2}-\frac{n_1(n_1+1)}{2}-\frac{n_2(n_2+1)}{2}\\&=\frac{n_1n_1+n_1n_2+n_1+n_2n_1+n_2n_2+n_2-n_1n_1-n_1-n_2n_2-n_2}{2}=n_1n_2\end{aligned} \quad (5.7.2446)$$

The average of the both U is therefore the arithmetic average of the sum. Hence:

$$m_U = \frac{n_1 n_2}{2} \tag{5.7.2447}$$

This means that U_1 or U_2 must be different enough of the latter average so that we reject the null hypothesis H_0 that suppose (for recall) that both samples are issued from the same distribution law. But to determine the p-value, we also need the standard deviation. So let us search it!

The standard deviation is the same a for the Wilcoxon rank sum test (as the second term in the expression of U is a constant and therefore is variance is equal to 0). Therefore, it only remains the variance of the sum of ranks that we have already proved earlier as having for value:

$$\sigma_U = \sqrt{\frac{n_1 n_2 (N+1)}{12}} \tag{5.7.2448}$$

✍**Example:**

Let us take the same example as done with the Wilcoxon rank sum test but slightly modified (for the example to be more easy to understand) that is to say:

$$X : 5.7, 3.2$$
$$Y : 8.1, 5.5, 1.2$$

That is to say grouped and sorted:

$$\underline{1.2}, 3.2, \underline{5.5}, 5.7, \underline{8.1}$$

We then have:

$$\begin{aligned} U_1 &= (2+4) - \frac{1}{2}2(2+1) = 3 \\ U_2 &= (1+3+5) - \frac{1}{2}3(3+1) = 3 \end{aligned} \tag{5.7.2449}$$

So we can choose anyone for the test since both U are equal. If we look at the table above, with $(U=3, n_1=2, n_2=3)$, we have therefore a cumulative probability of 60% that U is equal to 3. So we do not reject the null hypothesis H_0 (in unilateral) that the two samples are from the same distribution law.

The approximation by a Normal distribution gives then:

$$Z = \frac{U - m_U}{\sigma_U} = \frac{3 - \dfrac{n_1 n_2}{2}}{\sqrt{\dfrac{n_1 n_2 (N+1)}{12}}} = \frac{3 - \dfrac{3 \cdot 2}{2}}{\sqrt{\dfrac{3 \cdot 2(5+1)}{12}}} = 0 \tag{5.7.2450}$$

Then the cumulative probability is 50% with the Normal approximation which corresponds to a p-value of 50% in unilateral. Again we do not also not reject the null hypothesis H_0 here.

5.7.14.1.5.1 Treatment of equal ranks in Ranks based tests

When we do a Wilcoxon-Mann-Whitney rank sum test Mann-Whitney or other, equality of ranks may occur.

As theoretical introduction let us take an example:

$$N=n_x+n_y=2+3=5 \tag{5.7.2451}$$

with the following data:

Data	17	17	17	19	21
Rank	?	?	?	4	5

Table 5.84: **Example of problem in case of equalities**

A conventional solution (among others ...) is to assign to each "?" the average rank. So in this case we have:

$$?=\frac{1}{3}(1+2+3)=2 \tag{5.7.2452}$$

The table:

Possible ranks (Controls)	**Possible ranks (Treatments)**	W_S
$1,2$	$3,4,5$	12
$1,3$	$2,4,5$	11
$1,4$	$2,3,5$	10
$1,5$	$2,3,4$	9
$2,3$	$1,4,5$	10
$2,4$	$1,3,5$	9
$2,5$	$1,3,4$	8
$3,4$	$1,2,5$	8
$3,5$	$1,2,4$	7
$4,5$	$1,2,3$	6

Table 5.85: **Representation of ranks 2 control variables and 3 treatment variables**

becomes in this case:

Possible ranks (Controls)	**Possible ranks (Treatments)**	W_S^*
$2,2$	$2,4,5$	11
$2,2$	$2,4,5$	11
$2,4$	$2,2,5$	9
$2,5$	$2,2,4$	8
$2,2$	$2,4,5$	11
$2,4$	$2,2,5$	9
$2,5$	$2,2,4$	8
$2,4$	$2,2,5$	9
$2,5$	$2,2,4$	8
$4,5$	$2,2,2$	6

Table 5.86: **Representation of ranks 2 control variables and 3 treatment variables in case of equalities**

where W_S^* (notice the small upper right *!) is the Wilcoxon statistics when we are in the presence of statistical equalities. The law W_S^* can be more or less different from W_S. Indeed:

Wilcoxon statistics	6	7	8	9	10	11	12
Probability of W_S	$\frac{1}{10}$	$\frac{1}{10}$	$\frac{2}{10}$	$\frac{2}{10}$	$\frac{2}{10}$	$\frac{1}{10}$	$\frac{1}{10}$
Probability of W_S^*	$\frac{1}{10}$	0	$\frac{3}{10}$	$\frac{3}{10}$	0	$\frac{3}{10}$	0

Caution! From the mathematical derivation we have seen above, we can claim that at the opposite of the urban legend, the Mann-Whitney test compares the mean ranks - it does not compare medians and does not compare distributions (i.e. stochastic dominance/stochastic superiority)!!! More generally, this test answers this question: What is the probability that a randomly selected value from the population with the larger mean rank is greater than a randomly selected value from the other population? However if the compared distributions are independent and identically distributed and symmetric, then YES it's equivalent as comparing obviously two medians! It is possible, although not very common, for groups to have different rank sums and yet have equal or nearly equal medians (hence the Mann-Whitney test will be significant even if the medians are equals).

5.7.14.1.6 One sample Wilcoxon rank sum signed Test

The purpose of the "Wilcoxon signed rank sum test" also sometimes named "Wilcoxon median test", is to use a nonparametric technique for checking the symmetry or not of a distribution, and therefore make verbatim a hypothesis on the value of the median. The idea is both simple and subtle.

The principle is that if we compare the differences denoted D_i between individuals of a sample relatively to the median, we know that if we have (for example) an odd number of individuals all different (not equal), then we have 50% of the data above and below the median. Then, to control that distribution of the values satisfies a certain symmetry, the idea (simple but clever) then consists in:

1. Calculate the differences $|D_i|$ in absolute values relatively to the median.
2. Order these absolute differences by ascending order and assign them a respective rank.
3. Calculate the sum of the ranks of the differences D_i that are negative.
4. Calculate the sum of the ranks of the differences D_i that are positive.

and if the sample has a symmetric unimodal distribution (so the median is then confused with the average), there should be a sum of negative ranks S_- that is not statistically significantly different from the sum of positive ranks S^+.

We notice therefore that this hypothesis test for it to work is that the statistical distribution is symmetrical and unimodal!!

Remark

For recall, during our study of Wilcoxon or Mann-Whitney tests independent samples seen above (samples which do not necessarily have the same size), we ordered all the values of the two samples and we make a calculation on the ranks of these values. In tests for paired samples (i.e. of the same size), we ordered the differences values (not the original values!) and works on the ranks of the differences!!!

According to the idea (principle) described above, the sum of the rank bearing the sign $-$ has then for average:

$$\mu_-=\bar{R}_-=\mathrm{E}(R_-)=\mathrm{E}(1X_1+2X_2+\ldots+nX_n)=\sum_{i=1}^{n} i\mathrm{E}(X_n) \tag{5.7.2453}$$

But we have already shown that the expected mean of the binomial distribution is:

$$\mathrm{E}(X_n)=Np \tag{5.7.2454}$$

And as in our case N is equal to 1 (only one value ...) and p is equal to $1/2$ (one in two chance of having a negative sign), it comes immediately using the proofs of the section Sequences and Series:

$$\mu_-=\bar{R}_-=\mathrm{E}(R_-)=\frac{1}{2}\sum_{i=1}^{n} i=\frac{1}{2}\frac{n(n+1)}{2}=\frac{n(n+1)}{4} \tag{5.7.2455}$$

and for the variance using also the results of the section Sequences and Series:

$$\mathrm{V}(R_-)=\mathrm{V}\left(\sum_{i=1}^{n} iX_i\right)=\sum_{i=1}^{n}\mathrm{V}(iX_i)=\sum_{i=1}^{n} i^2\mathrm{V}(X_i) \tag{5.7.2456}$$

and again using the variance of the binomial distribution and the results of section Sequences and Series:

$$\mathrm{V}(R_-)=\sum_{i=1}^{n} i^2\mathrm{V}(X_i)=\sum_{i=1}^{n} i^2\frac{1}{4}=\frac{1}{4}\sum_{i=1}^{n} i^2=\frac{1}{4}\frac{n(n+1)(2n+1)}{6}=\frac{n(n+1)(2n+1)}{24} \tag{5.7.2457}$$

Obviously the sum of ranks of negative differences (respectively positive) will be at the minimum equal to zero and at maximum $n(n+1)/2$. Therefore, the expected mean in the case of a bilateral test should not be too close to one of these two extreme values.

In the case where n is large enough (more than thirty), we can use the approximation of the reduced centered Normal distribution for the variable:

$$\mathcal{N}(0,1)=\frac{S_- - \dfrac{n(n+1)}{4}}{\sqrt{\dfrac{n(n+1)(2n+1)}{24}}} \tag{5.7.2458}$$

where S_- is the sum of ranks of negative differences.

Finally let us notice that empirically if some differences from the median are zero, they will not be included in the ranks. If differences are equal we will take an average rank...

✍**Example:**

Let us start with the case with one sample compared to its experimental median (at the opposite with the comparison to a hypothesized a priori median when we consider the distribution symmetric and unimodal). Consider that we measured the following values for the diameter of a piece:

$$39, 20.2, 40, 32.2, 30.5, 26.5, 42.1, 45.6, 42.1, 45.6, 42.1, 29.9, 40.9$$

We wish to know if the calculated experimental median (which value is equal to 40 in this case) of this sample can not be rejected as a main indicator to threshold level of 5% in bilateral (which will be the case if the number of positive and negative differences is fairly balanced). We then construct the following table:

Measurement	**Differences**	**Absolute value**	**Rank**	R_+	R_-
39	-1	1	2		2
20.2	-19.8	19.8	11		11
40	0	0			
32.2	-7.8	7.8	6		6
30.5	-9.5	9.5	8		9
26.5	-13.5	13.5	10		10
42.1	2.1	2.1	4		4
45.6	5.6	5.6	6.5		6.5
42.1	2.1	2.1	4	4	
45.6	5.6	5.6	6.5	6.5	
42.1	2.1	2.1	4	4	
45.6	5.6	5.6	6.5	6.5	
42.1	2.1	2.1	4	4	
29.9	-10.1	10.1	9		9
40.9	0.9	0.9	1	1	
		Sum:		26	46

At first glance the equality of ranks does not look great but nevermind... we will going a little bit further...

Remark

According to some textbooks the sum of ranks does not give the same value as there are several techniques to calculate the ranks of values that are the equals... However, we have chosen the one used by Minitab software that is customary in the scientific community and which corresponds to that which we have already presented the rules earlier.

If we consider that the number of individuals is sufficient ... we use the approximation (even if in this case the conditions are not satisfied):

$$\mathcal{N}(0,1)=\frac{S_{+,-}-\dfrac{n(n+1)}{4}}{\sqrt{\dfrac{n(n+1)(2n+1)}{24}}} \qquad (5.7.2459)$$

Thus with this example:

$$\mathcal{N}(0,1)=\frac{S_{+}-\dfrac{n(n+1)}{4}}{\sqrt{\dfrac{n(n+1)(2n+1)}{24}}}\cong\frac{26-33}{12.747}\cong -0.549 \qquad (5.7.2460)$$

and respectively:

$$\mathcal{N}(0,1)=\frac{S_- - \dfrac{n(n+1)}{4}}{\sqrt{\dfrac{n(n+1)(2n+1)}{24}}}\cong\frac{46-33}{12.747}\cong 1.02 \quad (5.7.2461)$$

The first case corresponds with the approximation using a Normal distribution to a cumulative probability of 29.13% obtained with the English versions of Microsoft® Excel® 14.0.6123 using the function:

`=NORM.S.DIST(-0.549,TRUE)`

and thus obviously a bilateral p-value of about $2\cdot 29.13\%\cong 58.26\%$.

The second case corresponds with the approximation using a Normal distribution to a cumulative probability of 84.62% obtained with the English versions of Microsoft® Excel® 14.0.6123 using the function:

`=NORM.S.DIST(1.02,TRUE)`

which corresponds to a bilateral p-value of about $2\cdot(1-0.8462)/2=30.76\%$. Minitab gives a bilateral p-value of 32% as it does not use the Normal approximation.

Therefore for the both calculations we can prudently (and sadly) do not reject the null hypothesis H_0 as 40 (the median) is in the middle of the confidence interval (also the sign test leads to the same conclusion).

Remark

A software like Minitab even if offering the Wilcoxon median test for 1 sample gives for the median a value of 36.5 and gives for the median confidence interval the values 31.1 and 42.1. If we apply the bootstrapping method presented in detail in section of Theoretical Computing we get for estimated median 40 (and an average of 38.733) and as interval 30.50 and 42.10... Well in any case we anyway not to reject the null hypothesis H_0 but it is still boring not to know how these values are calculated in Minitab...

5.7.14.1.7 Wilcoxon rank sum signed test for two paired samples

The "Wilcoxon rank sum signed test for two paired samples" or simply "Wilcoxon signed rank test" is 100% based on the principle of the test sample with one sample. The only difference is that the null or alternative hypothesis are based on the difference in the median of the data taken in pairs (two by two) of each of the samples. In most cases, the null hypothesis H_0 is that the median of the differences is zero against the alternative hypothesis H_A that it is statistically significantly different from zero.

Like the T-test for paired samples, the Wilcoxon rank sum test applies to two-sample designs involving repeated measures, matched pairs, or "before" and "after" measures!!

As the mathematical developments are the same as for the one sample test let us attack it directly by an example.

First let us just emphasize that by extension, that an hypothesis for that test to work is that the statistical distribution of differences is therefore symmetrical and unimodal!!

Many introductory texts motivate the signed rank test as a test of median difference, or more rarely in our experience, mean difference, without mentioning that two fairly strict assumptions are required for this interpretation:

- The distribution of both groups must have the same shape.
- The variance of both groups must be equal.

If both these assumptions are true, then the signed rank test can validly be interpreted as having a null hypothesis of equal medians (or equal means).

Remark

Notice that in many statistical softwares, R_+ (see below) is denoted by the letter V.

✍**Example:**

We have two different softwares $(S1, S2)$ to compare and we want to submit to 12 tasks $(T1, T2, T3, \ldots, T12)$ of specific but similar calculations for each of the software. We would like to know if the software have a processing time that is statistically significantly different or not and if so which one is better.

We then have the following table where the time is in minutes and where the differences $x_i - y_i$ are denoted d_i:

Task	$S1$	$S2$	d_i	$\lvert d_i\rvert$	**Rank**	R_+	R_-
$T1$	24.0	23.1	0.9	0.9	1	1	
$T2$	16.7	20.4	−3.7	3.7	4		4
$T3$	21.6	17.7	3.9	3.9	5	5	
$T4$	23.7	20.7	3.0	3.0	2.5	2.5	
$T5$	37.5	42.1	−4.6	4.6	6		6
$T6$	31.4	36.1	−4.7	4.7	7		7
$T7$	14.9	21.8	−6.9	6.9	10		10
$T8$	37.3	40.3	−3.0	3.0	2.5		2.5
$T9$	17.9	26.0	−8.1	8.1	11		11
$T10$	15.5	15.5	0.0	0.0	–		
$T11$	29.0	35.4	−6.4	6.4	9		9
$T12$	19.9	25.5	−5.6	5.6	8		8
					Sum:	8.5	57.5

We already see that the software $S1$ is generally faster than $S2$ without using any tables of the Wilcoxon's exact sign test, we can therefore already say that qualitatively the difference is statistically significant.

If we consider that the number of individuals (sample sizes) is sufficient ... we use the Normal approximation (even in this special example the conditions are not satisfied):

$$\mathcal{N}(0,1)=\frac{S_{+,-}-\dfrac{n(n+1)}{4}}{\sqrt{\dfrac{n(n+1)(2n+1)}{24}}} \tag{5.7.2462}$$

That is to say in this example:

$$\mathcal{N}(0,1)=\frac{S_{+}-\dfrac{n(n+1)}{4}}{\sqrt{\dfrac{n(n+1)(2n+1)}{24}}}\cong\frac{8.5-39}{12.747}\cong-2.392 \tag{5.7.2463}$$

and respectively:

$$\mathcal{N}(0,1)=\frac{S_{-}-\dfrac{n(n+1)}{4}}{\sqrt{\dfrac{n(n+1)(2n+1)}{24}}}\cong\frac{57.5-39}{12.747}\cong 1.453 \tag{5.7.2464}$$

The first case corresponds in approximation to a Normal distribution with a cumulative probability of 0.836% obtained with the English version of Microsoft® Excel® 14.0.6123 using the function:

```
=NORM.S.DIST(-2.392,TRUE)
```

and thus a bilateral p-value of $2\cdot 0.836\%\cong 1.68\%$.

The second case corresponds in approximation to a Normal distribution with a cumulative probability of 92.668% obtained with the English version of Microsoft® Excel® 14.0.6123 using the function:

```
=NORM.S.DIST(1.453,TRUE)
```

and thus a bilateral p-value of $2 \cdot (1-0.92774)\% \cong 14.452\%$. With a software like Minitab 15.1.2 which does not offer the Wilcoxon test for paired samples but for which there is a trick to run it anyway, we get a p -value of 3.3% (same result as with the statistical software `R` which, on the other hand, has this Wilcoxon paired test implemented!). Other softwares gives a p-value always less than 5% (but the values differ from one software to another...).

Therefore, with manual calculations and using the Normal approximation, we would reject the null hypothesis H_0 at the threshold of 5% (if we only focus on the first result). It is the same with `R` and Minitab softwares, we would also reject the null hypothesis H_0 at the threshold of 5%!

Remark

As far as we know there are at least two different ways of calculating the variance of the Wilcoxon rank sum signed test for paired samples (and this is without taking into account the continuity correction which adds a $+0.5$ to the numerator). This is why most of the times results differs between statistical softwares.

5.7.14.1.8 Kruskal-Wallis Test

The Kruskal-Wallis test is a nonparametric test often compared (a bit faster ...) to a nonparametric one-way canonical ANOVA with fixed factor to compare if two or more populations have the same median (null hypothesis H_0) except that it does not requires the assumptions necessary for the parametric version of the ANOVA. When several compared populations pass through this test, the KW-test does not say which population is statistically significantly different but only that there is at least one who is. In fact, as we will show, the KW-test is only an extension of the Mann-Whitney U test seen earlier for a number of populations greater than or equal to three.

To study this test, we will assume that we have only two populations and we will afterwards make an intuitive generalization. This approach is that one that would have used Wilcoxon before that Kruskal and Wallis make the rigorous proof of the generalized case.

> Caution! The Mann-Whitney test and Kruskal-Wall tests fail most of the times as tests of medians. Indeed, that's because as already mentioned earlier above, they test something more complex which reduces to median only under STRONG assumption! Remember that they test "stochastic equality" $H_0: F_1(x)=F_2(x)$ (null hypothesis) vs "stochastic superiority" $H_1: F_1(x)<F_2(x)$ (alternative hypothesis). Their result is expressed in pseudo-median of differences if and only if both samples have same variance and same shape (skewness). This reduces to medians if the group-distributions are also symmetric.

To study this test, let us first recall that (relations whose origin and verbatim the proof have already been explained during our study of the Mann-Whitney test seen above) the average of the sum of ranks and the variance of the sum of ranks is given by:

$$\mu_R=\bar{R}=\frac{N+1}{2} \tag{5.7.2465}$$

$$\text{V}(R)=\sigma_R^2=\frac{N^2-1}{12} \tag{5.7.2466}$$

in the case where there is no duplicate values. Under this assumption, remember that $\bar{R}$ can be assimilated to the rank of the median value (in the case of an odd number of values).

Let us recall that the average values of n draws without replacement among N will be close to a Normal distribution when N big enough, and we have already proved at the beginning of this section that:

$$\sigma_{\bar{X}}=\frac{\sigma}{\sqrt{n}} \tag{5.7.2467}$$

and if the population is not very large, the variance must be corrected by the correction factor on finite population that we have already prove earlier:

$$\text{fpc}=\sqrt{\frac{N-n}{N-1}} \tag{5.7.2468}$$

Therefore it comes:

$$\sigma_{\bar{X}}=\frac{\sigma}{\sqrt{n}}\sqrt{\frac{N-n}{N-1}}\Leftrightarrow\sigma_{\bar{X}}^2=\frac{\sigma^2}{n}\frac{N-n}{N-1} \tag{5.7.2469}$$

We then have if we are concerned with the ranks (the variance of the ranks being the true variance: there is no estimator!):

$$\sigma_{\bar{R}}^2=\frac{\sigma_R^2}{n}\frac{N-n}{N-1}=\frac{\left(\dfrac{N^2-1}{12}\right)}{n}\frac{N-n}{N-1}=\frac{(N-1)(N+1)}{12n}\frac{N-n}{N-1}=\frac{(N+1)(N-n)}{12n} \tag{5.7.2470}$$

Now, to form a reduced centered Normal variable Z we can center and reduce the random variable $\hat{\bar{R}}$ obtained by sampling by writing:

$$Z\cong\frac{\hat{\bar{R}}-\bar{R}}{\sigma_{\bar{R}}}=\frac{\hat{\bar{R}}-\dfrac{N+1}{2}}{\sqrt{\dfrac{(N+1)(N-n)}{12n}}} \tag{5.7.2471}$$

where $\hat{\bar{R}}$ is the average of the sum of the ranks of a sample of the population. And in fact all the trick of the idea behind the Kruskal-Wallis test is here: the statistical distribution of the average of the sum of the ranks of a large number of samples of N values has approximately a Normal distribution (read again if necessary our study of limits of drawings samples of a population at the beginning of this section)!

Let us take the square:

$$Z^2\cong\frac{12}{(N+1)(N-n)}n\left(\hat{\bar{R}}-\frac{N+1}{2}\right)\cong\chi^2(1) \tag{5.7.2472}$$

The approximation by the chi-square law is only valid if n is large enough as we have already discussed in detail during our study of the test chi-square adjustment.

And so the parenthesis of the first equality is equal to the square of the deviation of the rank to the median. This is why we often say that this is a median test (but that is an abusive shortcut).

Before continuing, let us insist on the fact that the scenario in which we find ourselves is that of a random sample of n items from N, which is equivalent to end up with two samples (one of size n and the other of size $N-n$) of the same law (verbatim from the same population/distribution). It then comes that (relations that we will use later):

$$n_i+n_j=n_1+n_2=n+(N-n)=N \tag{5.7.2473}$$

and by extension of the case with one sample, if we denote by R_i the sum of ranks of the sample numbers i, we also have:

$$n_i\bar{R}_i+n_j\bar{R}_j=n_1\bar{R}_1+n_2\bar{R}_2=n\bar{R}_1+(N-n)\bar{R}_2=N\bar{R}=N\frac{N+1}{2}=\frac{1}{2}N(N+1) \tag{5.7.2474}$$

It follows that if we write for what will follow:

$$\bar{R}_1=\hat{\bar{R}}=\frac{R}{n} \tag{5.7.2475}$$

where R is the sum of the ranks of the sample $i=1$, we have:

$$\bar{R}_2=\frac{\dfrac{1}{2}N(N+1)-n\hat{\bar{R}}}{N-n}=\frac{\dfrac{1}{2}N(N+1)-R}{N-n} \tag{5.7.2476}$$

If we now write the relation proved above:

$$\frac{12}{(N+1)(N-n)}n\left(\hat{\bar{R}}-\frac{N+1}{2}\right)=\frac{12}{(N+1)(N-n)}n\left(\hat{\bar{R}}-\bar{R}\right)\cong\chi^2(1) \tag{5.7.2477}$$

as follows (this is a clever development in reverse order... starting from the third line):

$$\begin{aligned}
&\frac{12}{(N+1)(N-n)}n\left(\hat{\bar{R}}-\frac{N+1}{2}\right)=\frac{\hat{\bar{R}}^2-(N+1)\hat{\bar{R}}+\dfrac{1}{4}(N+1)^2}{\dfrac{(N+1)(N-n)}{12n}}=\frac{\dfrac{R^2}{n^2}-(N+1)\dfrac{R}{n}+\dfrac{1}{4}(N+1)^2}{\dfrac{(N+1)(N-n)}{12n}}\\
&=\frac{12\dfrac{R^2}{n}-12(N+1)R+3n(N+1)^2}{(N+1)(N-n)}=\frac{12NR^2-12Nn(N+1)R+3(N+1)^2Nn^2}{N(N+1)n(N-n)}\\
&=\frac{12NR^2-12Nn(N+1)R+3N^2(N+1)^2n}{N(N+1)n(N-n)}-\frac{3(N+1)N(N+1)n(N-n)}{N(N+1)n(N-n)}\\
&=\frac{12}{N(N+1)}\left(\frac{(N-n)R^2+\dfrac{1}{4}N^2(N+1)^2n-Nn(N+1)R+nR^2}{n(N-n)}\right)-3(N+1)\\
&=\frac{12}{N(N+1)}\left(\frac{R^2}{n}+\frac{\left(\dfrac{1}{2}N(N+1)-R\right)^2}{N-n}\right)-3(N+1)=\frac{12}{N(N+1)}\left(\frac{\bar{R}_1^2}{n_1}+\frac{\bar{R}_2^2}{n_2}\right)-3(N+1)\\
&=\frac{12}{N(N+1)}\left(\sum_{i=1}^{2}\frac{\bar{R}_i^2}{n_i}\right)-3(N+1)
\end{aligned} \tag{5.7.2478}$$

and we find ourselves at the end with the fact that we worked from the beginning with two samples, one of size n and therefore the other (verbatim by sampling) of size $N-n$.

The previous result (which was the one desired from the beginning) can be generalized as follows under the named "Kruskal-Wallis H test" to a given confidence level in unilateral (sometimes this relation is written without the parentheses around the sum which can lead to a bad reading):

$$\boxed{H=\frac{12}{N(N+1)}\left(\sum_{i=1}^{c}\frac{\bar{R}_i^2}{n_i}\right)-3(N+1)\cong\chi^2(c-1)} \tag{5.7.2479}$$

and if all the n_i are equals, we fall back on a well known notation of the previous relation:

$$H=\frac{12}{nN(N+1)}\left(\sum_{i=1}^{c}\bar{R}_i\right)-3(N+1)\cong\chi^2(c-1) \tag{5.7.2480}$$

The approximation according to a chi-square law, however, can be discussed when the sample size (c) is small (refer to our study of the Chi-square law earlier).

✍**Example:**

Let us take the original example of Kruskal-Wallis. We consider that we have three machines that are the same at the origin but two of them have undergone some modifications. We measured the daily production a number of times and got the following table:

Task	**Standard**	**Rank**	**Modified 1**	**Rank**	**Modified 2**	**Rank**
340	5	339	4	347	10	
345	9	333	2	343	7	
330	1	344	8	349	11	
342	6			355	12	
338	3					
			- - - - - - - - - - - - - - - - - - - -			
n	5		3		4	12
R	24		14		40	78
R^2/n	11.5		65.33		400	580.53

Table 5.87: **Example table for the Kruskal-Wallis test**

We then have well:

$$\begin{gathered}\sum n_i = N = 12\\ \sum R_i = \frac{1}{2}N(N+1) = 78\end{gathered} \tag{5.7.2481}$$

and:

$$H = \frac{12}{N(N+1)}\left(\sum_{i=1}^{3}\frac{\bar{R}_i^2}{n_i}\right) - 3(N+1) = \frac{12}{12\cdot 13}580.83 - 3.13 \cong \chi^2(2) \tag{5.7.2482}$$

Be we have:

$$P\left(\chi^2(2) \geq 5.656\right) \cong 0.059 \tag{5.7.2483}$$

That can be obtained easily with Microsoft® Excel® 14.0.7166 in English with the function:

```
=1-CHISQ.DIST(5.656,2,TRUE)
```

In the present case, to a threshold level of 5%, so we are at the limit with the approximation by a chi-square distribution. As shown by Kruskal and Wallis, a Monte Carlo simulation gives a p-value of 0.049.

In short, in this situation it would be better have to reject the null hypothesis as that the productions are similar. And therefore preferred the alternative hypothesis such that these are rather different. A recommendation is to redo the test by pairs to see what is statistically significantly one by one.

5.7.14.1.9 Friedman Test

The Friedman test, recommended by the norm NF ISO 8587 for sensory analysis (ranking test), consider an experiment with two factors (the first being considered as the treatment and the second as the blocks of tests as well as the ANOVA with two-fixed factor without repetition) that is analysed using the ranks, as the measurement values do not satisfy the conditions for the application of ANOVA. However, instead of ANOVA, Friedman test applies to paired data as we shall see now.

Let us associate, as we have already done it several times, the theory to an example starting from the following table where 8 subjects (blocks) denoted by B under hypnosis were subjected to 4 emotions (treatments) denoted by T. Their epidermal electrical potential was measured (millivolts) in each case (and the order of the treatments was randomized):

	Subjects (B)							
Emotions (T)	1	2	3	4	5	6	7	8
Fear	23.1	57.6	10.5	23.6	11.9	54.6	21.0	20.3
Joy	23.1	57.6	10.5	23.6	11.9	54.6	21.0	20.3
Sadness	22.5	53.7	10.8	21.1	13.7	39.2	13.7	16.3
Calm	22.6	53.1	8.3	21.6	13.3	37.0	14.8	14.8

Table 5.88: **Example table for the Friedman test**

The central and subtle idea is not to assign a rank to the entire population of the measures as is the case for the Kruskal-Wallis test (we would then lose the concept of the blocks: verbatim the second factor) but block by block all supposed therefore independent of each other.

Remark

We will not deal (as well as in our study of the Kruskal-Wallis test) the situation where some measurements are equal with some others in the same block, the existing proofs being not really convincing in my point of view.

So, to every value $\{x_{tb}\}_{T\times B}$ of the table we now associate the rank $\{r_{tb}\}_{T\times B}$ corresponding to each treatment. Which will give us:

	Subjects (B)							
Emotions (T)	1	2	3	4	5	6	7	8
Fear	4	4	3	4	1	4	4	3
Joy	3	2	2	1	4	3	1	4
Sadness	1	3	4	2	3	2	2	2
Calm	2	1	1	3	2	1	3	1

Well now that we have built such a kind of nonparametric ANOVA table with two fixed factors without repetitions what do we do? What is the idea? Well the basic idea is the same as the Kruskal-Wallis test: we use the property of the average of the sum of the ranks but while having in mind that this time that the numbering (ranking) was not made on all measures of the table but block by block.

In the context of our particular example we have therefore:

	Subjects (B)									
Emotions (T)	1	2	3	4	5	6	7	8		
Fear	4	4	3	4	1	4	4	3	$R_1 = 27$	$\bar{R}_1 = 3.375$
Joy	3	2	2	1	4	3	1	4	$R_2 = 20$	$\bar{R}_2 = 2.50$
Sadness	1	3	4	2	3	2	2	2	$R_3 = 19$	$\bar{R}_3 = 2.375$
Calm	2	1	1	3	2	1	3	1	$R_4 = 14$	$\bar{R}_4 = 1.75$

and in case of no influence of treatments, we expect to have:

$$R_1 = R_2 = R_3 = R_4 = R_t \tag{5.7.2484}$$

or alternatively (this is equivalent):

$$\bar{R}_1 = \bar{R}_2 = \bar{R}_3 = \bar{R}_4 = \bar{R}_t \tag{5.7.2485}$$

If there is no influence of the treatments this last four values should be equal and fluctuate around:

$$\mu_R = \bar{R} = \frac{T+1}{2} = \frac{4+1}{2} = 2.5 \tag{5.7.2486}$$

We can feel that the fluctuation of the $\bar{R}_t$ around μ_R must follow a Normal centered distribution if there is not any influence (there is a proof of this in the original article of Friedman but it has sometimes some unexplained gaps that refrain us to present it). We can the also reduce the Normal law such as:

$$Z \cong \frac{\bar{R}_r - \bar{R}}{\sigma_{\bar{R}}} = \frac{\bar{R}_r - \bar{R}}{\dfrac{\sigma_R}{\sqrt{B}}} = \frac{\bar{R}_r - \bar{R}}{\dfrac{\sqrt{\dfrac{T^2-1}{12}}}{\sqrt{B}}} \tag{5.7.2487}$$

It is not always intuitive that the standard error is obtained by dividing the root of B (the number of blocks) because the majority of practitioners have intuition to divide by the root of T of the number of treatments when they study the theoretical aspect of Friedman test. But this can be verified with a numerical application or by remembering that the calculation of the variance σ_R is done from the ranks of B for a given treatment, ranks which the values (in the example above these values are 8 time between 1 and 4) are obviously assumed for a given treatment to be independent and identically distributed.

So we have:

$$Z^2 = \frac{(\bar{R}_t - \bar{R})^2}{\sigma_{\bar{R}}^2} = \frac{(\bar{R}_t - \bar{R})^2}{\dfrac{\sigma_R^2}{B}} \tag{5.7.2488}$$

Unlike the Kruskal-Wallis, we don't do any sampling, so we should not correct the deviation with the correction factor on finite population (fpc) to decrease its value.

The idea of Friedmann (at least that is how we will present it) is to say that the standard deviation of the sum of ranks of treatments obtained in the same way as in the Kruskal-Wallis test (which origin has been detailed in our study of the Mann-Whitney test):

$$\hat{\sigma}_R^2=\frac{T^2-1}{12} \tag{5.7.2489}$$

is this time only an estimator of the true standard deviation and we must used the relation between the unbiased and biased estimator to correct this estimate (relation proved during our study of the estimators):

$$\hat{\sigma}_R^2=\frac{T}{T-1}\hat{\sigma}_R^2=\frac{T}{T-1}\frac{T^2-1}{12} \tag{5.7.2490}$$

Therefore:

$$\sum_{t=1}^{T} Z_t^2=\frac{\displaystyle\sum_{t=1}^{T}\left(\bar{R}_t-\frac{T+1}{2}\right)^2}{\displaystyle\frac{T}{T-1}\frac{\hat{\sigma}_R^2}{B}}=\frac{T-1}{T}\frac{\displaystyle\sum_{t=1}^{T}\left(\bar{R}_t-\frac{T+1}{2}\right)^2}{\dfrac{\frac{T^2-1}{12}}{B}} \tag{5.7.2491}$$

where we have removed a degree of freedom to the chi-square for the reason already met many times in this section.

Then after some elementary simplifications we get the "Q Friedman test" (which is therefore a nonparametric test):

$$\boxed{Q=\frac{12B}{T(T+1)}\sum_{t=1}^{T}\left(\bar{R}_t-\frac{T+1}{2}\right)^2\cong\chi^2(T-1)} \tag{5.7.2492}$$

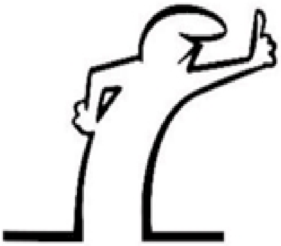
✍**Example:**

Going back to our example, then it comes:

$$\begin{aligned}&\frac{12B}{T(T+1)}\sum_{t=1}^{T}\left(\bar{R}_t-\frac{T+1}{2}\right)^2=\frac{12\cdot 8}{4(4+1)}\sum_{t=1}^{4}\left(\bar{R}_t-\frac{4+1}{2}\right)^2\\&=\frac{24}{5}\left[\left(3.375-\frac{5}{2}\right)^2+\left(2.50-\frac{5}{2}\right)^2+\left(2.375-\frac{5}{2}\right)^2+\left(1.75-\frac{5}{2}\right)^2\right]=6.45\end{aligned} \tag{5.7.2493}$$

The critical value of $\chi^2(T-1)$ at the 5% threshold is 7.81. So we sadly do not reject the null hypothesis H_0 as what treatments have no effect (no difference between the treatments). The cumulative probability corresponding to 6.45 (thus the p-value) is 90%.

And keep in mind that excellent meme by Adrian Olszewski:



- Variable transformation

Box-Cox, Logarithm, Johnson, Manly, etc.

⊳ Change a LOT of things

- Rank-based methods

Mann-Whitney, Kruskal-Wallis, Friedman, etc.

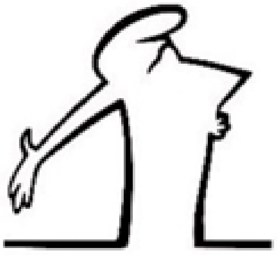
⊳ Totally change H_0; complex interpretation, may fool you about medians

---

- More general (semi-) parametric methods

GLM, GLS, [G]LMM, GEE

⊳ Retain null hypotheses, handle heteroscedasticity, dependency, non-normality



- Computer intensive testing

Permutation tests, Bootstrap & Jackknife resampling

⊳ Retain null hypotheses, handle heteroscedasticity, dependency, non-normality, partially - outliers

Or this table also by Adrian Olszewski:

Subject of comparisons H_0 **vs** H_1	**1 factor**				**2 factors + interactions**		
	2 levels		k **levels**		**of** k **levels**	+ **numerical covariates**	+ **repeated data**
	unpaired	**repeated data**	**unpaired**	**repeated data**			
stochastic equivalence vs stochastic superiority	• Mann-Whitney (Wilcoxon) • Brunner-Munzel	Signed rank (Wilcoxon)	Kruskal-Wallis	• Friedman • Skillings-Mack RM-ANOVA • ANOVA Type Statistics (ATS) • Wald Type Statistics (WTS) • Aligned Ranked Transform (ART) ANOVA	• ATS • Permuted WTS • ART ANOVA • Brunner-Dette-Munk	Ordinal Logistic Regression = Proportional-Odds Model + Wald or Likelihood Ratio Test (LRT) inference	GEE-fit Generalized Estimating Equations Ordinal Logistic Regression with appropriate correlation structure

Table 5.89: **Flexible distribution-free & robust testing common hypotheses about numerical data (author: Adrian Olszewski)**

5.7.14.1.10 Spearman's rank correlation coefficient

The "Spearman's rank correlation coefficient", denoted R_S is the correlation coefficient of the sequence $(R(i), S(i))\,, i=1\ldots n$, of the ranks naturally inspired by the linear correlation coefficient of Pearson that we saw at the beginning of this section:

$$R_S=\frac{\mathrm{E}\left[(R_i-\bar{R})(S_i\bar{S})\right]}{\sqrt{\mathrm{V}(R)\mathrm{V}(S)}}=\frac{\mathrm{E}(R\cdot S)-\mathrm{E}(R)\mathrm{E}(S)}{\sqrt{\left(\mathrm{E}(R^2)-\mathrm{E}(R)^2\right)\left(\mathrm{E}(S^2)-\mathrm{E}(S)^2\right)}} \tag{5.7.2494}$$

Let us also take an example before we tackle the theoretical aspect. Consider that the measurement of a sample of size 10 (we took the same values as that taken for the previous nonparametric rank test studies):

X	Y
5.7	8.1
3.2	5.5
8.4	3.4
4.1	7.9
6.9	4.6
5.3	1.6
1.7	8.5
3.2	7.1
2.5	8.7
7.4	5.7

with their respective ranks in accordance with the idea of Kendall (simple idea but that had to be found!):

X	$R(i)$	Y	$S(i)$
5.7	7	8.1	8
3.2	3	5.5	4
8.4	10	3.4	2
4.1	5	7.9	7
6.9	8	4.6	3
5.3	6	1.6	1
1.7	1	8.5	9
3.2	4	7.1	6
2.5	2	8.7	10
7.4	9	5.7	5

Now let us show that the above given relation is simplified drastically because the values of R, such as those of S, browse the first n integers. For this, remember that we have proved in the section of Sequences and Series, that:

$$\sum_{i=1}^{n} i=\frac{n(n+1)}{2} \tag{5.7.2495}$$

Therefore:

$$\mathrm{E}(R)=\mathrm{E}(S)=\frac{1}{n}\frac{n(n+1)}{2}=\frac{n+1}{2} \tag{5.7.2496}$$

Hence:

$$R_S=\frac{\mathrm{E}(R\cdot S)-\left(\dfrac{n+1}{2}\right)^2}{\sqrt{\left(\mathrm{E}(R^2)-\left(\dfrac{n+1}{2}\right)^2\right)\left(\mathrm{E}(S^2)-\left(\dfrac{n+1}{2}\right)^2\right)}} \tag{5.7.2497}$$

We also have proved in the section of Sequences and Series that:

$$\sum_{i=1}^{n} i^2=\frac{n(n+1)(2n+1)}{6} \tag{5.7.2498}$$

therefore:

$$\mathrm{E}(R^2)=\mathrm{E}(S^2)=\frac{1}{n}\frac{n(n+1)(2n+1)}{6}=\frac{(n+1)(2n+1)}{6} \tag{5.7.2499}$$

Therefore it comes:

$$\begin{aligned}
R_S&=\frac{\mathrm{E}(R\cdot S)-\left(\dfrac{n+1}{2}\right)^2}{\dfrac{(n+1)(2n+1)}{6}-\left(\dfrac{n+1}{2}\right)^2}=\frac{12\mathrm{E}(R\cdot S)-12\left(\dfrac{n+1}{2}\right)^2}{2(n+1)(2n+1)-3(n+1)^2}\\
&=\frac{12\mathrm{E}(R\cdot S)-3(n+1)^2}{(2n+2)(2n+1)-3(n^2+2n+1)}=\frac{12\mathrm{E}(R\cdot S)-3(n^2+2n+1)}{4n^2+2n+4n+2-3n^2-6n-3}\\
&=\frac{12\mathrm{E}(R\cdot S)-3n^2-6n-3}{n^2-1}=\frac{12\dfrac{1}{n}\displaystyle\sum_{i=1}^{n}R_iS_i-3n^2-6n-3}{n^2-1}\\
&=\frac{12\displaystyle\sum_{i=1}^{n}R_iS_i}{n^3-n}-\frac{3n^2+6n+3}{n^2-1}=\frac{12\displaystyle\sum_{i=1}^{n}R_iS_i}{n^3-n}-\frac{3(n+1)^2}{n^2-1}=\frac{12\displaystyle\sum_{i=1}^{n}R_iS_i}{n^3-n}-\frac{3(n+1)^2}{(n+1)(n-1)}\\
&=\frac{12\displaystyle\sum_{i=1}^{n}R_iS_i}{n(n^2-1)}-\frac{3(n+1)}{n-1}=\frac{6\displaystyle\sum_{i=1}^{n}2R_iS_i}{n(n^2-1)}-\frac{3(n+1)}{n-1}
\end{aligned} \tag{5.7.2500}$$

Now let us play a little bit more to get a more simplified expression by observing that:

$$\mathrm{E}(R_i-S_i)^2=\sum_{i=1}^{n}R_i^2-2R_iS_i+S_i^2=\sum_{i=1}^{n}R_i^2-2\sum_{i=1}^{n}R_iS_i+\sum_{i=1}^{n}S_i^2 \tag{5.7.2501}$$

Then it comes:

$$2\sum_{i=1}^{n}R_iS_i=\sum_{i=1}^{n}R_i^2+\sum_{i=1}^{n}S_i^2-\sum_{i=1}^{n}(R_i-S_i)^2=\sum_{i=1}^{n}R_i^2+\sum_{i=1}^{n}S_i^2-\sum_{i=1}^{n}d_i^2 \tag{5.7.2502}$$

Then we have:

$$\begin{aligned}R_S&=\frac{6\sum_{i=1}^{n}2R_iS_i}{n(n^2-1)}-\frac{3(n+1)}{n-1}=\frac{6\left(\sum_{i=1}^{n}R_i^2+\sum_{i=1}^{n}S_i^2-\sum_{i=1}^{n}d_i^2\right)}{n(n^2-1)}\frac{3(n+1)}{n-1}\\&=\frac{6\left(\sum_{i=1}^{n}R_i^2+\sum_{i=1}^{n}S_i^2\right)}{n(n^2-1)}-\frac{3(n+1)}{n-1}-\frac{6\sum_{i=1}^{n}d_i^2}{n(n^2-1)}\end{aligned}\tag{5.7.2503}$$

But we proved that:

$$\sum_{i=1}^{n}i^2=\sum_{i=1}^{n}R_i^2=\sum_{i=1}^{n}S_i^2=\frac{n(n+1)(2n+1)}{6}\tag{5.7.2504}$$

Therefore:

$$\begin{aligned}R_S=&\frac{6\left(\sum_{i=1}^{n}R_i^2+\sum_{i=1}^{n}S_i^2\right)}{n(n^2-1)}-\frac{3(n+1)}{n-1}-\frac{6\sum_{i=1}^{n}d_i^2}{n(n^2-1)}\\&=\frac{2n(n+1)(2n+1)}{n(n^2-1)}-\frac{3(n+1)}{n-1}-\frac{6\sum_{i=1}^{n}d_i^2}{n(n^2-1)}=\frac{2(n+1)(2n+1)}{n^2-1}-\frac{3(n+1)(n+1)}{(n-1)(n+1)}-\frac{6\sum_{i=1}^{n}d_i^2}{n(n^2-1)}\\&=\frac{2(n+1)(2n+1)-3(n+1)(n+1)}{(n-1)(n+1)}-\frac{6\sum_{i=1}^{n}d_i^2}{n(n^2-1)}\\&=\frac{2(2n+1)-3(n+1)}{n-1}-\frac{6\sum_{i=1}^{n}d_i^2}{n(n^2-1)}=\frac{4n+2-3n-3}{n-1}-\frac{6\sum_{i=1}^{n}d_i^2}{n(n^2-1)}\\&=\frac{n-1}{n-1}-\frac{6\sum_{i=1}^{n}d_i^2}{n(n^2-1)}=1-\frac{6\sum_{i=1}^{n}d_i^2}{n(n^2-1)}\end{aligned}\tag{5.7.2505}$$

Thus we find the famous relation available in all (good) statistics and Monte Carlo simulation[86] textbooks:

$$\boxed{R_S=1-\frac{6\sum_{i=1}^{n}d_i^2}{n(n^2-1)}}\tag{5.7.2506}$$

The Spearman coefficient takes the same essential properties as the Pearson coefficient namely that:

$$-1\leq R_S\leq +1\tag{5.7.2507}$$

---

[86] Indeed, the Spearman coefficient is quite important for the modelling of random correlated variables as we will see it at page **??** in the section of Numerical Methods.

and is equal to 0 when the variables are correlated (dot not forget the important subtleties already mentioned in our study of the Pearson coefficient!!!).

Note that this coefficient seems to be defined only for a pair of variables (I have never seen a generalization to a multivariate case at this day).

5.7.14.1.11 Kendall's tau correlation Coefficient

The "Kendall's tau-b correlation coefficient", τ_b, is a nonparametric (rank-statistics) measure of association based on the number of concordances and discordances in paired observations.

It's used in many fields of sociology, engineering and quantitative finance (for an example in quantitative finance see the reference [385]) and often compared or communicated at the same time with the Pearson's correlation coefficient and Spearman's correlation coefficient!

Suppose two observations (X_i,Y_i) and (X_j,Y_j). They are said to be *concordant* if they are in the same order with respect to each variable. That is, if:

(1) $X_i<X_j$ and $Y_i<Y_j$, or if

(2) $X_i>X_j$ and $Y_i>Y_j$

They are *discordant* if they are in the reverse ordering for X and Y, or the values are arranged in opposite directions. That is, if:

(1) $X_i<X_j$ and $Y_i>Y_j$, or if

(2) $X_i>X_j$ and $Y_i<Y_j$

The two observations are tied if $X_i=X_j$ and/or $Y_i=Y_j$.

Remark

The Kendall's tau-c τ_c ignore ties. We won't discuss Kendall's tau-c as it's not often used anymore. In the absence of ties, both formulas yield identical results.

The total number of pairs that can be constructed for a sample size of n is:

$$N=\binom{n}{2}=\frac{1}{2}n(n-1) \qquad (5.7.2508)$$

N can be decomposed into these five quantities:

$$N=P+Q+X_0+Y_0+(XY)_0 \qquad (5.7.2509)$$

where P is the number of concordant pairs, Q is the number of discordant pairs, X_0 is the number of pairs tied only on the X variable, Y_0 is the number of pairs tied only on the Y variable, and $(XY)_0$ is the number of pairs tied on both X and Y.

The Kendall's tau-b for measuring order association between variables X and Y is given by the following formula:

$$\boxed{\tau_b=\frac{P-Q}{\sqrt{(P+Q+X_0)(P+Q+Y_0)}}} \tag{5.7.2510}$$

If there are no ties $X_0=Y_0=0$ then we fall back on a common expression that we can find in many textbooks of the Kendall's tau-b:

$$\tau_b=\frac{P-Q}{\sqrt{(P+Q)(P+Q)}}=\frac{P-Q}{P+Q}=\frac{P-Q}{\frac{1}{2}n(n-1)} \tag{5.7.2511}$$

If we use the symmetric difference distance (see first example below), that latter can be written:

$$\tau_b=\frac{P-Q}{\frac{1}{2}n(n-1)}=\frac{\frac{1}{2}n(n-1)-d_\Delta}{\frac{1}{2}n(n-1)}=1-\frac{2d_\Delta}{n(n-1)} \tag{5.7.2512}$$

This value becomes scaled and ranges between -1 (perfect negative monotonous relation among two variables: a lower score on variable X is always associated with a higher score on variable Y) and $+1$ (perfect positive monotonous relation: a lower score on variable X is always associated with a lower score on variable Y).

Unlike Spearman's rank correlation coefficient it does estimate a population variance as:

$$\tau_b \text{ is the sample estimate of } \tau_b=P[\text{concordance}]-P[\text{discordance}] \tag{5.7.2513}$$

Furthermore, if two variables are independent, $\tau_b=0$ but the reverse does not always hold: a curvilinear or other non monotonous relation may still exist.

✍**Examples:**

E1. Suppose that two experts order four wines denoted $\{a,b,c,d\}$ The first expert gives the following order: $E_1=[a,c,b,d]$, which corresponds to the following ranks $R_1=[1,3,2,4]$ and the second expert orders the wines as $E_2=[a,c,d,b]$ which corresponds to the following ranks $R_2=[1,4,2,3]$. The order given by the first expert is composed of the following 6 ordered pairs:

$$\mathrm{P}_1=\{[a,c],[a,b],[a,d],[c,b],[c,d],[b,d]\}$$

The order given by the second expert is composed of the following 6 ordered pairs:

$$\mathrm{P}_2=\{[a,c],[a,b],[a,d],[c,b],[c,d],[d,b]\}$$

The set of pairs which are in only one set of ordered pairs is:

$$\{[b,d][d,b]\}$$

which gives a value of $d_\Delta(\mathrm{P}_1,\mathrm{P}_2)=2$. With this value of the symmetric difference distance we compute the value of the Kendall's rank correlation coefficient between the order given by these two experts as:

$$\tau_b=1-\frac{2d_\Delta(\mathrm{P}_1,\mathrm{P}_2)}{n(n-1)}=1-\frac{2\cdot 2}{12}=1-\frac{1}{3}=\frac{2}{3}\cong 0.67$$

Notice that the result is equal to:

$$\tau_b = \frac{P-Q}{P+Q} = \frac{5-1}{6} = \frac{2}{3} \cong 0.67$$

E2. Two interviewers ranked 12 candidates (A through L) for a position. The results from most preferred to least preferred are:

- Interviewer 1: ABCDEFGHIJKL
- Interviewer 2: ABDCFEHGJILK

we want to calculate the τ_b.

For that purpose we make a table of rankings. The first column, *Candidate* is optional and for reference only. The rankings for *Interviewer 1* should be in ascending order (from least to greatest):

Candidate	**Interviewer 1**	**Interviewer 2**
A	1	1
B	2	2
C	3	4
D	4	3
E	5	6
F	6	5
G	7	8
H	8	7
I	9	10
J	10	9
K	11	12
L	12	11

After we count the number of concordant pairs, using the second column. Concordant pairs are how many larger ranks are below a certain rank. For example, the first rank in the second interviewer's column is a 1, so all 11 ranks below it are larger:

Candidate	Interviewer 1	Interviewer 2	Concordant	Discordant
A	1	1	11	
B	2	2		
C	3	4		
D	4	3		
E	5	6		
F	6	5		
G	7	8		
H	8	7		
I	9	10		
J	10	9		
K	11	12		
L	12	11		

However, going down the list to the third row (a rank of 4), the rank immediately below (3) is smaller, so it doesn't count for a concordant pair:

Candidate	Interviewer 1	Interviewer 2	Concordant	Discordant
A	1	1	11	
B	2	2	10	
C	3	4	8	
D	4	~~3~~		
E	5	6		
F	6	5		
G	7	8		
H	8	7		
I	9	10		
J	10	9		
K	11	12		
L	12	11		

When all concordant pairs have been counted, it looks like this:

Candidate	Interviewer 1	Interviewer 2	Concordant	Discordant
A	1	1	11	
B	2	2	10	
C	3	4	8	
D	4	4	8	
E	5	6	6	
F	6	5	6	
G	7	8	4	
H	8	7	4	
I	9	10	2	
J	10	9	2	
K	11	12	0	
L	12	11		

Now we count the number of discordant pairs and insert them into the next column. The number of discordant pairs is similar to the previous steps, only we are looking for smaller ranks, not larger ones:

Candidate	Interviewer 1	Interviewer 2	Concordant	Discordant
A	1	1	11	0
B	2	2	10	0
C	3	4	8	1
D	4	4	8	0
E	5	6	6	1
F	6	5	6	0
G	7	8	4	1
H	8	7	4	0
I	9	10	2	1
J	10	9	2	0
K	11	12	0	1
L	12	11		

And we sum these two new columns:

Candidate	Interviewer 1	Interviewer 2	Concordant	Discordant
A	1	1	11	0
B	2	2	10	0
C	3	4	8	1
D	4	4	8	0
E	5	6	6	1
F	6	5	6	0
G	7	8	4	1
H	8	7	4	0
I	9	10	2	1
J	10	9	2	0
K	11	12	0	1
L	12	11		
		Total:	61	5

And, inserting the totals into the formula we get:

$$\tau_b=\frac{P-Q}{P+Q}=\frac{61-5}{61+5}=\frac{56}{66}=0.85 \tag{5.7.2514}$$

We don't need to have two judges to compare to each other. For example in sensitivity analysis we may consider that a company wants to bring a new food product to the market. Potential customers taste 10 versions of this product which have different lipid levels. Customers then rate each version. Once aggregated across all tasters, these ratings are not studied as such but are classified so as to obtain an overall order of preferences. We want to know if this classification can be linked to the lipid level:

Lipid concentration	**Preferences**
13	10
14	7
15	9
16	8
17	5
18	6
19	4
20	3
21	1
22	2

Then we apply the same procedure as above comparing both columns and we get $\tau_b = -0.822$.

Remark

Notice that when the Spearman's rank correlation coefficient can be thought of as the regular Pearson's product moment correlation coefficient as computed from ranks, Kendall's tau rather represents a probability. Specifically, it is the difference between the probability that the observed data are in the same order for the two variables versus the probability that the observed data are in different orders for the two variables.

The Kendall's correlation coefficient depends only the order of the pairs, and it can always be computed assuming that one of the rank order serves as a reference point (e.g. with $N=4$ elements we assume arbitrarily that the first order is equal to 1234). Therefore, with two rank orders provided on n objects, there are $n!$ different possible outcomes (each corresponding to a given possible order) to consider for computing the sampling distribution of τ_b. We can compute the probability p associated with each possible value of τ_b. For example, we find that the p-value associated with a one-sided test for a value of $\tau_b = \frac{2}{3}$ is equal to:

$$p = P\left(\tau_b \geq \frac{2}{3}\right) = \frac{\text{Number of } \tau \geq \frac{2}{3}}{\text{Total number of } \tau} = \frac{4}{24} = 0.17 \tag{5.7.2515}$$

Therefore for our Wine example above we cannot reject the null hypothesis, and we cannot conclude that the expert displayed a significant disagreement in their ordering of the wines.

The computation of the sampling distribution is always theoretically possible because it is finite. But this requires computing $n!$ coefficients of correlation, and therefore it becomes practically impossible to implement these computations for even moderately large values of n. This problem, however, is not as drastic as it seems because the sampling distribution of τ_b converges towards a Normal distribution (the convergence is satisfactory for values of n larger than 10), with a mean of 0 and a variance equal to[87]:

$$\sigma_{\tau_b}^2 = \frac{2(2n+5)}{9n(n-1)} \tag{5.7.2516}$$

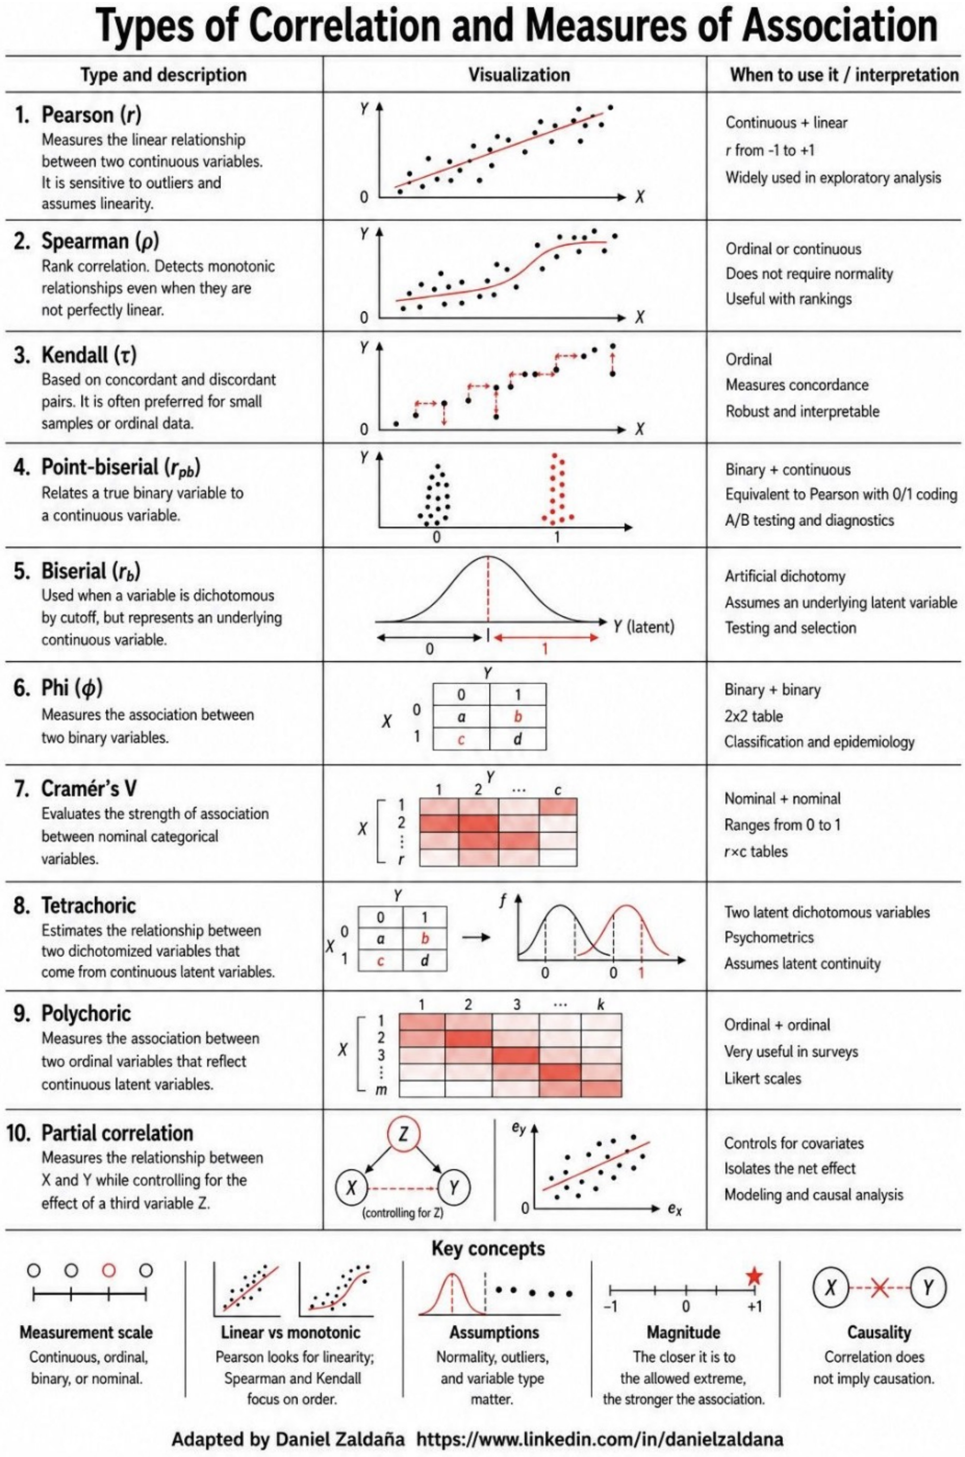
---

[87] We went as far as we could (11933 according to holocene calendar) to find the original detailed proof of this variance but we were not able to find it. Sadly we don't have the time and the fun to rewrite the proof on our own... So without proof - as always in science (!) - use that relation at your own risks!

Therefore, for n larger than 10, a null hypothesis test can be performed by transforming τ_b into a Z value as:

$$Z_{\tau_b} \cong \frac{\hat{\tau}_b}{\sigma_{\tau_b}} = \frac{\hat{\tau}_b}{\sqrt{\frac{2(2n+5)}{9n(n-1)}}} \tag{5.7.2517}$$

This Z value is Normally distributed with a mean of 0 and a standard deviation of 1.



Types of Correlation and Measures of Association

Type and description	Visualization	When to use it / interpretation
1. Pearson (r) Measures the linear relationship between two continuous variables. It is sensitive to outliers and assumes linearity.		Continuous + linear r from -1 to +1 Widely used in exploratory analysis
2. Spearman (ρ) Rank correlation. Detects monotonic relationships even when they are not perfectly linear.		Ordinal or continuous Does not require normality Useful with rankings
3. Kendall (τ) Based on concordant and discordant pairs. It is often preferred for small samples or ordinal data.		Ordinal Measures concordance Robust and interpretable
4. Point-biserial (r_{pb}) Relates a true binary variable to a continuous variable.		Binary + continuous Equivalent to Pearson with 0/1 coding A/B testing and diagnostics
5. Biserial (r_b) Used when a variable is dichotomous by cutoff, but represents an underlying continuous variable.		Artificial dichotomy Assumes an underlying latent variable Testing and selection
6. Phi (ϕ) Measures the association between two binary variables.		Binary + binary 2x2 table Classification and epidemiology
7. Cramér's V Evaluates the strength of association between nominal categorical variables.		Nominal + nominal Ranges from 0 to 1 r×c tables
8. Tetrachoric Estimates the relationship between two dichotomized variables that come from continuous latent variables.		Two latent dichotomous variables Psychometrics Assumes latent continuity
9. Polychoric Measures the association between two ordinal variables that reflect continuous latent variables.		Ordinal + ordinal Very useful in surveys Likert scales
10. Partial correlation Measures the relationship between X and Y while controlling for the effect of a third variable Z.		Controls for covariates Isolates the net effect Modeling and causal analysis

Key concepts

Measurement scale Continuous, ordinal, binary, or nominal.

Linear vs monotonic Pearson looks for linearity; Spearman and Kendall focus on order.

Assumptions Normality, outliers, and variable type matter.

Magnitude The closer it is to the allowed extreme, the stronger the association.

Causality Correlation does not imply causation.

5.7.14.2 Range Statistics

The "range statistics" is a very important tool in finance and quality engineering (to mention only the two best-known examples). As the reader will see in what follows below, these statistics are by construction a subdomain of order statistics and the result that we will obtain here will be absolutely useful to us in the context of quality control charts (see section Engineering page 8934) and therefore also in trading signals in finance.

Given $X_1, X_2, \ldots, X_n$ supposed independent and identically distributed random variables from a law of distribution F and density f. Let us recall that we define the order statistic $X_{(i)}$ by:

$$X_{(1)} \leq \ldots \leq X_{(i)} \leq \ldots \leq X_{(n)} \tag{5.7.2518}$$

By writing:

$$\begin{aligned} W_n &= \min(X_{(1)}, X_{(2)}, \ldots, X_{(n)}) \\ M_n &= \max(X_{(1)}, X_{(2)}, \ldots, X_{(n)}) \end{aligned} \tag{5.7.2519}$$

The variables W_n and M_n define the extreme order statistics and their difference:

$$D_n = M_n - W_n \tag{5.7.2520}$$

is named the "extreme deviation".

For what will follow, we will consider as obvious the relation:

$$\min\left(X_{(1)}, X_{(2)}, \ldots, X_{(n)}\right) = \max\left(-X_{(1)}, -X_{(2)}, \ldots, -X_{(n)}\right) \tag{5.7.2521}$$

Let us now determine the distribution function of the maximum M_n:

$$F_M(x) = P\left(\{M_n \leq x\}\right) = P\left(\bigcap_{i=1}^{n} \left(X_{(i)} \leq x\right)\right) \tag{5.7.2522}$$

because writing that $M_n \leq x$ is equivalent to write that for every $X_{(i)}$ we have $X_{(i)} \leq n$ (not easy to guess that you must have this approach...).

We then have as the variables are independent (see section Probabilities page 480):

$$F_M(x) = P\left(\bigcap_{i=1}^{n} \left(X_{(i)} \leq x\right)\right) = \prod_{i=1}^{n} P(X_{(i)} \leq x) = \prod_{i=1}^{n} F(x) = [F(x)]^n \tag{5.7.2523}$$

and therefore we obviously have the distribution function:

$$f_M(x) = nf(x)\left[F(x)\right]^{n-1} = \frac{\partial}{\partial x} F_M(x) = \frac{\partial}{\partial x}\left[F(x)\right]^n \tag{5.7.2524}$$

Respectively based on the same idea:

$$\begin{aligned} F_W(x) &= P\left(\{W_n \leq x\}\right) = 1 - P\left(\{W_n > x\}\right) = 1 - P\left(\bigcap_{i=1}^{n} \left(X_{(i)} > x\right)\right) \\ &= 1 - \prod_{i=1}^{n} P\left(X_{(i)} > x\right) = 1 - \prod_{i=1}^{n} \left(1 - P\left(X_{(i)} < x\right)\right) = 1 - \prod_{i=1}^{n} (1 - F(x)) \\ &= 1 - (1 - F(x))^n \end{aligned} \tag{5.7.2525}$$

and therefore we obviously have the distribution function:

$$f_W(x)=nf(x)\left[1-F(x)\right]^{n-1}=\frac{\partial}{\partial x}F_W(x)=\frac{\partial}{\partial x}\left(1-(1-F(x))^n\right) \tag{5.7.2526}$$

Hence:

$$\begin{gathered}\mathrm{E}(R)=\mathrm{E}(M_n-W_n)=\mathrm{E}(M_n)-\mathrm{E}(W_n)=\int\limits_{-\infty}^{+\infty}xf_M(x)\mathrm{d}x-\int\limits_{-\infty}^{+\infty}xf_W(x)\mathrm{d}x\\=\int\limits_{-\infty}^{+\infty}x\left(f_M(x)-f_W(x)\right)\mathrm{d}x=\int\limits_{-\infty}^{+\infty}xf_D(x)\mathrm{d}x=\int\limits_{-\infty}^{+\infty}\frac{\partial}{\partial x}\left[[F(x)]^n-(1-[1-F(x)]^n)\right]\mathrm{d}x\end{gathered} \tag{5.7.2527}$$

having used the linearity of the expected mean and using the fact that for the two distribution functions we are working on the same random variable.

Using an integration by parts (see section Differential and Integral Calculus page 1532):

$$\begin{aligned}\mathrm{E}(R)=\bar{R}=&\int\limits_{-\infty}^{+\infty}\frac{\partial}{\partial x}\left[[F(x)]^n-(1-[1-F(x)]^n)\right]\mathrm{d}x\\&=x\left[[F(x)]^n-(1-[1-F(x)]^n)\right]\Big|_{-\infty}^{+\infty}-\int\limits_{-\infty}^{+\infty}\left(\left[[F(x)]^n-(1-[1-F(x)]^n)\right]\right)\mathrm{d}x\\&=\int\limits_{-\infty}^{+\infty}\left(1-[F(x)]^n-[1-F(x)]^n\right)\mathrm{d}x\end{aligned} \tag{5.7.2528}$$

remembering that $F(-\infty)$ and $F(+\infty)=1$.

Now let us consider the special case where the distribution function follows a Normal centered reduced distribution such as:

$$F(x)=\Phi\left(\frac{x-\mu}{\sigma}\right) \tag{5.7.2529}$$

Then we have:

$$\bar{R}=\int\limits_{-\infty}^{+\infty}\left(1-[F(x)]^n-[1-F(x)]^n\right)\mathrm{d}x=\int\limits_{-\infty}^{+\infty}\left(1-\Phi\left(\frac{x-\mu}{\sigma}\right)^n-\left[1-\Phi\left(\frac{x-\mu}{\sigma}\right)\right]^n\right)\mathrm{d}x \tag{5.7.2530}$$

Let us do a change of variable:

$$y=\frac{x-\mu}{\sigma}\Rightarrow\frac{\mathrm{d}y}{\mathrm{d}x}=\frac{1}{\sigma}\Rightarrow\mathrm{d}x=\sigma\mathrm{d}y \tag{5.7.2531}$$

Then we have:

$$\bar{R}=\sigma\int\limits_{-\infty}^{+\infty}(1-\Phi(y)^n-[1-\Phi(y)]^n)\,\mathrm{d}y \qquad (5.7.2532)$$

and then we found the relation given (almost 99% of the time without proof) in the (good) books about statistical process control:

$$d_2(n)=\int\limits_{-\infty}^{+\infty}(1-\Phi(y)^n-[1-\Phi(y)]^n)\,\mathrm{d}y \qquad (5.7.2533)$$

named "Hartley constant" (Leonard Henry Caleb Tippett was the first to develop this theory in the year 11925 according to holocene calendar) and therefore:

$$\boxed{\bar{R}=\sigma d_2(n)} \qquad (5.7.2534)$$

This constant is as far as we know not possible to calculate to calculate formally. Either we have to use Taylor series approximations of the terms of the integral, which becomes a nightmare for large n, either through a calculation using Monte Carlo simulation (see section Numerical Methods page 6708). As it is relatively long to implement in a spreadsheet, quality engineers prefer to use tables in which we find for example:

Values of n	**Values of $d_2(n)$ with a Normal distribution**
2	1.128
3	1.693
4	2.059
5	2.326
6	2.534
7	2.704
8	2.847
9	2.970
10	3.078
...	...

Table 5.90: **Tabulated values of the Hartley constant $d_2(n)$**

The previous relation is mainly know by quality engineers under the form of an estimated of the unknown process standard deviation:

$$\sigma=\frac{\bar{R}}{d_2(n)} \qquad (5.7.2535)$$

where n is a sample sub-group sample size.

Let us now see the variance of the range using always the Huygens theorem:

$$\mathrm{V}(R)=\mathrm{E}(R^2)-\mathrm{E}(R)^2=\mathrm{E}(R^2)-\sigma^2 d_2^2(n) \qquad (5.7.2536)$$

The calculation of $\mathrm{E}(R^2)$ is not nice (at least I have found nothing that satisfies the pedagogical goal of this textbook), the smallest complete proof held on three to four A4 pages and formally bring anything because we end with an integral that cannot be calculate by hand (by cons if anyone has a simple, elegant and detailed proof do not hesitate to send it to us!). It is for this reason that after having written:

$$W = \frac{R}{\sigma} \tag{5.7.2537}$$

...if we write now as do many technical books:

$$\mathrm{V}(R) = \left[\mathrm{E}(W^2) - d_2^2(n)\right]\sigma^2 \tag{5.7.2538}$$

Then we have:

$$\sigma_R = \sigma\sqrt{\mathrm{E}(W^2) - d_2^2(n)} = \sigma d_3(n) \tag{5.7.2539}$$

But as we do not know the maximum likelihood unbiased estimator of the standard deviation σ, we will use the proven relation:

$$\bar{R} = \sigma d_2(n) \tag{5.7.2540}$$

To finally have a biased estimator of the variance of the range:

$$\boxed{\hat{\sigma}_R = \frac{d_3(n)\bar{R}}{d_2(n)} = \frac{d_3\bar{R}}{d_2}} \tag{5.7.2541}$$

Here are some tabulated values of $d_3(n)$:

Values of n	**Values of $d_3(n)$ with a Normal distribution**
2	0.852
3	0.888
4	0.879
5	0.864
6	0.848
7	0.833
8	0.819
9	0.807
10	0.797
...	...

Table 5.91: **Tabulated values of the $d_3(n)$ constant**

In a typical statistical process control (SPC) application involving sample ranges, data are collected in subgroups of a constant size, say n. For each subgroup, the range is computed and plotted. The average range, $\bar{R}$, for k such subgroups is used to calculate trial control limits from which statistical control may be judged. If the process has been in a state of statistical control and is approximately normally distributed, an estimate of the process standard deviation, σ, based on $\bar{R}$ can be obtained. This estimator is $\bar{R}/d_2$. The factor d_2 depends only on the subgroup sample size n and that the process is normally distributed.

5.7.14.2.1 Tukey's Range Test

"Tukey's range test", also known as "Tukey's test", "Tukey method", "Tukey's honest significance test", or "Tukey's HSD" (honestly significant difference) test, is a single-step multiple comparison procedure and statistical test developed in 11949 (holocene). It can be used to correctly interpret the statistical significance of the difference between means that have been selected for comparison because of their extreme values.

The method was initially developed and introduced by John Tukey for use in Analysis of Variance (ANOVA), and usually has only been taught in connection with ANOVA (i.e. linear regression) under the name of "Tukey's constrast". However, the studentized range distribution used to determine the level of significance of the differences considered in Tukey's test has vastly broader application: It is useful for researchers who have searched their collected data for remarkable differences between groups, but then cannot validly determine how significant their discovered stand-out difference is using standard statistical distributions used for other conventional statistical tests, for which the data must have been selected at random. Since when stand-out data is compared it was by definition not selected at random, but rather specifically chosen because it was extreme, it needs a different, stricter interpretation provided by the likely frequency and size of the studentized range; the modern practice of "data mining" is a example where it is used.

Let us suppose that we have we have Z_k independent centered reduced random variables. And let us denote by U a random variable following a chi-square law with v degrees of freedom.

Let us now define, for reasons that will seem obvious a little further below, the "Studentized range" (the origin of the name comes from its resemblance with the definition of the Student law) by:

$$Q_{k,v}=\frac{\max(Z_i)-\min(Z_i)}{\sqrt{U/v}}=\frac{R_Z}{\sqrt{U/v}} \tag{5.7.2542}$$

and let us try to determine if this relation follows a known law and has a possible application (the find in the numerator what we defined earlier as the "extreme deviation" but with a different notation).

For this, let us show that we fall on the above definition by considering a somewhat more general case where we have X_i independent random variables that follow a Normal distribution $\mathcal{N}(\mu,\sigma)$ and the standard deviation:

$$S_*^2=\frac{1}{n}\sum_{i=1}^{n}(X_i-\mu)^2 \tag{5.7.2543}$$

And let us study the ratio:

$$\frac{\max(Z_i)-\min(Z_i)}{S_*}=\frac{R_X}{S_*} \tag{5.7.2544}$$

Let us now proceed to the classical transformations already seen and proved and used many times since the beginning of this section:

$$Z_i=\frac{X_i-\mu}{\sigma} \tag{5.7.2545}$$

$$U=\chi_v^2=\frac{vS_*^2}{\sigma^2} \tag{5.7.2546}$$

and therefore we have:

$$\frac{\max(Z_i)-\min(Z_i)}{S_*}=\frac{\max\left(\dfrac{X_i-\mu}{\sigma}\right)-\min\left(\dfrac{X_i-\mu}{\sigma}\right)}{\sqrt{\dfrac{U}{v\sigma^2}}}$$

$$=\frac{\max\left(\dfrac{X_i}{\sigma}\right)-\min\left(\dfrac{X_i}{\sigma}\right)}{\sqrt{\dfrac{1}{\sigma}\dfrac{U}{v}}}=\frac{1}{\sigma}\frac{\max\left(X_i\right)-\min\left(X_i\right)}{\dfrac{1}{\sigma}\sqrt{\dfrac{U}{v}}}=\frac{\max\left(X_i\right)-\min\left(X_i\right)}{\sqrt{\dfrac{U}{v}}})=Q_{k,v} \tag{5.7.2547}$$

So that's it already for the first step For the moment, even if we do not know if this definition follows a known distribution law, we can already write the following very interesting definition (notice that the term on the left is always positive):

$$\max\left(X_i\right)-\min\left(X_i\right)=Q_{k,v,1-\alpha}S_* \tag{5.7.2548}$$

or written in another way:

$$R_X=Q_{k,v,1-\alpha}S_* \tag{5.7.2549}$$

and therefore we can calculate what is the cumulative probability of a range of measurements compared to a critical range $R_{X,\text{crit}}$ directly corresponding to a prescribed threshold α. Which brings us to the possibility to write:

$$P\left(R_X\leq R_{X,\text{crit}}\right)=1-\alpha \tag{5.7.2550}$$

Let us now recall that we have seen that the distribution function of the extreme deviation was given by a relation that was to our knowledge not calculable analytically:

$$f_R(x)=\partial_x\left[[F(x)]^2-(1-[1-F(x)]^n)\right] \tag{5.7.2551}$$

So the distribution function $Q_{k,v,1-\alpha}$ can therefore not be assimilate to a known law when $F(x)$ is any law. We must therefore unfortunately tabulate this distribution using Monte Carlo simulations (see section Numerical Methods page 6708) or refer to existing tables.

Now to continue, we make a detour to the one-way fixed factor ANOVA that we studied earlier. Let us first recall that we have shown that for independent and identically Normal distributed random variables we had:

$$\sigma_{\bar{X}}=\frac{\sigma}{\sqrt{n}} \tag{5.7.2552}$$

and since a the ANOVA with fixed factor is also based on the assumption that:

$$\sigma_R^2=\sigma_A^2=\sigma_T^2=\sigma^2 \tag{5.7.2553}$$

this implies that asymptotically the estimators have the same property:

$$S_R^2=S_A^2=\sigma_T^2=S^2 \tag{5.7.2554}$$

We also know that the standard deviation of the mean of a sample of a fixed-factor ANOVA is given in the framework and assumptions of the one-way fixed factor ANOVA by:

$$\sigma_i = \frac{\sigma}{\sqrt{n}} \tag{5.7.2555}$$

But within the framework of one-way fixed factor ANOVA, we have also proved that under the assumptions imposed, we had:

$$S^2 = \text{MSE} = \frac{\sum_{ij}(x_{ij} - \bar{x}_i)^2}{N-k} \tag{5.7.2556}$$

Therefore it comes:

$$S_i = \sqrt{\frac{\text{MSE}}{n}} \tag{5.7.2557}$$

that is an estimator of:

$$\sigma_i = \frac{\sigma}{\sqrt{n}} \tag{5.7.2558}$$

And as we have proved that:

$$\frac{(N-k)\text{MSE}}{\sigma^2} = \chi^2_{N-k} \tag{5.7.2559}$$

Therefore it comes:

$$\frac{(N-k)\dfrac{\text{MSE}}{k}}{\dfrac{\sigma^2}{k}} = \chi^2_{N-k} \tag{5.7.2560}$$

Therefore, we are naturally led to conclude that the relation we defined earlier:

$$\max{(X_i)} - \min{(X_i)} \leq Q_{k,v,1-\alpha} S_* \tag{5.7.2561}$$

may be used in the study of the one-way fixed factor ANOVA under the form:

$$\max{(\bar{x}_i)} - \min{(\bar{x}_i)} \leq Q_{k,N-k,1-\alpha}\sqrt{\frac{\text{MSE}}{n}} \tag{5.7.2562}$$

to do a pre- or posterior-test (post hoc) to a one-way fixed factor ANOVA to check the hypothesis of equality of means and identify which are the aberrant means (multiple comparison test). So the Tukey's test is often accompanied by the Cochran C-test that we have already discussed earlier when we make a one-way fixed factor ANOVA.

Therefore within the ANOVA framework, we must reject the hypothesis of equality of the sample means if:

$$\boxed{\max{(\bar{x}_i)} - \min{(\bar{x}_i)} \geq Q_{k,N-k,1-\alpha}\sqrt{\frac{\text{MSE}}{n}}} \tag{5.7.2563}$$

or written in another way:

$$\max\left(\bar{x}_i\right)-\min\left(\bar{x}_i\right)\geq R_{\mu,\text{crit}} \tag{5.7.2564}$$

In this case, it is then almost immediate we can build the following confidence interval:

$$\boxed{\left(\bar{x}_i-\bar{x}_j\right)-R_{\mu,\text{crit}}\leq\mu_i-\mu_j\leq\left(\bar{x}_i-\bar{x}_j\right)+R_{\mu,\text{crit}}} \tag{5.7.2565}$$

This is the "Tukey's range test" or also simply named "Tukey's test".

It should be known now that there is a Tukey's post-hoc test for the one-way fixed factor ANOVA where the relation:

$$\max\left(\bar{x}_i\right)-\min\left(\bar{x}_i\right)\geq Q_{k,N-k,1-\alpha}\sqrt{\frac{\text{MSE}}{n}} \tag{5.7.2566}$$

will not take the two most extreme means but will compare all the means pairwise (and why not after all!) with the highest average (well we could also have fun making all possible combinations as do some statistical softwares). In this case the relation to use is the same as above except that if we have for example a one-way fixed factor ANOVA with 4 levels then we will have 3 pairwise comparisons (average differences must always be positive!!!). Thus, imagining that the third average is the largest and that in descending order the biggest averages are the 4th, 2nd and 1st (the first is therefore smaller) then it comes:

$$\begin{aligned}\bar{x}_3-\bar{x}_1&\geq Q_{4,N-4,1-\alpha}\sqrt{\frac{\text{MSE}}{n}}\\\bar{x}_3-\bar{x}_2&\geq Q_{3,N-4,1-\alpha}\sqrt{\frac{\text{MSE}}{n}}\\\bar{x}_3-\bar{x}_4&\geq Q_{2,N-4,1-\alpha}\sqrt{\frac{\text{MSE}}{n}}\end{aligned} \tag{5.7.2567}$$

This approach (to extend the basic principle of Tukey's test), is named the "Newman-Keuls test" or "Student-Newman-Keuls test" (SNK).

5.7.14.3 Extreme Value Theory

"Extreme value theory" or "extreme value analysis" (EVA) is a branch of statistics dealing with the extreme deviations from the median of probability distributions. It seeks to assess, from a given ordered sample of a given random variable, the probability of events that are more extreme than any previously observed. Extreme value analysis is widely used in many disciplines, such as structural engineering, finance, Earth sciences, traffic prediction, and geological engineering. For example, EVA might be used in the field of hydrology to estimate the probability of an unusually large flooding event, such as the 100-year flood. Similarly, for the design of a breakwater, a coastal engineer would seek to estimate the 50-year wave and design the structure accordingly.

To finish depending on donations

5.7.15 Multivariate Statistics

Obviously Multivariate statistics is a subdivision of statistics encompassing the simultaneous observation and analysis of more than one random variable.

Before we continue, remember that we have already derived two multivariate distribution earlier above! The Normal multivariate distribution (see page 720) and the Student-T canonical multivariate distribution (see page 789). We have also already introduced the multivariate ANOVA (i.e. MANOVA) earlier above at page 1091.

Remark

Certain types of problem involving multivariate data, for example simple linear regression and multiple regression that we saw earlier above, are not usually considered as special cases of multivariate statistics because the analysis is dealt with by considering the (univariate) conditional distribution of a single outcome variable given the other variables.

There are many different models, each with its own type of analysis that we will try to address in this textbook as always with a maximum of details and as accessible as possible (with softwares examples in the companion book for sure!):

1. Principal Components Analysis (PCA) that creates a new set of orthogonal variables that contain the same information as the original set. It rotates the axes of variation to give a new set of orthogonal axes, ordered so that they summarize decreasing proportions of the variation (see below page 1213).

2. Factor Analysis that is similar to PCA but allows the user to extract a specified number of synthetic variables, fewer than the original set, leaving the remaining unexplained variation as error. The extracted variables are known as latent variables or factors; each one may be supposed to account for covariation in a group of observed variables (see section of Numerical Methods page 6925).

3. Canonical Correlation Analysis (CCA) that finds linear relations among two sets of variables; it is the generalised (i.e. canonical) version of bivariate correlation.

4. Correspondence Analysis (CA), or reciprocal averaging, that finds (like PCA) a set of synthetic variables that summarise the original set. The underlying model assumes chi-squared dissimilarities among records (cases). The fundamental formal difference is that PCA decomposes relations between columns only (e.g. by decomposing their covariance matrix), treating rows as "cases"; while CA decomposes columns and rows simultaneously. Where conventional Factor Analysis determines which variables cluster together, correspondence analysis determines which category values are close together.

5. Canonical (or "constrained") Correspondence Analysis (CCA) for summarising the joint variation in two sets of variables; combination of correspondence analysis and multivariate regression analysis. The underlying model assumes chi-squared dissimilarities among records (cases).

6. Multidimensional Scaling comprises various algorithms to determine a set of synthetic

variables that best represent the pairwise distances between records. The original method is principal coordinates analysis (PCoA based on PCA).

7. Discriminant Analysis (linear or quadratic), or canonical variate analysis, attempts to establish whether a set of variables can be used to distinguish between two or more groups of cases.
8. Simultaneous Equations Models involve more than one regression equation, with different dependent variables, estimated together.
9. Multivariate Analysis of Variance (MANOVA) that extends the analysis of variance to cover cases where there is more than one dependent variable to be analyzed simultaneously (see page 1091).
10. Multivariate Analysis of Covariance (MANCOVA) that is an extension of analysis of covariance (ANCOVA) methods to cover cases where there is more than one dependent variable and where the control of concomitant continuous independent variables (covariates) is required.
11. Mixed Models that contains both fixed effects and random effects. These models are useful in a wide variety of disciplines in the physical, biological and social sciences. They are particularly useful in settings where repeated measurements are made on the same statistical units (longitudinal study).

5.7.15.1 Principal Component Analysis

Principal component analysis (P.C.A.) is a mathematical method of graphical data analysis that consist to look for directions in space that best represent the correlations between n random variables (supposed to have linear relations between them). In other terms it is a dimension reduction process (as for the singular values decomposition process - SVD - proved in the section of Linear Algebra or the Linear Discriminant Analysis proved in the section of Numerical Methods among many others techniques as visible on the Data Science mind map at page 6770) as it gives the possibility to the analyst to choose what are the variables in a model that explain the best the variability.

Simply said, a P.C.A. allows for example to find in a dataset buying behaviour similarities between observed classes.

Even if the PCA is mainly used to visualize data, we must not forget that this is also a way to:

- To decorrelate the data. In the new base, consisting in new axis, the points have a zero correlation (we will prove it).
- To classify data into correlated clusters (in the industry it is mainly this possibility that is interesting!).

Remarks

R1. There are several versions of P.C.A. known under the name of "Karhunen-Loeve transformation" or "Hotelling transformation" and that can also be applied without programming in spreadsheet softwares or in specialized one (where the computing time will be shorter by cons ... and the results most accurate too...).

R2. Depending on the authors and the point of view P.C.A. belong to the field of statistics named "Explanatory statistics".

When we consider only two effects, it is customary to characterize their joint effect via the correlation coefficient. When we stands in two dimension, the available points (the sample of points drawn following the joint distribution) can be represented in a plane. The result of the P.C.A. in this plane is the determination of the two axes that best explain the dispersion of the available points.

When there are more than two effects, for example three effects, there are three coefficients of correlations to be taken into account. The issue that gave rise to the P.C.A. is how to have a quick intuition of the joint effects?

In dimension larger than two, a P.C.A. will always determine the axes that best explain the dispersion of the cloud of available points.

The objective of the P.C.A. is to graphically describe a data array of individual with large quantitative variables:

individuals/variables	**var**$_1, \ldots,$ **var**$_j, \ldots,$ **var**$_n$
ind$_1$	
$\vdots$	
ind$_i$	x_{ij}
$\vdots$	
ind$_n$	

Table 5.92: **Generic representation of a P.C.A. table**

In order not to complicate the presentation of this method and to allow the reader to completely redo the calculations, we will work on the theory with a direct famous example.

Let us consider for example a study of a botanist who measured the dimensions of 15 iris flowers (the P.C.A. is also widely used in finance to determine the elements that most influences the volatility of a portfolio). The three variables ($p = 3$) measured are:

- x_1: Length of sepal
- x_2: Width of sepal
- x_3: Length of the petal

The data are the following:

Flower n°	x_1	x_2	x_3
1	5.1	3.5	1.4
2	4.9	3.0	1.4
3	4.7	3.2	1.3

Table 5.93: **Practical tabulated data example for P.C.A.**

For us, such a data table is simply a real components matrix with n rows (the individuals) with p columns (the variables):

$$X=(x_{ij})_{\substack{i=1\ldots n\\ \text{æ}=1\ldots p}} \tag{5.7.2568}$$

Thereafter the index i will correspond to the line index and therefore to individuals. We will identify the individual i with point line $x_{i.}=(x_{i1},\ldots,x_{ip})$ which will be considered as a point in an affine space (see section Vector Calculus page 1815) of dimension p. The index j will correspond to the index column so the variables. We will identify the variable j with the column vector:

$$\vec{x}_{.j}=\begin{pmatrix}x_{1j}\\ \vdots\\ x_{nj}\end{pmatrix} \tag{5.7.2569}$$

this is therefore a vector in the vector space of dimension n in $\mathbb{R}^n$.

We will place ourselves in what will follow in two perspectives: either we will take the table data as n points an affine space of dimension p, or we will take this table as p points in a vector space of dimension n. We will see that there are dualities between these two perspectives.

The mathematical tool that we will use here is linear algebra (see section Linear Algebra page 1924), with the concepts of dot product, Euclidean norm and Euclidean distance.

To simplify the presentation, we will initially consider that each individual as each variable has the same importance, the same weight. We also consider the case of the Euclidean distance.

We will start by centering the data, that is to say to put origin of the reference frame on the center of gravity of the point cloud. This does not change the appearance of the cloud, but allows us to get the coordinates of a point M, equal to the coordinates of the vector $\overrightarrow{GM}$, and thus to place ourselves in the vector space to be able to do the math! Since we assume throughout what will follow that the weights of the individuals are identical, we will take $m_i = 1/n$ with $i = 1 \ldots n$.

We consider the orthonormal reference frame $(\text{O}, \vec{e}_1, \vec{e}_2, \ldots, \vec{e}_p)$ in the canonical basis $(\vec{e}_1, \vec{e}_2, \ldots, \vec{e}_p)$ of $\mathbb{R}^p$. Given G being therefore the center of gravity of the point cloud. As each variable and each individual is assumed to have the same weight, then G has for coordinates the reference frame $(\text{O}, \vec{e}_1, \vec{e}_2, \ldots, \vec{e}_p)$:

$$\overrightarrow{\text{O}G} = \begin{pmatrix} \bar{x}_{.1} \\ \vdots \\ \bar{x}_{.j} \\ \vdots \\ \bar{x}_{.p} \end{pmatrix} \tag{5.7.2570}$$

with:

$$\bar{x}_{.j} = \frac{1}{n} \sum_{i=1}^{n} x_{ij} \tag{5.7.2571}$$

We then have yet graphically:

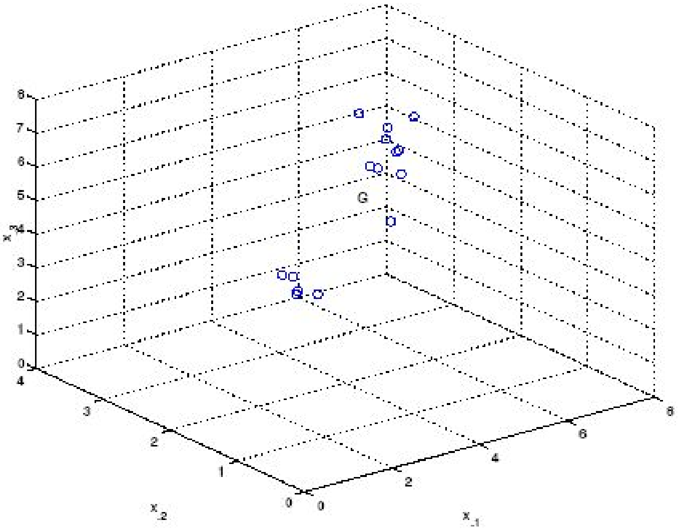

Figure 5.232: **Measurement points and center of gravity**

We name "centered matrix" the matrix:

$$X_c = \begin{bmatrix} x_{11} - \bar{x}_{.1} & \cdots & x_{1j} - \bar{x}_{.j} & \cdots & x_{1p} - \bar{x}_{.p} \\ \vdots & & \vdots & & \vdots \\ x_{i1} - \bar{x}_{.1} & \cdots & x_{ij} - \bar{x}_{.j} & \cdots & x_{ip} - \bar{x}_{.p} \\ \vdots & & \vdots & & \vdots \\ x_{n1} - \bar{x}_{.1} & \cdots & x_{nj} - \bar{x}_{.j} & \cdots & x_{np} - \bar{x}_{.p} \end{bmatrix} \tag{5.7.2572}$$

Remark

The matrix of centered data contains the centered coordinates (which we will denote by xc_{ij}) of the individuals in the reference frame $(G,\vec{e}_1,\vec{e}_2,\ldots,\vec{e}_p)$. We place ourselves for what will follow always in this reference frame for point cloud of the individuals and we will take O $=G$.

For our example we have:

$$G=\vec{x}=(5.91,3.06,3.87) \tag{5.7.2573}$$

and for the centered matrix:

$$X_c=\begin{bmatrix} -0.8067 & 0.440 & -2.4733 \\ -1.0067 & -0.0600 & -2.4733 \\ -1.2067 & 0.1400 & -2.5733 \\ -1.3067 & 0.0400 & -2.3733 \\ -0.9067 & 0.1400 & -2.4733 \\ 1.0933 & 0.5400 & 0.8267 \\ 0.4933 & 0.1400 & 0.6257 \\ 0.933 & 0.0400 & 1.0267 \\ -0.4067 & -0.7600 & 0.1267 \\ 0.5933 & -0.2600 & 0.7267 \\ 0.3933 & 0.2400 & 2.1267 \\ -0.1067 & -0.3600 & 1.2267 \\ 1.1933 & -0.0600 & 2.0267 \\ 0.3933 & -0.1600 & 1.7267 \\ 0.5933 & -0.0600 & 1.9267 \end{bmatrix} \tag{5.7.2574}$$

and graphically:

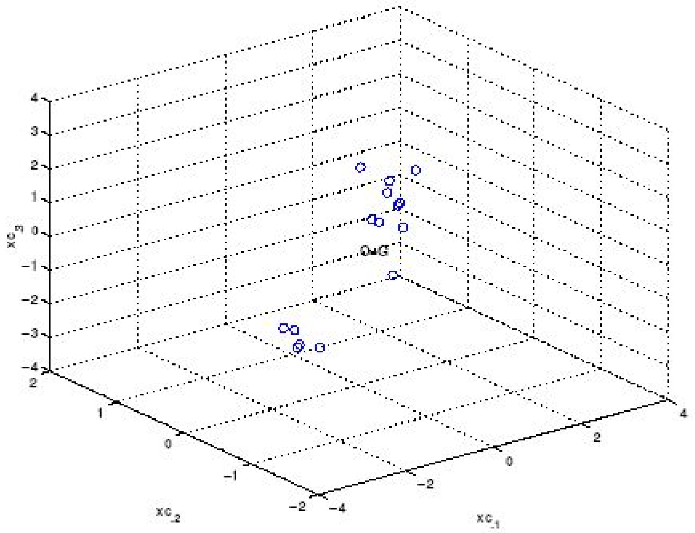

Figure 5.233: Centered measured points

To give an equal importance to each variable so that the type of units of the measurement does not influence the analysis (and also as we have proved it at page 621 that the correlation matrix is equal to the variance-covariance matrix!), we will work with reduced centered data (see section Statistics page 595). For this, we will denote first:

$$\sigma_j^2=\frac{1}{n}\sum_{i=1}^{n}(x_{ij}-\bar{x}_{.j})^2=\frac{1}{n}\sum_{i=1}^{n}c_{ij}^2=\frac{1}{n}\|\vec{c}_{.j}\|^2 \qquad (5.7.2575)$$

where the reader may have perhaps noticed that we take the biased variance. But in the reality, we will take obviously the variance estimator and we will therefore divide by $n-1$ rather than by n.

The variance of the sample centered variable is equal near to a factor of $1/n$ to the norm of this same variable but centered. The matrix of reduced centered data (dimensionless) is therefore:

$$Y=\begin{bmatrix}\dfrac{x_{11}-\bar{x}_{.1}}{\sigma_1} & \cdots & \dfrac{x_{1j}-\bar{x}_{.j}}{\sigma_j} & \cdots & \dfrac{x_{1p}-\bar{x}_{.p}}{\sigma_p}\\ \vdots & & \vdots & & \vdots\\ \dfrac{x_{i1}-\bar{x}_{.1}}{\sigma_1} & \cdots & \dfrac{x_{ij}-\bar{x}_{.j}}{\sigma_j} & \cdots & \dfrac{x_{ip}-\bar{x}_{.p}}{\sigma_p}\\ \vdots & & \vdots & & \vdots\\ \dfrac{x_{n1}-\bar{x}_{.1}}{\sigma_1} & \cdots & \dfrac{x_{nj}-\bar{x}_{.j}}{\sigma_j} & \cdots & \dfrac{x_{np}-\bar{x}_{.p}}{\sigma_p}\end{bmatrix} \qquad (5.7.2576)$$

If we denote by $D_{1/\sigma}$ the following diagonal matrix:

$$D_{1/\sigma}=\begin{bmatrix}1/\sigma_1 & \cdots & 0\\ \vdots & \ddots & \vdots\\ 0 & \cdots & 1/\sigma_p\end{bmatrix} \qquad (5.7.2577)$$

Then we have:

$$Y=X_cD_{1/\sigma} \qquad (5.7.2578)$$

Remark

Each component of the matrix Y is therefore of zero mean and unit variance (which is equivalent to say that the norm of the standard reduced variable is equal to the unit as we will prove it immediately).

We define the "matrix of centered normalized data" by (we then speak of "normalized PCA" which is not mandatory but simplifies interpretation):

$$Z=\frac{1}{\sqrt{n}}Y \qquad (5.7.2579)$$

Or also (it is simply the mean squared error that we have introduced earlier in the section):

$$z_{ij}=\frac{x_{ij}-\bar{x}_{.j}}{\sqrt{n}\sigma_j} \qquad (5.7.2580)$$

The terminology comes of course from the fact that the sum of the square of the components of each column of the matrix Z has a unit norm. Indeed:

$$\|\vec{z}_{.j}\|^2=\sum_{i=1}^{n}z_{ij}^2=\sum_{i=1}^{n}\left(\frac{x_{ij}-\bar{x}_{.j}}{\sqrt{n}\sigma_j}\right)^2=\frac{1}{\sigma_j^2}\frac{1}{n}\sum_{i=1}^{n}(x_{ij}-\bar{x}_{.j})^2=1 \qquad (5.7.2581)$$

Which gives:

$$Z=\begin{bmatrix} -0.2383 & 0.3572 & -0.3375 \\ -0.2974 & -0.0487 & -0.3375 \\ -0.3565 & 0.1136 & -0.3512 \\ -0.3861 & 0.0324 & -0.3239 \\ -0.2679 & 0.4384 & -0.3375 \\ 0.3230 & 0.1136 & 0.1128 \\ 0.1457 & 0.1136 & 0.0855 \\ 0.2935 & 0.0324 & 0.1401 \\ -0.1201 & -0.6170 & 0.0172 \\ 0.1753 & -0.2110 & 0.0991 \\ 0.1162 & 0.1948 & 0.2902 \\ -0.0315 & -0.2922 & 0.1674 \\ 0.3526 & -0.0487 & 0.2765 \\ 0.1161 & -0.1298 & 0.2356 \\ 0.1753 & -0.0487 & 0.2629 \end{bmatrix} \tag{5.7.2582}$$

We have graphically:

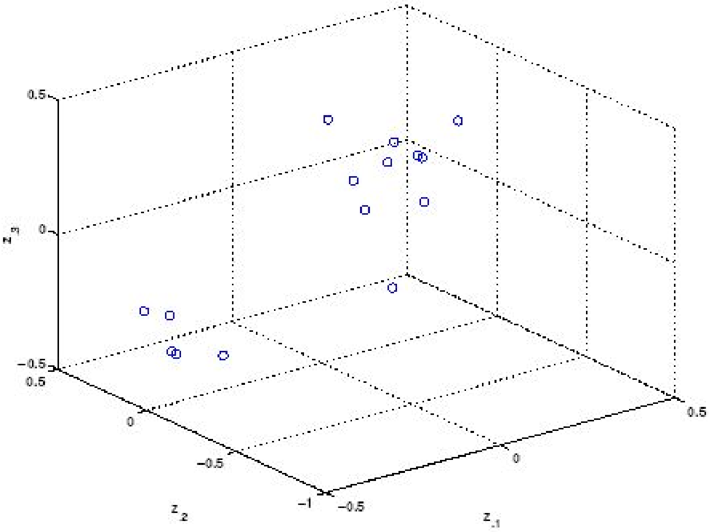

Figure 5.234: **Centered reduced measured points**

Represent the point cloud of the reduced centered data or reduced normalized data don't change the shape of it. Indeed, the difference between the two is only a change of scale.

The interesting information on individuals is the distance between the points! Indeed more this distance is great between two individuals $z_{i.}$ and $z_{i'.}$ plus the two individuals will be different and better we can characterize them. But we must first choose a distance. We will take the Euclidean distance (see section Topology page 2446):

$$d^2(z_{i.},z_{i'.})=||\overrightarrow{z_{i.}z_{i'.}}||^2=\sum_{j=1}^{p}(z_{ij}-z_{i'j})^2 \tag{5.7.2583}$$

The following figures show the orthogonal projections in space of this scatter cloud respectively in the planes $(\text{O},\vec{e}_1,\vec{e}_2)$, $(\text{O},\vec{e}_2,\vec{e}_3)$ and finally in $(\text{O},\vec{u}_1,\vec{u}_3)$ that is the best projection, named "factorial plane" (or sometimes "scores diagram"), in the sense that it best respect the distances between individuals (verbatim, it deforms the least the cloud of points in space). The objective of the principal component analysis is to determine this best plan and we will prove now how!

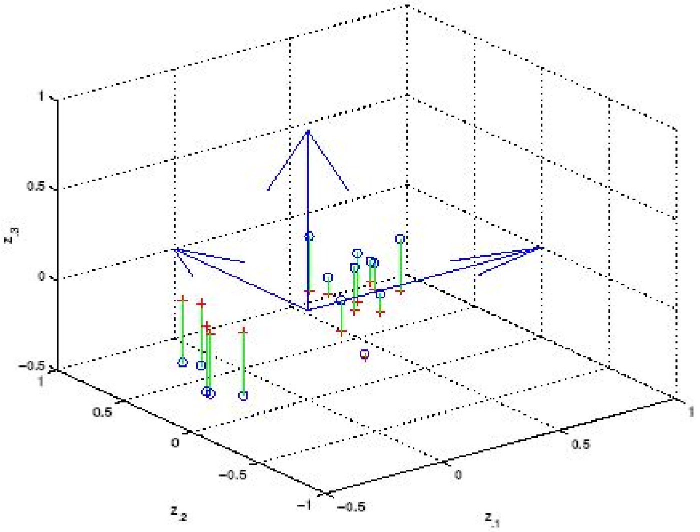

Figure 5.235: Projection of the points on the horizontal plane of the center reduced basis

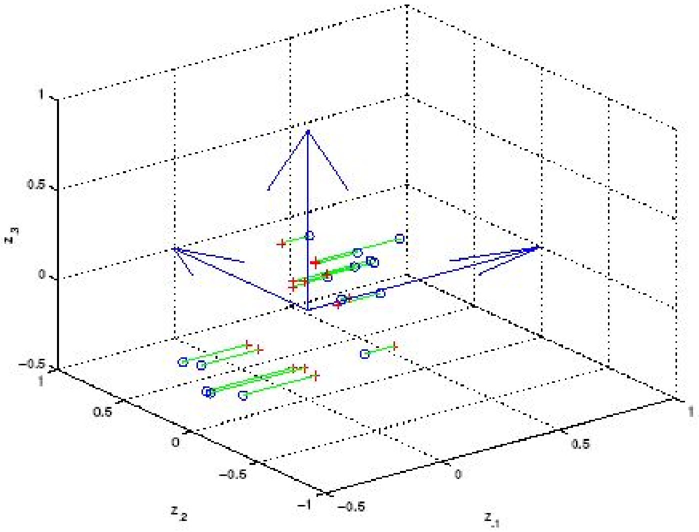

Figure 5.236: Projection of the points on the vertical plane of the center reduced basis

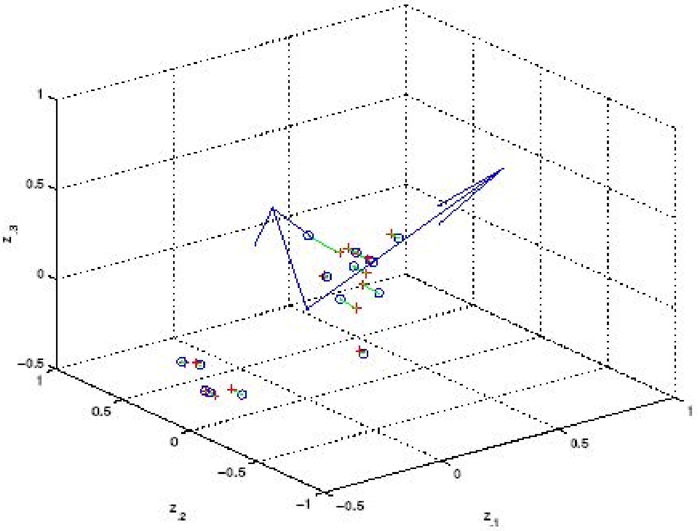

Figure 5.237: **Projection of the points on the factorial plane of the center reduced basis**

And the plane view of each of the projections:

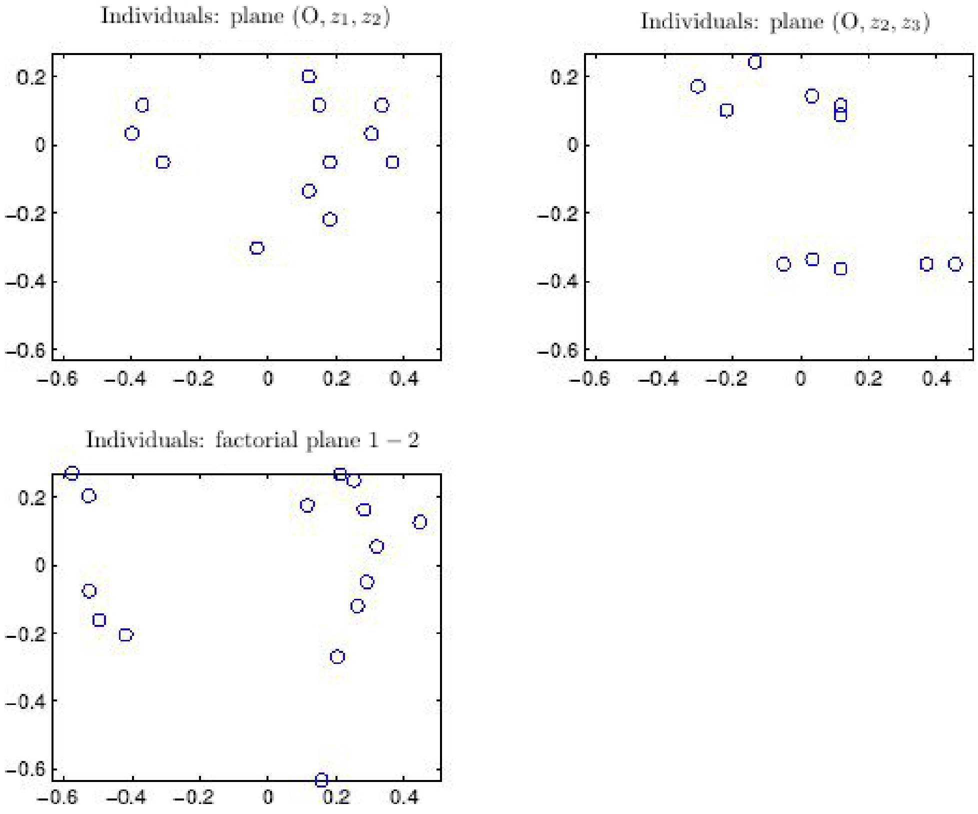

Figure 5.238: **Plane view of each of the projections**

Before determining the factorial plane, we will first now try to detect possible links between variables.

We recall (see section Statistics page 597) that the covariance between two variables $x_{.j}$ and $x_{.j'}$

is given by:

$$\text{cov}(x_j,x_{.j'})=\text{E}\left[(x_{.j}-\bar{x}_{.j})(x_{.j'}-\bar{x}_{.j'})\right]=\frac{1}{n}\sum_{i=1}^{n}(x_{ij}-\bar{x}_{.j})(x_{ij'}-.\bar{j}')=\frac{1}{n}\sum_{i=1}^{n}c_{ij}c_{ij'} \tag{5.7.2584}$$

and that the linear correlation coefficient (see section Statistics page 614) is:

$$R(x_{.j},x_{.j'})=\frac{\text{cov}(x_{.j},x_{.j'})}{\sigma_j\sigma_{j'}} \tag{5.7.2585}$$

We will denote for later:

$$c_{j,j'}=\text{cov}(x_{.j},x_{.j'}) \qquad \text{and} \qquad r_{j,j'}=R(x_{.j},x_{.j'}) \tag{5.7.2586}$$

the matrices of variance-covariance and of correlation (both being for recall square and symmetric matrices) with $j=1\ldots p, j'=1\ldots p$.

We see quite easily that the matrix of covariance is at a given coefficient $1/n$ near, the matrix of canonical dot products of vectors of the centered reduced matrix X_c (in other words, each component of the variance-covariance matrix is equal to the dot product of the centered variables). We deduce the following relation:

$$c_{j,j'}=\frac{1}{n}X_c^TX_c \tag{5.7.2587}$$

Remark

For a given matrix A, the expression A^TA plays an important role in statistics. For example, it is an important part of the analytical solution of ordinary least squares. Or, for PCA, its eigenvectors are the principal components of the data. Geometrically, matrix A^TA is named "matrix of scalar products" (as it contains all the inner products of all columns in A). Algebraically, it's named "sum-of-squares-and-cross-products matrix" (SSCP). Dividing SSCP matrix by n, the sample size or number of rows of A, we get what is commonly named the MSCP (mean-square-and-cross-product) matrix. If we center the columns of A the $A^TA/(n-1)$ is the covariance matrix. If we Z-standardized the columns of A the $A^TA/(n-1)$ is the Pearson correlation matrix.

The matrix of variance-covariance (since, as we was it in the section Statistics, the diagonal contains the variances ... for recall!) is a well known interpretation in this textbook. By cons, what is new and we will be very useful to determine the factorial plane is the matrix of linear correlations that can also be written as follows:

$$R=r_{j,j'}=\frac{1}{m}Y^TY=Z^TZ \tag{5.7.2588}$$

Which gives for our example where we have three variables (very easy to calculate using a spreadsheet software like Microsoft® Excel®), the following square matrix (the data are centered or not the components of the matrix are the same):

$$R=\begin{bmatrix}1 & -0.1609 & 0.8854\\ -0.1609 & 1 & -0.3818\\ 0.8854 & -0.3818 & 1\end{bmatrix} \tag{5.7.2589}$$

To continue, always with the aim to determine the factorial plane, let us define the concept of inertia of a point cloud.

Definition (#5.7.158): We name "inertia of a point cloud" the quantity:

$$I=\frac{1}{n}\sum_{i=1}^{n} d^2(G,M_i) \tag{5.7.2590}$$

where G is the center of gravity of the point cloud and M_i a point of $\mathbb{R}^p$ of coordinates x_i^T.

Remark

The square of the distance is taken by anticipation of the developments that will follow.

Then we prove the following relation:

$$\sum_{i=1}^{n}\sum_{i'=1}^{n} d^2(M_i,M'_i)=2nI \tag{5.7.2591}$$

Proof 5.48.8.

$$\begin{aligned}\sum_{i=1}^{n}\sum_{i'=1}^{n} d^2(M_i,M'_i)&=\sum_{i,i'}\|\overrightarrow{M_iM_{i'}}\|^2=\sum_{i,i'}\|\overrightarrow{M_iG}+\overrightarrow{GM_{i'}}\|^2\\&=\sum_{i,i'}\left(\sum_{i}\|\overrightarrow{M_iG}\|^2+\|\overrightarrow{GM_{i'}}\|^2+2\overrightarrow{M_iG}\cdot\overrightarrow{GM_{i'}}\right)\\&=\sum_{i'}\left(\sum_{i}d^2(M_i,G)\right)+\sum_{i}\left(\sum_{i'}d^2(G,M_{i'})\right)+2\sum_{i}\left(\overrightarrow{M_iG}\cdot\vec{0}\right)\\&=\sum_{i'}nI+\sum_{i}nI+1+0\\&=2nI\end{aligned} \tag{5.7.2592}$$

■ Q.E.D.

We will in all the remaining text with normalized centered data, verbatim with the matrix Z. The points M_i will therefore have here for coordinates z_i^T.

The problem now is to find the best affine space of dimension p in the sense that it respects the best the distances between points. For this, we will seek the best vectorial line $\Delta_{\vec{u}}$ that is perfectly determined by the vector $\vec{u}$. Let us denote H_i the orthogonal projection of M_i on the line Δ_u. So our problem is to find the line (verbatim the vector $\vec{u}$) that makes the sum of the squares of the distances between the points H_i is maximized. We write the problem as a quadratic programming problem (see section Numerical Methods page 6662):

$$\begin{aligned}\underset{\vec{u}}{\text{maximize}}\quad&\sum_{i,i'}d^2(H_i,H'_i)\\\text{subject to}\quad&\vec{u}\in\mathbb{R}^p\\&\|\vec{u}\|=1\end{aligned} \tag{5.7.2593}$$

But here we have:

$$\sum_{i,i'} d^2(H_i, H'_i) = 2nI \tag{5.7.2594}$$

Indeed, the projected centroid (barycentre) of the cloud points is also the origin. Consequently, our problem can be written:

$$\begin{aligned} \underset{\vec{u}}{\text{maximize}} \quad & I \\ \text{subject to} \quad & \vec{u} \in \mathbb{R}^p \\ & \|\vec{u}\| = 1 \end{aligned} \tag{5.7.2595}$$

Itself therefore being equivalent to:

$$\begin{aligned} \underset{\vec{u}}{\text{maximize}} \quad & \sum_{i,i'} d^2(\text{O}, H_i,) \\ \text{subject to} \quad & \vec{u} \in \mathbb{R}^p \\ & \|\vec{u}\| = 1 \end{aligned} \tag{5.7.2596}$$

Let us solve this problem:

First, since H_i is the orthogonal projection of the point M_i on $\Delta_{\vec{u}}$ we have $\overrightarrow{\text{O}H}_i = \alpha_i \vec{u}$ for all i with $\alpha_i = \overrightarrow{\text{O}M}_i \circ \vec{u}$. Following this, the coordinates of the points H_i on the straight line $\Delta_{\vec{u}}$ are:

$$\begin{pmatrix} \alpha_1 \\ \vdots \\ \alpha_n \end{pmatrix} = Z\vec{u} \tag{5.7.2597}$$

If follows that we have:

$$\sum_i d^2(\text{O}, H_i) = \sum_i \alpha_i^2 = ||Z\vec{u}||^2 = Z\vec{u} \circ Z\vec{u} \tag{5.7.2598}$$

Here we seek the unit vector $\vec{u}$. The matrix Z is perfectly known to us. But, we have:

$$(Z\vec{u}) \circ (Z\vec{u}) = (Z^T Z\vec{u}) \circ \vec{u} = (R\vec{u}) \circ \vec{u} \tag{5.7.2599}$$

The correlation matrix R is symmetrical therefore, following the spectral theorem proved in the section of Linear Algebra page 2004, it is diagonalizable in an orthonormal basis of eigenvectors. Thus, we have proved that in the spectral theorem:

$$\Lambda = S^{-1} R S \tag{5.7.2600}$$

is diagonal (up to us to choose the content) if R is symmetrical and S is orthogonal (which is in our special example a square 3×3 matrix). Then we deduce the following relation (factorization) that it is common to name the "eigenvalue decomposition" of R:

$$R = S^{-1} \Lambda S \tag{5.7.2601}$$

and as S has been proven as being orthogonal (and that there exists a family of eigenvectors for this!), we have (see section Linear Algebra page 1954):

$$S^{-1} = S^T \tag{5.7.2602}$$

Therefore:

$$R=S\Lambda S^T \tag{5.7.2603}$$

where we choose for Λ the diagonal matrix of the eigenvalues sorted in descending order: $\lambda_1\geq\lambda_2\geq\ldots\geq\lambda_p$.

We then have:

$$(R\vec{u})\circ\vec{u}=(S\Lambda S^T\vec{u})\circ\vec{u}=(\Lambda S^T\vec{u})\circ S^T\vec{u})=(\Lambda\vec{w})\circ\vec{w}=\sum_{j=1}^p\lambda_j w_j^2 \tag{5.7.2604}$$

In the literature, this sum is often denoted as follows (in statistical software often named "eigenvalue decomposition"):

$$\sum_{j=1}^p\lambda_j w_j^2=\begin{pmatrix}\sqrt{\lambda_1}w_1 & \sqrt{\lambda_2}w_2 & \ldots & \sqrt{\lambda_p}w_p\end{pmatrix}\begin{pmatrix}\sqrt{\lambda_1}w_1\\ \sqrt{\lambda_2}w_2\\ \vdots\\ \sqrt{\lambda_p}w_p\end{pmatrix} \tag{5.7.2605}$$

But S being orthogonal, we have therefore:

$$\left\{\vec{w}=S^T\vec{u}|\vec{u}\in\mathbb{R}^p\quad\|\vec{u}\|=1\right\}\Rightarrow\{\vec{w}\in\mathbb{R}^p\quad\|\vec{w}\|=1\} \tag{5.7.2606}$$

and this is comes from the fact that the orthogonal matrix is as we proved in the section Linear Algebra an isometry (it conserves the norm!).

Since the eigenvalues are in descending order, we will write:

$$\sum_{j=1}^p\lambda_j w_j^2=\lambda_1\left(w_1^2+\sum_{j=2}^p\frac{\lambda_j}{\lambda_1}w_j^2\right) \tag{5.7.2607}$$

Or the term in brackets is strictly less than or equal to 1 by the previous involvement. Therefore:

$$\lambda_1\left(w_1^2+\sum_{j=2}^p\frac{\lambda_j}{\lambda_1}w_j^2\right)\leq\lambda_1 \tag{5.7.2608}$$

Therefore:

$$\sum_{j=1}^p\lambda_j w_j^2\leq\lambda_1 \tag{5.7.2609}$$

But remember that our objective is to maximize this inequality. In other words to seek w_1 such that the equality is respected. We see quickly enough that will be the case if $w_1=1$ and that the other terms are zero. Thus, a trivial solution to our maximization problem is:

$$\vec{w}=\begin{pmatrix}1\\0\\0\\ \vdots\\0\end{pmatrix} \tag{5.7.2610}$$

either because:

$$\vec{w}=S^T\vec{u}=S^{-1}\vec{u}\Rightarrow=S\vec{w} \tag{5.7.2611}$$

which is then the first eigenvector of the matrix R (since R is diagonalized in this base) associated with the largest eigenvalue λ_1. Hence the fact that this solution is often denoted as:

$$\vec{u}_1=S\vec{w}_1 \tag{5.7.2612}$$

always with $\Lambda=S^{-1}RS$ (it is therefore quite easy to determine S using softwares when R and Λ are known).

Once we have found the first vector line, we seek a second orthogonal line in the subspace to the vector line that maximizes the inertia of the projected point cloud. We prove, and guess, that the solution is given by the vector line directed by the eigenvector associated to the second eigenvalue of the correlation matrix and so on ...

Thus, we obtain a new basis $(\vec{u}_1,\ldots,\vec{u}_p)$ whose one of the plane is the factorial plane. However, we need to know the components of Z in this base. As this base was built under the condition that R is diagonalizable via the matrix S then the latter matrix is the linear application that will allow us to express Z in the base $(\vec{u}_1,\ldots,\vec{u}_p)$ via the relation:

$$\Psi=ZS \tag{5.7.2613}$$

Thus, in our example the three eigenvalues of the correlation matrix R are (see section Linear Algebra page 1997):

$$\lambda_1=2.0303 \qquad \lambda_2=0.8846 \qquad \lambda_3=0.0853 \tag{5.7.2614}$$

and therefore:

$$\Lambda=\begin{pmatrix}2.0303 & 0 & 0\\ 0 & 0.8846 & 0\\ 0 & 0 & 0.0853\end{pmatrix} \tag{5.7.2615}$$

Remark

Some softwares indicate the weights in respective and cumulated $\%$ for each of the eigenvalues. Thus we have in our special case the following respective weights in $\%$ of the total:

$$P_{\lambda_1}=\dfrac{2.0303}{\sum\limits_i\lambda_i}=66.67\% \qquad P_{\lambda_2}=\dfrac{0.8846}{\sum\limits_i\lambda_i}=29.48\% \qquad P_{\lambda_3}=\dfrac{0.0853}{\sum\limits_i\lambda_i}=2.84\% \tag{5.7.2616}$$

So the first component explains 66.67% of the effect. The first two components explain 96.15%, etc. This is why, for example, that in finance that among ten or more components, we will take only those that "explain" for example the 95%.

By having the three eigenvalues, to determine the three eigenvectors $(\vec{u},\vec{u}_2,\vec{u}_3)$ that form the main base, we need to solve the following system of three equations with three unknowns (see section Linear Algebra page 1929) for each eigenvalue:

$$\underbrace{\begin{bmatrix} 1-\lambda_i & -0.1609 & 0.8854 \\ -0.1609 & 1-\lambda_i & -0.3818 \\ 0.8854 & -0.3818 & 1-\lambda_i \end{bmatrix}}_{R}\underbrace{\begin{pmatrix} u_{1,i} \\ u_{2,i} \\ u_{3,i} \end{pmatrix}}_{\vec{u}_i}=\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} \tag{5.7.2617}$$

Which gives therefore (expected if someone request the details we will not provide them here as they can be simply made by hand or with any spreadsheet software) for the matrix of eigenvectors:

$$S=(\vec{u}_1,\vec{u}_2,\vec{u}_3)=\begin{bmatrix} 0.6410 & 0.3803 & -0.6666 \\ -0.3527 & 0.9174 & 0.1841 \\ 0.6816 & 0.1171 & 0.7222 \end{bmatrix} \tag{5.7.2618}$$

which satisfies therefore:

$$R=S\Lambda S^T \tag{5.7.2619}$$

or written in another way (following the remark from a reader who wanted to check the calculations and was trapped):

$$R=S(\Lambda S^T) \tag{5.7.2620}$$

We then have for coordinates of the points M_i in the base $(\vec{u}_1,\vec{u}_2,\vec{u}_3)$ using:

$$\Psi=ZS \tag{5.7.2621}$$

The following matrix:

$$\Psi=\begin{bmatrix} -0.5268 & 0.2045 & -0.0198 \\ -0.4178 & -0.2043 & -0.564 \\ -0.5259 & -0.0750 & 0.0052 \\ -0.4966 & -0.1604 & 0.0305 \\ -0.5760 & 0.2699 & 0.0161 \\ 0.2525 & 0.2488 & -0.1169 \\ 0.1156 & 0.1757 & -0.0150 \\ 0.2818 & 0.1634 & -0.0916 \\ 0.1578 & -0.6311 & -0.0218 \\ 0.2634 & -0.1194 & -0.0871 \\ 0.2108 & 0.2660 & 0.1739 \\ 0.2039 & -0.2697 & 0.0912 \\ 0.4469 & 0.1261 & -0.459 \\ 0.2908 & -0.0490 & 0.0712 \\ 0.3196 & 0.0546 & 0.0663 \end{bmatrix} \tag{5.7.2622}$$

The coordinates of the projection of the point cloud in the best plane defined by the vectors $(\vec{u}_1,\vec{u}_2)$ are then the first two columns of the previous matrix (thus corresponding the sepal length and sepals width).

Indeed, we immediately see that these are the two columns that will maximize the sum of the norms in the given plane:

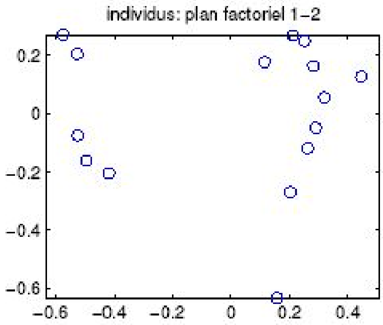

Figure 5.239: **Factorial plane already shown above ...**

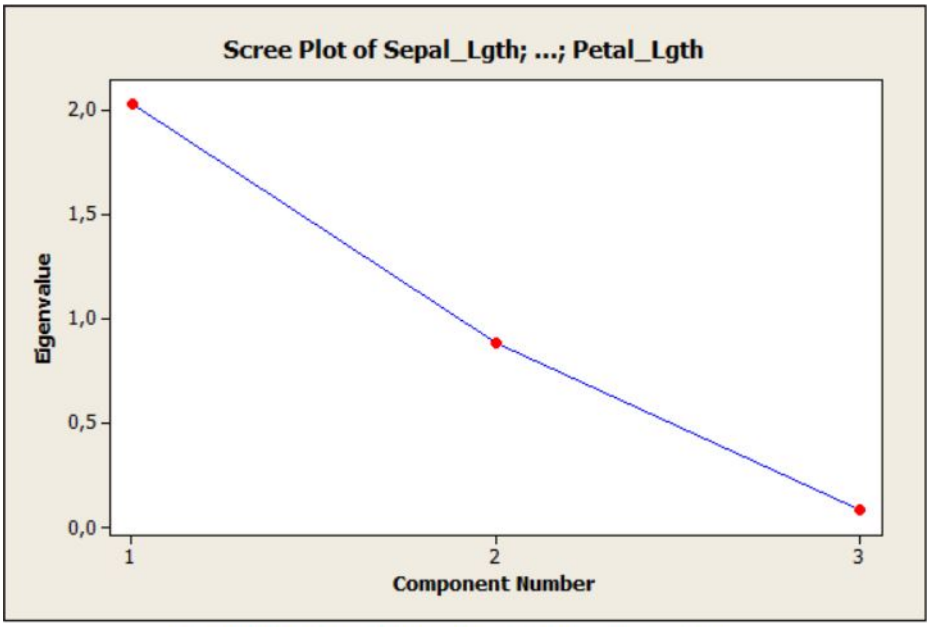
A software like Minitab 15.1 (reference in quality management industry) gives the following information for the eigenvalues (not very useful info graphically ... in my opinion):



```
Eigenanalysis of the Correlation Matrix

Eigenvalue  2,0302  0,8846  0,0853
Proportion   0,677   0,295   0,028
Cumulative   0,677   0,972   1,000
```

Figure 5.240: **Eigenvalues for the PCA as given by Minitab 15.1 ("scree plot")**

and the following factorial plane (remains the question how the values are calculated in Minitab because they are not identical to those we got here my manual calculations... but the graphic is corresponding and this is the most important!):

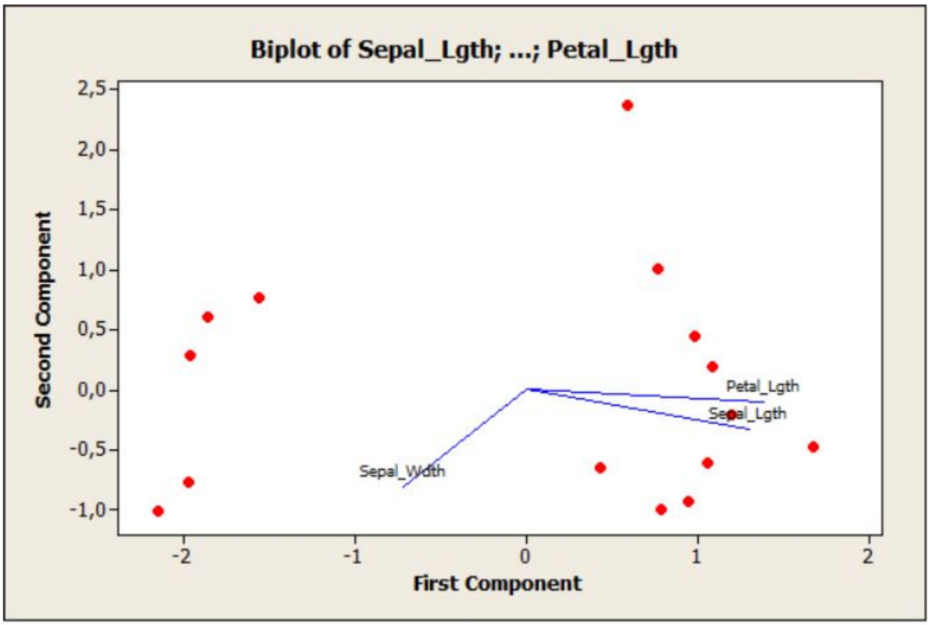


Figure 5.241: **Factorial plane as given by Minitab 15.1**

If the reader has carefully followed all the steps we did so far, he may have notice that we did:

1. Zero-center the data (mean normalization)
2. Reduced the data
3. Decorrelate the data by:
   (a) Calculating the covariance matrix
   (b) Calculating the eigenvectors of the covariance matrix
   (c) Applying the matrix of eigenvectors to the data (this will apply the rotation)

Furthermore some softwares and practitioners scale the uncorrelated matrix in order to obtain a covariance matrix corresponding to the identity matrix (ones on the diagonal and zeros on the other cells). To do that we scale the decorrelated data by dividing each dimension by the square-root of its corresponding eigenvalue.

All the 7 steps enumerated above are named "PCA whitening" or just "Whitening" (also sometimes "sphering data"). So "whitening" data means that we want to transform them in a way to have a covariance matrix that is the identity matrix (1 in the diagonal and 0 for the other cells) and is named "whitening" in reference to "white noise".

To close this subject, the reader must know that many software use the fact that the vectors $z_{.j}$ are of unit norm to do the scalar product which corresponds in this case simply the cosine between vectors such as:

$$z_{.j}\circ z_{.i}=||z_{.j}||\cdot||z_{.i}||\cos(\widehat{z_{.j}z_{.i}})=\cos(\widehat{z_{.j}z_{.i}}) \tag{5.7.2623}$$

and as we have proved earlier above that:

$$R=r_{j,j'}=\frac{1}{n}Y^TY=Z^TZ \tag{5.7.2624}$$

Therefore it comes:

$$R=r_{j,j'}=\cos(\widehat{z_{.j}z_{.i}}) \tag{5.7.2625}$$

and as in our special example we have 3 vectors $z_{.j}$, there is therefore 3 possible dot products if we omit the scalar products of the vectors with themselves. Therefore the matrix:

$$R=\begin{bmatrix} 1 & -0.1609 & 0.8854 \\ -0.1609 & 1 & -0.3818 \\ 0.8854 & -0.3818 & 1 \end{bmatrix} \tag{5.7.2626}$$

also contains the angles (in radian) between the vectors $z_{.j}$.

Finally, let us indicate that the PCA being sensitive to outliers, it is sometimes better to transform the values of the original array in their ranks (see the study of rank statistics earlier above!) and applying exactly the same algorithm or using the Spearman's rank correlation coefficient. We then speak of a "PCA by ranks".

Remark

A user-friendly software like XL-Stats proposes automatically in the PCA menu five "different types" of Principal Component Analysis that are respectively: Pearson (n), Pearson ($n-1$), Spearman, Kendall, Covariance. Obviously the same can be done with other statistical softwares but actually is not visually simple available choices (we have to write very little scripts).

There is also a group of robust PCA methods that have been developed and that are better suited for handling high-dimensional data in the situation where the sample size is lower than the dimension. These methods are: Robust PCA by projection-pursuit (PP-PCA), Spherical PCA (SPCA), Robust PCA (ROBPCA), Robust Sparse PCA (ROSPCA).

We can also compute the variance of the PCA using bootstrapping techniques (see section Numerical Methods page 6740) like for all statistical analysis!

5.7.15.1.1 SVD and PCA

Now we will prove an important theorem that is not quite obvious.

Theorem 5.49. The PCA above (using the spectral theorem, i.e. eigendecomposition) is a special case of the SVD (that latter is therefore less restrictive)!!!

Proof 5.49.1. We have proved before that:

$$R=Z^TZ \tag{5.7.2627}$$

Using the properties of the transposed matrices (see section Linear Algebra page 1951):

$$R=ZZ^T \tag{5.7.2628}$$

And that:

$$R=ZZ^T=S\Lambda S^T \tag{5.7.2629}$$

And we have build in the section of Linear Algebra the singular value decomposition (see section Linear Algebra page 2004):

$$M = UDV^T \tag{5.7.2630}$$

That is in our case here:

$$R = UDV^T \tag{5.7.2631}$$

Therefore:

$$RR^T = (UDV^T)(UDV^T)^T = (UDV^T)(VDU^T) \tag{5.7.2632}$$

and since V is an orthogonal matrix ($V^TV = \mathbb{1}$):

$$\boxed{R = UD^2U^T} \tag{5.7.2633}$$

So if we compare:

$$R = UD^2U^T \qquad \text{and} \qquad R = UDV^T \tag{5.7.2634}$$

the correspondence is quite easily seen!

So that means in order for the spectral theorem of R to be equal to its SVD, we need R to:

- Have orthonormal eigenvectors (meaning all it does is to scale its input along n orthogonal directions, where R is $n \times n$)
- Have positive eigenvalues (colloquially, it must be a real matrix and not "flip" anything)

It turns out that the above conditions are equivalent to the following:

- R must be a symmetric real matrix (this is equivalent to R having real eigenvalues and orthonormal eigenvectors)
- R's (real) eigenvalues must be positive

So, we say: Both are equal when R is symmetric positive-semidefinite (see section Linear Algebra page 1957)! This can be denoted technically as $R \succeq 0 \ \wedge \ R^\dagger = R$.

In facts, using the SVD to perform PCA makes much better sense numerically than forming the covariance matrix to begin with, since the construction of ZZ^T can cause loss of precision. Indeed in some cases the PCA can diverge very quick and give inaccurate results! This is why many statistical softwares gives the option to run a PCA based on SVD (singular value decomposition theorem) or on the spectral theorem.

■ Q.E.D.

A common question on Internet forums is: *Intuitively, what is the difference between Spectral Theorem (eigendecomposition) and Singular Value Decomposition?*. Also, if: *Is one of them more general than the other? Is either a special case of the other?*

First, according to what has been written earlier, it should be quite obvious that eigendecomposition arises from asking in which directions a quadratic form has the greatest impact, when the SVD by construction arises from asking in which directions a linear transformation[88] has the greatest impact!

Now the reader must keep in mind that the spectral theorem describes the effect of a matrix A on a vector as the following 3-steps process $A = Q\Lambda Q^{-1}$:

1. An invertible linear transformation (Q^{-1}, hence Q must be invertible, i.e. square!)
2. A scaling (Λ with $\Lambda = \text{diag}(\vec{\lambda})$)
3. The inverse of the initial transformation (Q)

This decomposition doesn't always exist, but the spectral theorem describes the conditions under which such a decomposition exists.

When for the SVD we have the following 3-steps process $A = U\Sigma V^T$:

1. A first rotation in the input space (V is a rotation matrix as $V^TV = \mathbb{1}$)
2. A simple positive scaling that takes a vector in the input space to the output space (Σ diagonal with positive entries!)
3. And another rotation in the output space (U is a rotation matrix as $U^TU = \mathbb{1}$)

The fundamental theorem of linear algebra says that such a decomposition always exists (especially because no inverse is involved and therefore doesn't apply only to square matrices).

---

[88] Hence the fact that PCA produces linear transformations, thereby capturing linear relationships between the original variables so that we might lose predictive information that are non-linear!

5.7.15.2 Chi-square Correspondence Factor Analysis (C2CFA)

The Chi-square factor correspondence analysis, abbreviated C2CFA is a method of data analysis widely used in biostatistics and survey analysis. The C2CFA technique is mainly used for large tables to compare all data (if possible all expressed in the same unit, like a currency, a dimension, a frequency or any other measurable quantity). It may in particular allow the study of contingency tables (or co-occurrence cross tables) and describe the connection between two variables. It serves to identify and prioritize all the dependencies between the rows and columns of the table.

If more than two variables are to be taken into considerations we speak of Chi-square multiple correspondence analysis (C2MCA).

Let us tackle now directly the theory with an example. For this we consider the following table (with two variables) of the areas of the types of tree that stands in Picardy (France) in 11984 (holocene calendar) in hectares:

	Leafy	**Resinous**	**Mixes**	**Total by Area**
Aisne (A)	$106,500$	$3,380$	$1,470$	$111,350$
Oise (O)	$101,700$	$310,000$	0	$111,700$
Somme (S)	$45,200$	$4,350$	50	$49,600$
Total	$253,400$	$17,730$	$1,520$	$272,650$

Table 5.94: **Contingency table (crosstab) of CFA**

The experts in the domain sometimes name the totals for rows and columns, respectively, the "line margins" and "column margins". When the whole table is put in percentages, relatively to the total of the totals, it is named "joint frequency representation":

	Leafy	**Resinous**	**Mixes**	**Total by Area**
Aisne (A)	39.06%	1.24%	0.54%	40.84%
Oise (O)	37.30%	3.67%	0%	40.97%
Somme (S)	16.58%	1.60%	0.02%	18.19%
Total	92.93%	6.50%	0.56%	100%

Table 5.95: **Joint frequency table of CFA**

We wish to analyse whether there are degrees of similarity and difference between the variables. Let us notice that we are not trying to compare equality of means or variances therefore statistical tools seen in previously are not suitable for this kind of analysis.

If we choose the Euclidean distance (see section Vector Calculus page 1818):

$$d^2(x_i,x_{i'})=\left|\left|\overrightarrow{(x_ix_{i'})}\right|\right|^2=\sum_{j=1}^{p}(x_{ij}-x_{i'j})^2 \qquad (5.7.2635)$$

on the raw data to measure the differences between departments, we get the following differences:

$$\begin{aligned}d^2(A,O)&=\sum_{j=1}^{3}(x_{1j}-x_{2j})^2=(106,500-101,700)^2+(3,380-10,000)^2+(1,470-0)^2\\&=69,025,300\Rightarrow d(A,O)=\sqrt{69,025,300}=8,308.1\ [\text{ha}]\end{aligned} \tag{5.7.2636}$$

and so on for the other regions. We then get:

$$\begin{aligned}d(A,O)&=8,308.1\ [\text{ha}]\\d(A,S)&=61,324.1\ [\text{ha}]\\d(O,S)&=56,781.8\ [\text{ha}]\end{aligned} \tag{5.7.2637}$$

We see by looking at the table and before any calculation that the departments of Aisne and Oise seems to be similar and that the department of the Somme differs significantly. The distances put in evidence that observation.

But in the above table the profiles of the Oise and the Somme, with a very small mixed forest, are however very similar in proportion.

In this context, we see that the Euclidean distance transcribed quite well the mass differences between the departments. In other words, the Aisne and the Oise are similar because their surfaces are close. To eliminate the artifact related to the orders of magnitude, we need to transform the data into percentages (percentages of regions). We then get:

	Leafy	**Resinous**	**Mixes**	**% Area**
Aisne (A)	95.6%	3.0%	1.3%	40.8%
Oise (O)	91.0%	9.0%	0.0%	41.0%
Somme (S)	91.1%	8.8%	0.1%	18.2%

Table 5.96: **Transformation into percentages of the contingency table**

where the experts in the field sometimes name the column %Area "marginal profile rows" or "mass" (and respectively when they indicate the rows of the percents for the trees).

If we choose the Euclidean distance on the proportions (relative data), we get:

$$d^2(p_i,p_{i'})=||\overrightarrow{p_ip_{i'}}||^2=\sum_{j=1}^{p}\left(\frac{x_{ij}}{x_{i.}}-\frac{x_{i'j}}{x_{i'.}}\right)^2=\sum_{j=1}^{p}\left(\frac{x_{ij}}{\displaystyle\sum_j x_{ij}}-\frac{x_{i'j}}{\displaystyle\sum_j x_{i'j}}\right)^2 \tag{5.7.2638}$$

Therefore:

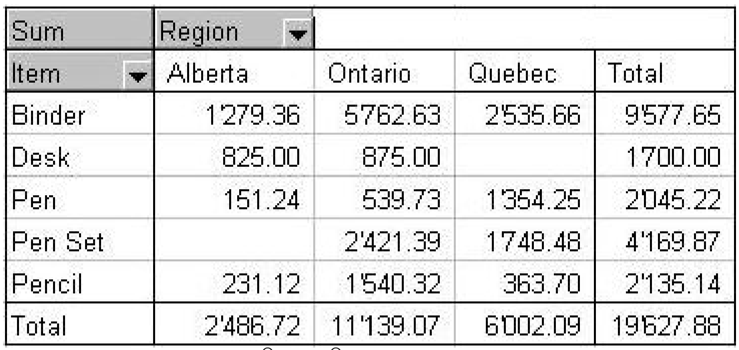
$$\begin{aligned}d(A,O)&=7.6\%\\d(A,S)&=7.4\%\\d(O,S)&=0.2\%\end{aligned} \tag{5.7.2639}$$

This time, the Oise and Somme appear well as have the most similar forests. We see that work with relative data seems more relevant in this case!

Now let us borrow an idea to economists who, when they have tables of the same kind as the previous one, calculate what they named the "index" or "elasticity" (also often name "specificity index" in statistics) and which is given by the ratios between the joint frequency and the marginal frequency:

$$I=\frac{\dfrac{x_{ij}}{x_{i.}}}{\dfrac{x_{.j}}{x_{..}}}=\frac{\dfrac{x_{ij}}{x_{j.}}}{\dfrac{x_{i.}}{x_{..}}} \tag{5.7.2640}$$

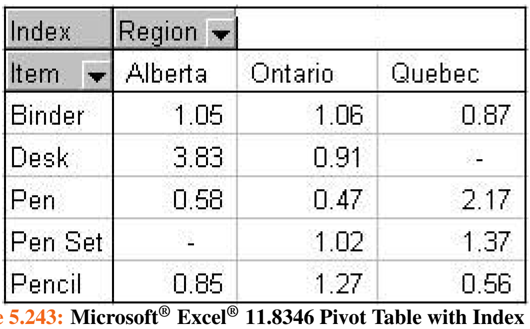
Here is an example obtained with the Pivot Table tool in Microsoft® Excel® 11.8346 which includes natively the Index function. First the starting table:



Sum	Region			
Item	Alberta	Ontario	Quebec	Total
Binder	1'279.36	5762.63	2'535.66	9'577.65
Desk	825.00	875.00		1700.00
Pen	151.24	539.73	1'354.25	2'045.22
Pen Set		2'421.39	1748.48	4'169.87
Pencil	231.12	1'540.32	363.70	2'135.14
Total	2'486.72	11'139.07	6'002.09	19'627.88

Figure 5.242: **Microsoft® Excel® 11.8346 Pivot Table for Index analysis**

and by activating the Index function in the Pivot Table properties we get:



Index	Region		
Item	Alberta	Ontario	Quebec
Binder	1.05	1.06	0.87
Desk	3.83	0.91	-
Pen	0.58	0.47	2.17
Pen Set	-	1.02	1.37
Pencil	0.85	1.27	0.56

Figure 5.243: **Microsoft® Excel® 11.8346 Pivot Table with Index values**

To understand where these values comes from, let us look for example the article *Desk* in the region *Alberta*. It has a return (joint frequency) of:

$$\frac{x_{21}}{x_{2.}}=\frac{825}{1700}\cong 48.52\% \tag{5.7.2641}$$

compared to all regions, which is above the value of 33.33% that this article would have for yield for all regions if there is no region of preference!

The *Alberta* region a yield (marginal rate) of:

$$\frac{x_{1}}{x_{..}}=\frac{2486.72}{19627.88}\cong 12.66\% \tag{5.7.2642}$$

with respect to all regions which is below to the yield of 33.33% that it would have if there were no regions of preference. Thus, this index table shows whether the differences are qualitatively significant!!

The ratio therefore gives:

$$I=\frac{\dfrac{x_{21}}{x_{2.}}}{\dfrac{x_{.1}}{x_{..}}}\cong 3.83 \qquad (5.7.2643)$$

which shows a strong shift between the value obtained and the value we would have if the proportions were respected (over-representation of 283%).

So it is a kind of conformity compliance: if the ratio was equal to 1, it is that the regional sales performance of this particular article would be consistent with respect to all sales of this region with respect to the national market. There would be no anomalies. Let us see this example for our trees where we had seen the effectives:

	Leafy	**Resinous**	**Mixes**	**Total by Area**
Aisne (A)	$106,500$	$3,380$	$1,470$	$111,350$
Oise (O)	$101,700$	$10,000$	0	$111,700$
Somme (S)	$45,200$	$4,350$	50	$49,600$
Total	$253,400$	$17,730$	$1,520$	$272,650$

Table 5.97: **Contingency table (crosstab) of CFA**

and for which we get the following Pivot Table of the effective index in Microsoft® Excel® 14.0.7166:

	A	B	C	D
1				
2				
3	**Sum of Quantity**	**Column Labels**		
4	**Row Labels**	**Leafy**	**Mixtes**	**Resinous**
5	Somme	0.98	0.18	1.35
6	Aisne	1.03	2.37	0.47
7	Oise	0.98	-	1.38

Figure 5.244: **Microsoft® Excel® 14.0.7166 Pivot Table for Index analysis**

and we still see clearly with this table that it is well the Oise and Somme are most alike!

Before continuing, we might ask ourselves the following most important question: What are the theoretical numbers that we would have been obtained if the proportions of the trees in the regions were strictly equivalent to the overall proportions (i.e. so that the index are all unitary)?

Well simply by making the following calculations (it is merely a rule of three calculated in each cell) where the reader must - if possible - understand the meaning without applying this foolishly:

	Leafy	**Resinous**	**Mixes**
Aisne (A)	$=(253,400/272,650)\cdot 111,350$ $=103,488$	$=(17,730/272,650)\cdot 111,350$ $=7,241$	$=(1,520/272,650)\cdot 111,350$ $=621$
Oise (O)	$=(253,400/272,650)\cdot 111,700$ $=103,813$	$=(17,730/272,650)\cdot 111,700$ $=7,264$	$=(1,520/272,650)\cdot 111,700$ $=623$
Somme (S)	$=(253,400/272,650)\cdot 49,600$ $=46,098$	$=(17,730/272,650)\cdot 49,600$ $=3,225$	$=(17,730/272,650)\cdot 49,600$ $=276$
Total	$253,400$	$17,730$	$1,520$

Table 5.98: **Proportions respect of CFA**

Or in a more readable way:

	Leafy	**Resinous**	**Mixes**	**Total by Area**
Aisne (A)	$E_{11}=103,488$	$E_{12}=7,241$	$E_{13}=621$	$r_1=111,350$
Oise (O)	$E_{21}=103,813$	$E_{22}=7,264$	$E_{23}=623$	$r_2=111,700$
Somme (S)	$E_{31}=46,098$	$E_{32}=3,225$	$E_{33}=276$	$r_3=49,600$
Total	$c_1=253,400$	$c_2=17,730$	$c_3=1,520$	$N=272,650$

Notice that in the table above, each cell (denoted E_{ij}), is obtained by computing:

$$E_{ij}=\frac{c_j\cdot r_i}{N} \tag{5.7.2644}$$

Remark

Notice that if the cells have to be given in percentage, rather than in counts, we would then have to calculate instead: $p_{ij}=E_{ij}/N=(c_j\cdot r_i)/N^2$. Hence obviously: $E_{ij}=Np_{ij}$.

And we get with these new values of the table the following theoretical index with Microsoft® Excel® 14.0.7166:

	A	B	C	D
1				
2				
3	**Sum of Quantity**	**Column Labels**		
4	**Row Labels**	**Aisne**	**Oise**	**Somme**
5	Leafy	1.00	1.00	1.00
6	Mixtes	1.00	1.00	1.00
7	Resinous	1.00	1.00	1.00

Figure 5.245: **Microsoft® Excel® 14.0.7166 Pivot Table for Theoretical Index analysis**

which shows now that the proportions are now observed! Parenthesis closed (but on which will come back later)!

Well when we want to make a factorial correspondence analysis, our relation:

$$d^2(x_i,x_{i'})=\sum_{j=1}^{p}\left(\frac{x_{ij}}{x_{i.}-\dfrac{x_{i'j}}{x_{i'.}}}\right)^2 \tag{5.7.2645}$$

Therefore becomes:

$$\boxed{d^2(x_i,x_{i'})=\sum_{j=1}^{p}\frac{\left(\dfrac{x_{ij}}{x_{i.}}-\dfrac{x_{i'j}}{x_{i'.}}\right)^2}{\dfrac{x_{.j}}{x_{..}}}} \tag{5.7.2646}$$

hence:

$$\begin{aligned}d(A,O)&=0.30\\ d(A,S)&=0.39\\ d(O,S)&=0.02\end{aligned} \tag{5.7.2647}$$

Again, the Oise and the Somme appear as the most similar.

The distance above is named the "Chi-square metric" because it looks like (but that's all!) to the distance used in the independence test of the same name (see section Statistics page 1238) but here, it only helps to establish a hierarchy in the context of a contingency table and to observe similar the variables in a more easy way!!

Remark

There is another way to calculate a CFA based on an Euclidean distance but by taking care beforehand to transform in a special way to the contingencies table so that the calculation are the same that when we use the Chi-square metric.

5.7.15.3 Chi-squared Test of Independence

The χ^2-test is applied when you have two categorical variables from a single population. It is used to determine whether there is a significant association between the two variables.

For example, in an election survey, voters might be classified by gender (male or female) and voting preference (Democrat, Republican, or Independent). We could use a chi-square test for independence to determine whether gender is related to voting preference.

Suppose that a categorical variable A has r levels, and another categorical variable B has c levels. The null hypothesis H_0 states that knowing the level of variable A does not help you predict the level of variable B. That is, the variables are independent.

$$\begin{aligned}&H_0: \text{Variable } A \text{ and variable } B \text{ are independent}\\ &H_1: \text{Variable } A \text{ and variable } B \text{ are not independent}\end{aligned} \tag{5.7.2648}$$

We will present this test with a companion example because we know from experience that it is more effective for learning and understanding.

Let us recall that during the introduction of the previous method for comparing numbers (values) and detect which were the closest we gave the following observed effectives:

	Leafy	Resinous	Mixes	Total by Area
Aisne (A)	$106,500$	$3,380$	$1,470$	$111,350$
Oise (O)	$101,700$	$3,380$	$1,470$	$111,700$
Somme (S)	$45,200$	$4,350$	50	$49,600$
Total	$253,400$	$17,730$	$1,520$	$272,650$

Table 5.99: **Contingency table (crosstab) for χ^2 analysis**

and we also showed how to find the table of theoretical effectives (rounded to the nearest whole number) where the proportions should have possibly be respected:

	Leafy	Resinous	Mixes	Total by Area
Aisne (A)	$103,488$	$7,241$	621	$111,350$
Oise (O)	$103,813$	$7,264$	623	$111,700$
Somme (S)	$46,098$	$3,225$	276	$49,600$
Total	$253,400$	$17,730$	$1,520$	$272,650$

Table 5.100: **Contingency table (crosstab) for χ^2 analysis with theoretical effective**

We know that building the last table above assumes that the three regions are in identical conditions for everything related to the growth and multiplication of trees and the number of trees is in direct causal relation (!!!!) with regions and there is no other intermediate causes ... what is a strong assumption!

But under this assumption, let us suppose that we would like know if the differences observed between the number of trees and the regions are statistically significant or purely random because of the experimental sample? In other words, we want to know if the number of trees actually depends on the regions in which they grow or if these values are only due to the sample chance? This is why this test is named the "Chi-square test of independence".

So keep in mind that in the Chi-square test of independence, all subjects/units are collected at random from a population, and two categorical variables are observed for each unit.

Remark

The chi-square test of independence is recommended in sensory analysis by the standard ISO 8588:1987 under the name "test A-Not A".

To answer this questions we must first have a reference. And this reference is precisely the assumption of direct causal link (proportions respected) that we have given just previously.

If we consider that each cell of the table of observed effective corresponds to a random variable of unknown law and that each cell of theoretical table is considered as following a random binomial variable (and asymptotically as a Normal distribution) then as we proved it earlier we know that we can use the chi-square test of adjustment (see page 1113):

$$D=\sum_{i=1}^{N}E_i^2=\sum_{i=1}^{N}\frac{(k_i-np_i)^2}{np_i} \tag{5.7.2649}$$

to have a good idea (but still pretty rough considering the assumptions!) if the differences between the observed effective values are due to chance or are significant. But, if D is small, the probability that it is due to chance is great but if D is large so we have a real - significant - difference (so we use the chi-square test of adjustment but in reverse way in fact!).

It remains to determine the number of degrees of freedom of the χ^2 law that follows this sum in this configuration!

In the particular case (but quite easily generalized by recurrence) of a table with two inputs with two categorized variables X with l levels and Y with c we will have respectively the l rows and c columns.

Thus, the table will have obviously $l \cdot c$ cells. In the table of theoretical effectives (where each cell is treated as a random variable) each cell will be entirely determined by the sum of the other so that the number of degrees of freedom will be logically as we have seen during our study of degrees of freedom:

$$N-1=l\cdot c-1 \tag{5.7.2650}$$

Thus, taking our example of forests, the total of total is $272,650$ which allows us to write this last relation and thus determine the value of a possibly empty cell, all other data being known!

A chi-square test on this type of table tests the hypothesis of independence against the alternative hypothesis of non-independence. Under the assumption of independence we believe we need only:

$$(l-1)+(c-1) \tag{5.7.2651}$$

values on the N one to determine all of them (assuming implicitly known the sum of all rows and columns).

So if we have a table of 2 rows by 2 columns, we only need if we know the total rows and columns, to know 2 values (i.e. $(2-1)+(2-1)=2$) to determine the 2 missing values. The reasoning is the same for a table of 3 rows by 3 columns where we just have to know at least 4 values (i.e. $(3-1)+(3-1)=4$) to determine the missing 5 values.

The degrees of freedom for the chi-square is then:

$$\text{df}=(lc-1)-[(l-1)+(c-1)]=lc-1-l+1-c+1=lc-l-c+1=(l-1)(c-1) \tag{5.7.2652}$$

It is this relation that we say us (trivially!) that if in a table of 2 rows by 2 columns so with 4 cells (total of rows and columns being known!) that being known only one single values (df being equal to 1), we can determine the other 3 missing values.

As we know a possible definition of the number of degrees of freedom df is that it is the maximum number of values of the model such that none of them is calculable from the others.

Similarly, for a table of 3 rows by 3 columns with 9 cells as is the case of our example above with forests, the knowledge of only 4 cells allows us thanks to total lines and columns to determine the other 5 that would possibly not be known.

Hence the relation in the context of the application of chi-square for the final equation:

$$\boxed{\chi^2((l-1)(c-1))=\chi^2_{(l-1)(c-1)}=\sum_{i,j}\frac{(O_{ij}-E_{ij})^2}{E_{ij}}} \tag{5.7.2653}$$

by making use of notations used in the industry. The term:

$$\frac{(O_{ij}-E_{ij})^2}{E_{ij}} \tag{5.7.2654}$$

is often named "square of standardized residual". The squared root is more commonly used and named the "standardized residual":

$$\frac{O_{ij}-E_{ij}}{\sqrt{E_{ij}}} \tag{5.7.2655}$$

The standardized residual is a measure of the strength of the difference between observed and expected values. It's a measure of how significant your cells are to the chi-square value. When you compare the cells, the standardized residual makes it easy to see which cells are contributing the most to the value, and which are contributing the least. If your sample is large enough, the standardized residual can be roughly compared, as we already know it, to a Z-score! Standardization can work even if your variables are not Normally distributed.

A general rule of thumb for figuring out what the standardized residual means, is:

- If the standardised residual is less than -2, the cell observed frequency is less than the expected frequency.
- Greater than $+2$ and the observed frequency is greater than the expected frequency.

If your standardised residuals are ± 3, then it means that something extremely unusual is happening. If you get ± 4, its something from the Twilight Zone! This makes sense if you think about the 68 95 99.7 rule: if your data is normally distributed, 95% of your data should be within two standard deviations from the mean. If you have something greater than that, then you're looking at an outlier.

The ratio:

$$\frac{\dfrac{(O_{ij}-E_{ij})^2}{E_{ij}}}{\displaystyle\sum_{i,j}\frac{(O_{ij}-E_{ij})^2}{E_{ij}}} \tag{5.7.2656}$$

is often named the "contribution to the Chi-square of independence".

Remark

To use this test properly, the practitioner should check first that the differences (numerator) follow a Normal distribution or that all terms of the sum follow a Chi-square distribution or approximately (asymptotically) a Normal centered reduced distribution centered and that the effective in each cell are greater than 5 otherwise Monte Carlo simulations have to be used to determine the p-value.

In our example, we have:

$$D=\sum_{i,j}\frac{(O_{ij}-E_{ij})^2}{E_{ij}}=\sum_{i=1}^{3}\sum_{j=1}^{3}\frac{(O_{ij}-E_{ij})^2}{E_{ij}}\cong 5,602.35 \tag{5.7.2657}$$

and the p-value of this value with the chi-square distribution with 4 degrees of freedom:

$$\chi^2((l-1)(c-1))=\chi^2(4)=\chi^2_4 \tag{5.7.2658}$$

is so close to zero (not statistically significant) that we have no chance of being mistaken in asserting that the observed differences in the table are statistically significant between the 3 and so that there is very likely independence.

Remark

Let us recall that there are plenty of statistical tests with the name that contains "chi-square" in it. For example:

- Chi-square Goodness-of-fit test (allow us to determine whether a specified population distribution is valid)
- Chi-square test of association/independence (allow us to determine whether the distribution of one variable has been influenced by another variable)
- Chi-square test of homogeneity (allow us to compare two or more population proportions), also named Chi-square test of heterogeneity
- Chi-square test for outliers (allow us to detect if there is at least one outlier in comparison of a specific distribution)
- Chi-square test for difference of two count data (special case of homogeneity test with only one category!)

Even if all those tests have different purposes, their mathematical framework and procedure are EXACTLY the same and therefore any of these five tests can be run to get at the same time the five conclusions with the same p-values and the same critical chi-square values!!!

5.7.15.3.1 Equivalence of Z-test and χ^2 test for proportions

We have mentioned during our study of the Z-test for the comparison of two proportions that softwares like `R` use the χ^2 test to compare proportions rather than the Z-test. It's time now to see why there is an equivalence between the 2-sample Wald's Z-statistic for comparing proportions with pooled variances and the Pearson's χ^2 (independence) test for a 2×2 contingency table.!

Say now that we have a study of two categorical variables each with only two levels. One of the response levels is considered the *Success* response and the other the *Failure* response (typical of an A/B test as used sensitivity analysis and especially well known in webdesign...). A general 2×2 table of the observed counts would be as follows:

	Success	**Failure**	**Total**
Group 1	$A\,(O_{11})$	$B\,(O_{12})$	$n_1=A+B$
Group 2	$C\,(O_{21})$	$D\,(O_{22})$	$n_2=C+D$

The observed counts in this table represent the following proportions:

	Success	**Failure**
Group 1	$\hat{p}_1=\frac{A}{A+B}=\frac{A}{n_1}$	$1-\hat{p}_1$
Group 2	$\hat{p}_2=\frac{C}{C+D}=\frac{C}{n_2}$	$1-\hat{p}_2$

What is also often denoted in this special case:

	Success	**Failure**	**Total**
Group 1	p_1	q_1	100%
Group 2	p_2	q_2	100%
Total	p	q	100%

Let us now use the table above blindly as our "contingency" table by noticing that if we take the above table as reference, then $N=100\%=1$.

The usual χ^2 of this table written after we substitute proportions instead of frequencies in its formula, looks like this (as $N=100\%=1$ and the total rows are also equal to 100% it simplifies things quite a lot):

$$\begin{aligned}\chi_1^2&=\sum_{i,j}^{n}\frac{(O_{ij}-E_{ij})^2}{E_{ij}}\\&=\frac{(n_1p_1-n_1p/100\%)^2}{n_1p/100\%}+\frac{(n_2p_2-n_2p/100\%)^2}{n_2p/100\%}+\frac{(n_1q_1-n_1q/100\%)^2}{n_1q/100\%}+\frac{(n_2q_2-n_2q/100\%)^2}{n_2q/100\%}\\&=\frac{(n_1p_1-n_1p)^2}{n_1p}+\frac{(n_2p_2-n_2p)^2}{n_2p}+\frac{(n_1q_1-n_1q)^2}{n_1q}+\frac{(n_2q_2-n_2q)^2}{n_2q}\end{aligned}\tag{5.7.2659}$$

But this can be simplified even more. Indeed, if you remember how we computer the p_{ij}, these are the multiplication of the row total and column total. But in our special case above (with a table containing only proportions!), the rows are always equal to $100\%=1$. Therefore only the total column terms need to be written. This bring us to write:

$$\begin{aligned}\chi_1^2&=\frac{(O_{11}-p\cdot 100\%)^2}{p\cdot 100\%}+\frac{(O_{21}-p\cdot 100\%)^2}{p\cdot 100\%}+\frac{(O_{12}-q\cdot 100\%)^2}{q\cdot 100\%}+\frac{(O_{22}-q\cdot 100\%)^2}{q\cdot 100\%}\\&=\frac{(O_{11}-p)^2}{p}+\frac{(O_{21}-p)^2}{p}+\frac{(O_{12}-q)^2}{q}+\frac{(O_{22}-q)^2}{q}\\&=n_1\frac{(p_1-p)^2}{p}+n_2\frac{(p_2-p)^2}{p}+n_1\frac{(q_1-q)^2}{q}+n_2\frac{(q_2-q)^2}{q}\end{aligned}\tag{5.7.2660}$$

We can simplify even more:

$$\begin{aligned}\chi_1^2&=n_1\frac{(p_1-p)^2}{p}+n_1\frac{(q_1-q)^2}{q}+n_2\frac{(p_2-p)^2}{p}+n_2\frac{(q_2-q)^2}{q}\\&=n_1\left[\frac{(p_1-p)^2}{p}+\frac{(q_1-q)^2}{q}\right]+n_2\left[\frac{(p_2-p)^2}{p}+\frac{(q_2-q)^2}{q}\right]\\&=\frac{n_1(p_1-p)^2q}{pq}+\frac{n_1(q_1-q)^2p}{pq}+\frac{n_2(p_2-p)^2q}{pq}+\frac{n_2(q_2-q)^2p}{pq}\\&=\frac{n_1(p_1-p)^2(1-p)+n_1(1-p_1-1+p)^2p+n_2(p_2-p)^2(1-p)+n_2(1-p_2-1+p)^2p}{pq}\\&=\frac{n_1(p_1-p)^2(1-p)+n_1(p-p_1)^2p+n_2(p_2-p)^2(1-p)+n_2(p-p_2)^2p}{pq}\\&=\frac{[n_1(p_1-p)^2][(1-p)+p]+[n_2(p_2-p)^2][(1-p)+p]}{pq}\\&=\frac{n_1(p_1-p)^2+n_2(p_2-p)^2}{pq}\end{aligned}\tag{5.7.2661}$$

Remember that:

$$p=\frac{n_1p_1+n_2p_2}{n_1+n_2}\tag{5.7.2662}$$

Plug-in that latter in the numerator in the above relation, we get:

$$\begin{aligned}\chi_1^2 &= \frac{n_1\left(p_1-p\right)^2+n_2\left(p_2-p\right)^2}{pq}\\ &= \frac{n_1\left(p_1-\frac{n_1p_1+n_2p_2}{n_1+n_2}\right)^2+n_2\left(p_2-\frac{n_1p_1+n_2p_2}{n_1+n_2}\right)^2}{pq}\\ &= \frac{n_1\left(p_1(n_1+n_2)-(n_1p_1+n_2p_2)\right)^2+n_2\left(p_2(n_1+n_2)-(n_1p_1+n_2p_2)\right)^2}{pq(n_1^2+n_2^2)}\\ &= \frac{n_1\left(p_1n_2-n_2p_2\right)^2+n_2\left(p_2n_1-n_1p_1\right)^2}{pq(n_1^2+n_2^2)}\\ &= \frac{n_1\left(p_1^2n_2^2-2p_1n_2n_2p_2+n_2^2p_2^2\right)+n_2\left(p_2^2n_1^2-2p_2n_1n_1p_1+n_1^2p_1^2\right)}{pq(n_1^2+n_2^2)}\\ &= \frac{n_1p_1^2n_2^2-2n_1p_1n_2n_2p_2+n_1n_2^2p_2^2+n_2p_2^2n_1^2-2n_2p_2n_1n_1p_1+n_2n_1^2p_1^2}{pq(n_1^2+n_2^2)}\\ &= \frac{p_1^2(n_1n_2^2+n_2n_1^2)+p_2^2(n_1n_2^2+n_2n_1^2)-2p_1p_2(n_1n_2^2+n_2n_1^2)}{pq(n_1^2+n_2^2)}\\ &= \frac{(p_1-p_2)^2(n_1n_2^2+n_2n_1^2)}{pq(n_1^2+n_2^2)}\end{aligned}\tag{5.7.2663}$$

We divide both numerator and denominator by the $(n_1n_2^2+n_2n_1^2)$ and get:

$$\begin{aligned}\chi_1^2 &= \frac{(n_1n_2^2+n_2n_1^2)}{(n_1n_2^2+n_2n_1^2)}\frac{(p_1-p_2)^2(n_1n_2^2+n_2n_1^2)}{pq(n_1^2+n_2^2)}=\frac{(p_1-p_2)^2}{pq\dfrac{(n_1^2+n_2^2)}{n_1n_2^2+n_2n_1^2}}\\ &= \frac{(p_1-p_2)^2}{pq\dfrac{(n_1+n_2)(n_1-n_2)}{n_1n_2(n_1+n_2)}}=\frac{(p_1-p_2)^2}{pq\dfrac{n_1-n_2}{n_1n_2}}=\frac{(p_1-p_2)^2}{pq\left(\dfrac{1}{n_1}+\dfrac{1}{n_2}\right)}\end{aligned}\tag{5.7.2664}$$

and as the χ_1^2 is equal to Z^2 this lead us to:

$$Z^2=\frac{(p_1-p_2)^2}{pq\left(\dfrac{1}{n_1}+\dfrac{1}{n_2}\right)}\tag{5.7.2665}$$

that is the squared Z-statistic of the Z-test of proportions (pooled version as seen at page 881) for *Success* response!!

Thus, the 2×2 homogeneity Chi-square statistic (and test) is equivalent to the Z-test of two proportions. The so called expected frequencies computed in the chi-square test in a given column is the weighted (by the group n) average vertical profile (i.e. the profile of the "average group") multiplied by that group's n. Thus, it comes out that chi-square tests the deviation of each of the two groups profiles from this average group profile, - which is equivalent to testing the groups' profiles difference from each other, which is the Z-test of proportions. This is why quite a significant percentage of webdesigner refer to A/B proportion test as Z-test or χ^2 test because they are simply the same (however rigorously we should always mention if we use the pooled or unpooled version with or without Yates correction...)

This result demonstrates of a link between variables association measure (χ^2) and a group difference measure (Z-test statistic). Attribute associations and group differences are (often) the two facets of the same thing.

Recall from our Z-test of two proportions that our null hypothesis is that the two population proportions, p_1 and p_2, were assumed equal while the two-sided alternative hypothesis was that they were not equal.

This null hypothesis would be analogous to the two groups being independent. Also, if the two success proportions are equal, then the two failure proportions would also be equal.

Remark

For a practical (i.e. numerical) example of the equivalent between the pooled proportions Z-test and the pooled 2×2 contingency χ^2 test, the reader can refer to our `R` companion book where we will show that in facts `R` always use the chi-square version whatever the function we use (`prop.test()` function or `chisq.test()` both use the chi-square test anyway!).

5.7.15.3.2 Cramér's V

The "Cramér's V" (sometimes referred to as "Cramér's phi" and denoted as φ_c) is a measure of association between two nominal variables, giving a value between 0 and $+1$ (inclusive). It is based on Pearson's chi-squared statistic and was published by Harald Cramér in 11946 (holocene calendar).

As we will prove it, φ_c is the intercorrelation of two discrete variables and may be used with variables having two or more levels. φ_c is a symmetrical measure, it does not matter which variable we place in the columns and which in the rows. Also, the order of rows/columns doesn't matter, so φ_c may be used with nominal data types or higher (ordered, numerical, etc.)

We have seen just previously that the chi-square test of independence may be used to measure the degree of association of two categorical variables in a contingency table of l rows and c columns:

$$D=\sum_{ij}\frac{(O_{ij}-E_{ij})^2}{E_{ij}} \tag{5.7.2666}$$

and that this distance follows a chi-square distribution with $(l-1)(c-1)$ degrees of freedom. We will prove intuitively that the maximum value of the distance D is given by:

$$D_{\max}=N\left(\min(l,c)-1\right) \tag{5.7.2667}$$

and that maximum value is achieved if and only if each row or column contains exactly one non-zero value. Under the latter condition, we can always rearrange the contingency table so to have all non-zero terms on the diagonal of the table.

Obviously if the table is not square as below:

Row/Column	c_1	c_2	c_3	c_4	**Total**
l_1	a_1	0	0	0	a_1
l_2	0	a_2	0	0	a_2
l_3	0	0	a_3	0	a_3
l_4	0	0	0	a_4	a_4
l_5	0	0	0	0	0
Total	a_1	a_2	a_3	a_4	N

Table 5.101: **Rectangular contingency table**

The case that maximize D request diagonal terms on the smallest dimension in row or column (row dimension in the example above) denoted by tradition q. In the special example above we have:

$$q=\min(l,c)=c=4 \tag{5.7.2668}$$

In this special case and obviously theoretical one, the rows that have only zero values can be omitted and therefore the previous table can be reduced to:

Row/Column	c_1	c_2	c_3	c_4	**Total**
l_1	a_1	0	0	0	a_1
l_2	0	a_2	0	0	a_2
l_3	0	0	a_3	0	a_3
...	...	...	...	...	...
l_q	0	0	0	a_q	a_q
Total	a_1	a_2	...	a_q	N

Table 5.102: **Squared rectangular contingency table**

Of course, ignoring the rows or columns that have only zero values bring us to assume that for the distance D of the chi-square we request that:

$$\frac{(0-0)^2}{0}=0 \tag{5.7.2669}$$

which is quite indisputable ... For what will follow, we will need the following relations:

$$N=\sum_{i=1}^{q} a_i \tag{5.7.2670}$$

and:

$$N^2=\left(\sum_{i=1}^{q} a_i\right)^2=\sum_{i=1}^{q} a_i\sum_{j=1}^{q} a_j=\sum_{i=1}^{q}\sum_{j=1}^{q} a_ia_j=\sum_{i=1}^{q} a_i^2+\sum_{i\neq j}^{q} a_ia_j \tag{5.7.2671}$$

Therefore it comes:

$$\begin{aligned}
D_{\max}&=\sum_{ij}\frac{(O_{ij}-E_{ij})^2}{E_{ij}}=\sum_{i}^{q}\frac{\left(a_i-\dfrac{a_i^2}{N}\right)^2}{\dfrac{a_i^2}{N}}+\sum_{i\neq j}^{q}\frac{\left(0-\dfrac{a_ia_j}{N}\right)^2}{\dfrac{a_ia_j}{N}}=\sum_{i}^{q}\frac{\left(\dfrac{Na_i-a_i^2}{N}\right)^2}{\dfrac{a_i^2}{N}}+\sum_{i\neq j}^{q}\frac{a_ia_j}{N}\\
&=\sum_{i}^{q}\frac{(a_i(N-a_i))^2}{a_i^2N}+\frac{1}{N}\left(\sum_{i\neq j}^{q}a_ia_j+\sum_{i}^{q}a_i^2\right)-\frac{1}{N}a_i^2\\
&=\sum_{i}^{q}\frac{(N-a_i)^2}{N}+\frac{1}{N}N^2-\frac{1}{N}\sum_{i}^{q}a_i^2=\frac{1}{N}\sum_{i}^{q}(N-a_i)^2-\frac{1}{N}\sum_{i}^{q}a_i^2+\frac{1}{N}N^2\\
&=\frac{1}{N}\left[\sum_{i}^{q}(N-a_i)^2-\sum_{i}^{q}a_i^2\right]+N=\frac{1}{N}\sum_{i}^{q}\left((N-a_i)^2-a_i^2\right)+N=\sum_{i}^{q}\frac{((N-a_i)^2-a_i^2)}{N}+N\\
&=\sum_{i}^{q}\frac{N^2-2Na_i+a_i^2-a_i^2}{N}+N=\sum_{i}^{q}\frac{N^2-2Na_i}{N}+N=\sum_{i}^{q}(N-2a_i)+N\\
&=qN-2\sum_{i}^{q}a_i+N=qN-2N+N=N(q-1)=N(\min(l,c)-1)
\end{aligned} \tag{5.7.2672}$$

We then define the following value:

$$\boxed{V=\sqrt{V^2}=\sqrt{\frac{\chi^2(l-1)(c-1)}{N(q-1)}}=\sqrt{\frac{\chi^2_{(l-1)(c-1)}}{N(q-1)}}} \tag{5.7.2673}$$

as being the "Cramér's V coefficient" (the majority of software, however, give the value of V squared). The latter is such that it never exceeds 1 and allows a more intuitive interpretation of the degree of association in a contingency table.

In the case where the table size is of 2 rows and 2 columns, the previous relation reduces then immediately to:

$$V=\sqrt{\frac{\chi_1^2}{N}} \tag{5.7.2674}$$

Relation that is traditional to note in this case as follows:

$$\varphi=\sqrt{\frac{\chi_1^2}{N}} \tag{5.7.2675}$$

and to name "Cramér's phi" or "phi coefficient".

✍ **Example:**

Consider the following table (even if the conditions are not met for a chi-square test of independence):

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	8	1	9
Deadlines not met	4	5	9
Total	12	6	18

Table 5.103: **Example of a contingency table for calculating the Cramér's V**

with the theoretical effectives:

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	$(12/18)\cdot 9=6$	$(6/18)\cdot 9=3$	9
Deadlines not met	$(12/18)\cdot 9=6$	$(6/18)\cdot 9=3$	9
Total	12	6	18

Table 5.104: **Contingency table of the example with theoretical effectives**

Then we have:

$$\begin{aligned}D=\chi^2_{(l-1)(c-1)}=\chi_1^2&=\sum_{ij}\frac{(O_{ij}-E_{ij})^2}{E_{ij}}\\&=\frac{(8-6)^2}{6}+\frac{(4-6)^2}{6}+\frac{(1-3)^2}{3}+\frac{(5-3)^2}{3}\\&=0.\bar{6}+0.\bar{6}+1.\bar{3}+1.\bar{3}=4\end{aligned} \tag{5.7.2676}$$

And to a threshold level of 95%, we get with Microsoft® Excel® 14.0.6123:

$$\chi^2_{95\%}(1)=\texttt{=CHISQ.INV(0.95,1)}=3.841 \tag{5.7.2677}$$

or with the corresponding p-value:

$$=\texttt{1-CHISQ.DIST(4,1,TRUE)}=0.045 \tag{5.7.2678}$$

It then comes immediately:

$$V=\sqrt{V^2}=\sqrt{\frac{\chi^2_{(l-1)(c-1)}}{N(q-1)}}=\sqrt{\frac{4}{18(2-1)}}=\sqrt{0.\bar{2}}\cong 0.4714 \tag{5.7.2679}$$

We are a bit at the limit here ... since the p-value is very close to the traditional 0.05. However, take a decision in this case where the effectives are so low would be equivalent to conclude anything and even more that this statistical tool is built on an accumulation of approximations.

5.7.15.4 Pearson's phi coefficient

In statistics, the "Pearson's phi coefficient" is an another measure of association for two binary variables. Introduced by Karl Pearson, this measure is similar to the Pearson correlation coefficient in its interpretation. In fact, a Pearson correlation coefficient estimated for two binary variables (Bernoulli variables) will return the Pearson's phi coefficient.

To introduce this correlation coefficient and proof that it is only a special case of the Pearson correlation coefficient, let us consider the following table:

		Y		
		$Y=1$	$Y=0$	**Total**
X	$X=1$	n_{11}	n_{12}	$n_{1.}$
	$X=0$	n_{21}	n_{22}	$n_{2.}$
	Total	$n_{.1}$	$n_{.2}$	n

Table 5.105: **Dichotomous example of a table of contingencies**

or written in another way:

		Y		
		$Y=1$	$Y=0$	**Total**
X	$X=1$	a	b	$a+b$
	$X=0$	c	d	$c+d$
	Total	$a+c$	$b+d$	1

Let us recall that the Pearson's correlation coefficient:

$$\rho_{X,Y}=\frac{\operatorname{cov}(X,Y)}{\sigma_X\sigma_Y}=\rho_{X,Y}=\frac{\mathrm{E}[XY]-\mathrm{E}[X]\,\mathrm{E}[Y]}{\sqrt{\mathrm{E}[X^2]-[\mathrm{E}[X]]^2}\,\sqrt{\mathrm{E}[Y^2]-[\mathrm{E}[Y]]^2}} \tag{5.7.2680}$$

Now let X and Y be Bernoulli random variables (see page 652). We don't assume independence or identical distribution, but we do assume that all 4 of the following probabilities are non-zero.

Let:

$$a:=P[X=1,Y=1],b:=P[X=1,Y=0],c:=P[X=0,Y=1],d:=P[X=0,Y=0] \tag{5.7.2681}$$

We have first:

$$\begin{aligned}\mathrm{E}[X]&=a+b=p\\ \mathrm{E}[Y]&=a+c=q\end{aligned}\tag{5.7.2682}$$

We also have:

$$\begin{aligned}\mathrm{V}(X)&=\mathrm{E}[(X-\mathrm{E}[X])^2]=\mathrm{E}[(X-p)^2]=p(1-p)^2+(1-p)(-p)^2\\ &=p(1-2p+p^2)+p^2-p^3=p-2p^2+p^3+p^2-p^3\\ &=p-p^2=p(1-p)\end{aligned}\tag{5.7.2683}$$

and:

$$\begin{aligned}\sigma_X&=\sqrt{\mathrm{V}(X)}=\sqrt{p(1-p)}=\sqrt{(a+b)(1-(a+b))}\\ \sigma_Y&=\sqrt{\mathrm{V}(Y)}=\sqrt{q(1-q)}=\sqrt{(a+c)(1-(a+c))}\end{aligned}\tag{5.7.2684}$$

and:

$$\operatorname{cov}(X,Y)=\mathrm{E}[XY]-\mathrm{E}[X]\mathrm{E}[Y]=a-pq=a-(a+b)(a+c)\tag{5.7.2685}$$

Finally, by substitution into the equation for ρ_{XY}:

$$\begin{aligned}\rho_{XY}&=\frac{\operatorname{cov}(X,Y)}{\sigma_X\sigma_Y}\\ &=\frac{a-(a+b)(a+c)}{\sqrt{(a+b)(1-(a+b))}\sqrt{(a+c)(1-(a+c))}}\\ &=\frac{a-(a+b)(a+c)}{\sqrt{(a+b)(1-(a+b))(a+c)(1-(a+c))}}\end{aligned}\tag{5.7.2686}$$

Doing the right substitutions, this lead us to:

$$\boxed{\phi=\frac{nn_{11}-n_{1.}n_{.1}}{\sqrt{n_{1.}(n-n_{1.})n_{.1}(n-n_{.1})}}}\tag{5.7.2687}$$

If we replace n by $n_{11}+n_{12}+n_{22}+n_{21}$ and $n_{1.}$ by $n_{11}+n_{12}$ and $n_{.1}$ by $n_{11}+n_{21}$ then we get after some very easy simplification:

$$\phi=\frac{n_{11}n_{22}-n_{12}n_{21}}{\sqrt{(n_{11}+n_{12})(n_{21}+n_{22})(n_{11}+n_{21})(n_{12}+n_{22})}}\tag{5.7.2688}$$

The interpretation for the phi coefficient is similar to the Pearson correlation coefficient. The range is from -1 to $+1$, where:

- 0 is no relationship
- $+1$ is a perfect positive relationship: most of your data falls along the diagonal cells.
- -1 is a perfect negative relationship: most of your data is not on the diagonal

The Political Science Department at Quinnipiac University posted this useful list of the meaning of Pearson's Correlation coefficients. The same rule of thumb can be used for the Phi coefficient. Note that these are "crude estimates" for interpreting strengths of relationships:

Interval	Interpretation
$0.7 \leq \varphi \leq 1$	Very strong positive relationship
$0.4 \leq \varphi < 0.70$	Strong positive relationship
$0.3 \leq \varphi < 0.4$	Moderate positive relationship
$0.2 \leq \varphi < 0.3$	Weak positive relationship
$0.0 < \varphi < 0.2$	No or negligible positive relationship
$\varphi = 0$	No relationship
$0.0 > \varphi > -0.2$	No or negligible negative relationship
$-0.2 > \varphi > -0.3$	Weak negative relationship
$-0.3 > \varphi > -0.4$	Moderate negative relationship
$-0.4 > \varphi > -0.70$	Strong negative relationship
$-0.7 > \varphi \geq 1$	Very strong negative relationship

Table 5.106: φ **Pearson correlation coefficient**

Although computationally the Pearson correlation coefficient reduces to the Pearson's phi coefficient in the 2×2 case, they are not in general the same. The Pearson correlation coefficient ranges from -1 to $+1$, where ± 1 indicates perfect agreement or disagreement, and 0 indicates no relationship. The phi coefficient has a maximum value that is determined by the distribution of the two variables if one or both variables can take on more than two values.

✍**Example:**

Consider the following table (even if the conditions are not met for a chi-square test of independence):

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	8	1	9
Deadlines not met	4	5	9
Total	12	6	18

Table 5.107: **Squared rectangular contingency table**

Then we have:

$$\phi = \frac{nn_{11} - n_{1.}n_{.1}}{\sqrt{n_{1.}(n-n_{1.})n_{.1}(n-n_{.1})}} = \frac{18 \cdot 8 - 9 \cdot 12}{\sqrt{9(18-9) \cdot 12(18-12)}} \cong 0.471 \qquad (5.7.2689)$$

We can prove that Pearson's phi coefficient is equal to Cramèr's phi coefficient seen just before (that's by the way why the notation is the same!) and that was given for recall:

$$\varphi = \sqrt{\frac{\chi_1^2}{N}} \qquad (5.7.2690)$$

To simplify the notation, let us put:

$$n_{11}=a, n_{12}=b, n_{21}=c, n_{22}=d \tag{5.7.2691}$$

We then have for a contingency table of size 2×2:

$$\chi^2=\sum_{l=1}^{2}\sum_{c=1}^{2}\frac{(n_{lc}-e_{lc})^2}{e_{lc}}=\frac{(a-e_{11})^2}{e_{11}}+\frac{(b-e_{12})^2}{e_{12}}+\frac{(c-e_{21})^2}{e_{21}}+\frac{(d-e_{22})^2}{e_{22}} \tag{5.7.2692}$$

With same as for our study of the Cramèr's V coefficient:

$$e_{11}=\frac{(a+b)(a+c)}{n}, e_{12}=\frac{(a+b)(b+d)}{n}, e_{21}=\frac{(a+c)(c+d)}{n}, e_{22}=\frac{(b+d)(c+d)}{n} \tag{5.7.2693}$$

Which implies:

$$\begin{aligned}\chi^2&=\frac{\left(a-\dfrac{(a+b)(a+c)}{n}\right)^2}{\dfrac{(a+b)(a+c)}{n}}+\frac{\left(b-\dfrac{(a+b)(b+d)}{n}\right)^2}{\dfrac{(a+b)(b+d)}{n}}+\frac{\left(c-\dfrac{(a+c)(c+d)}{n}\right)^2}{\dfrac{(a+c)(c+d)}{n}}+\frac{\left(d-\dfrac{(b+d)(c+d)}{n}\right)^2}{\dfrac{(b+d)(c+d)}{n}}\\&=\frac{\dfrac{1}{n^2}}{\dfrac{1}{n}}\left[\frac{(na-(a+b)(a+c))^2}{(a+b)(a+c)}+\frac{(nb-(a+b)(b+d))^2}{(a+b)(b+d)}+\frac{(nc-(a+c)(c+d))^2}{(a+c)(c+d)}+\frac{nd-(b+d)(c+d))^2}{(b+d)(c+d)}\right]\end{aligned} \tag{5.7.2694}$$

But we have:

$$\begin{aligned}na-(a+b)(a+c)&=(a+b+c+d)a-(a+b)(a+c)\\&=a^2+ab+ac+ad-a^2-ac-ba-bc=ad-bc\end{aligned} \tag{5.7.2695}$$

and:

$$\begin{aligned}nb-(a+b)(b+d)&=(a+b+c+d)b-(a+b)(b+d)\\&=ab+b^2+bc+bd-ab-ad-b^2-bd=bc-ad\end{aligned} \tag{5.7.2696}$$

and:

$$\begin{aligned}nc-(a+c)(c+d)&=(a+b+c+d)c-(a+c)(c+d)\\&=ac+bc+c^2+cd-ac-ad-c^2-cd=bc-ad\end{aligned} \tag{5.7.2697}$$

and:

$$\begin{aligned}nd-(b+d)(c+d)&=(a+b+c+d)d-(b+d)(c+d)\\&=ad+bd+dc+d^2-bc-bd-dc-d^2=ad-bd\end{aligned} \tag{5.7.2698}$$

Hence:

$$\begin{aligned}\chi^2&=\frac{1}{n}\left[\frac{(ad-bc)^2}{(a+b)(a+c)}+\frac{(bc-ad)^2}{(a+b)(b+d)}+\frac{(bc-ad)^2}{(a+c)(c+d)}+\frac{(ad-bc)^2}{(b+d)(c+d)}\right]\\&=\frac{(ad-bc)^2}{n}\left[\frac{1}{(a+b)(a+c)}+\frac{1}{(a+b)(b+d)}+\frac{1}{(a+c)(c+d)}+\frac{1}{(b+d)(c+d)}\right]\\&=\frac{(ad-bc)^2}{n}\frac{(b+d)(c+d)+(a+c)(c+d)+(a+b)(b+d)+(a+c)(a+b)}{(a+c)(a+b)(b+d)(c+d)}\end{aligned} \tag{5.7.2699}$$

Notice that:

$$\begin{aligned}(b+d)(c+d)&+(a+c)(c+d)+(a+b)(b+d)+(a+c)(a+b)\\&=dc+d^2+ac+ad+c^2+cd+ab+ad+b^2+bd+a^2+ab+ca+bc\\&=a^2+b^2+c^2+d^2+2bc+2bd+2dc+2ac+2ab+2ad\\&=(a+b+c+d)^2=n^2\end{aligned}\tag{5.7.2700}$$

This last result bring us to:

$$\begin{aligned}\chi^2&=\frac{(ad-bc)^2}{n}\frac{n^2}{(a+c)(a+b)(b+d)(c+d)}=n\frac{(ad-bc)^2}{(a+c)(a+b)(b+d)(c+d}\\&=n\varphi^2\end{aligned}\tag{5.7.2701}$$

Hence:

$$\phi=\sqrt{\frac{\chi^2}{n}}\tag{5.7.2702}$$

Pearson's phi coefficient is the source of inspiration of "Matthews correlation coefficient" (M.C.C.) that is used in Machine Learning as a measure of the quality of binary (two-class) classifications. Only the vocabulary differs. Indeed, it is defined as:

$$\boxed{\text{MCC}=\frac{\text{TP}\cdot\text{TN}-\text{FP}\cdot\text{FN}}{\sqrt{(\text{TP}+\text{FP})(\text{TP}+\text{FN})(\text{TN}+\text{FP})(\text{TN}+\text{FN})}}}\tag{5.7.2703}$$

While there is no perfect way of describing the confusion matrix $\mathcal{C}$ of true and false positives and negatives by a single number (we will see in the chapter of Numerical Methods what are "confusion matrices"!), the Matthews correlation coefficient is generally regarded as being one of the best such measures in this beginning of the 121st century (holocene calendar).

In this relation, TP is the number of true positives, TN the number of true negatives, FP the number of false positives and FN the number of false negatives. If any of the four sums in the denominator is zero, the denominator can be arbitrarily set to one; this results in a Matthews correlation coefficient of zero, which can be shown to be the correct limiting value.

5.7.15.5 Exact Fisher's Test

When the effective in the contingency table are too small or that the values are really too irregular, the use of chi-square (Pearson's test) is not possible because the application conditions are no longer valid. We will see that the Fisher exact test can be formalized analytically in 2×2 contingency tables (the majority of statistical software only support this particular scenario for the Fisher exact test) otherwise what must be used Monte Carlo simulations.

The principle of the "Fisher's exact test" (usable both in bilateral or unilateral even if this latter is far more common in practice), so based on the crossover frequency, is to determine whether the pattern observed in the table contingency is an extreme situation with respect to all possible situations. As we will prove it, this test has the special property that any cell of the table can be referred for the test because the underlying distributions (marginals) of probability are equivalent.

To study this test, as often in this section, we use directly an example as theoretical companion.

Let us consider the following contingency table (which now is known to us ...):

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	8	1	9
Deadlines not met	4	5	9
Total	12	6	18

Table 5.108: **Squared rectangular contingency table**

which is not really suitable for chi-square test of independence since the content of the cells is less than 10 units and the number of degrees of freedom would be equal to unity.

The same table in percentages will give (even if it is unnecessary for the study of this test):

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	88.88%	11.12%	50%
Deadlines not met	44.44%	55.56%	50%
Total	66.66%	33.34%	100%

The theoretical effectives are given by (even if it is as useless to study this test but statistical software also frequently communicate these values):

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	$(12/18)\cdot 9=6$	$(6/18)\cdot 9=3$	9
Deadlines not met	$(12/18)\cdot 9=6$	$(6/18)\cdot 9=3$	9
Total	12	6	18

The question we will begin to ask ourselves is the following: knowing the totals for each row and each column, what is the probability of having the values present in each cell?!

This question can be reformulated if we change the table in the following generic form:

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	$a=k$	b	$a+b=m$
Deadlines not met	c	d	$c+d$
Total	$a+c=p$	$b+d$	$a+b+c+d=n$

Explicitly and relatively to our example by adopting the notation in use of the hypergeometric law, the question is to know what is the probability of having 8 ($a=k$) projects among the 18

(n) whose deadlines were met by certified project managers knowing that there are 9 projects (m) at total whose deadlines were met and 12 projects (p) at total managed by certified project managers.

We saw earlier that in this case it is an exhaustive drawing, we then have to use the hypergeometric law given by for recall by as proven earlier above by:

$$P(n,p,m,k)=\mathcal{H}(k)=\frac{C_k^m C_{p-k}^{n-m}}{C_p^n}=\frac{\dfrac{m!}{k!(m-k)!}\dfrac{(n-m)!}{(p-k)!((n-m)-(p-k))!}}{\dfrac{n!}{p!(n-p)!}} \qquad (5.7.2704)$$

Thus with of Microsoft® Excel® 11.8346:

```
=HYPGEOM.DIST(k,p,m,n,FALSE)
=HYPGEOM.DIST(8,12,9,18,FALSE)=0.06108597
```

where for recall, k is the number of successes in the sample, p is the sample size, m the number of successes in the population and n the size of the population.

In fact, as already mentioned, the probabilities are all equal regardless of the selected cell of the contingency table !! This can be checked numerically for sceptics using again a spreadsheet software like Microsoft® Excel® 14.0.6123 by creating the following structure:

	A	B	C
1	**Contingency Table:**		
2	=RANDBETWEEN(0,15)	=RANDBETWEEN(0,15)	=SUM(A2:B2)
3	=RANDBETWEEN(0,15)	=RANDBETWEEN(0,15)	=SUM(A3:B3)
4	=SUM(A2:A3)	=SUM(B2:B3)	=SUM(A4:B4)
5			
6	**Check:**		
7	=HYPGEOM.DIST(A2,A4,C2,C4,FALSE)	=HYPGEOM.DIST(B2,B4,C2,C4,FALSE)	
8	=HYPGEOM.DIST(A3,A4,C3,C4,FALSE)	=HYPGEOM.DIST(B3,B4,C3,C4,FALSE)	

Figure 5.246: **Exact Fisher test symmetry with Microsoft® Excel® 14.0.6123**

and therefore each time that the reader presses the F9 keyboard key he can check that all probabilities are always equal.

This can also be checked formally by selecting a cell of the table and writing:

$$P(n,p,m,k)=\frac{C_k^m C_{p-k}^{n-m}}{C_p^n}=\frac{\dfrac{m!}{k!(m-k)!}\dfrac{(n-m)!}{(p-k)!((n-m)-(p-k))!}}{\dfrac{n!}{p!(n-p)!}} \qquad (5.7.2705)$$

and for another cell of the same column, we will have:

$$P(n,p,n-m,p-k)=\frac{\dfrac{(n-m)!}{(p-k)!((n-m)-(p-k))!}\dfrac{(n-(n-m))!}{(p-(p-k))!((n-(n-m))-(p-(p-k)))!}}{\dfrac{n!}{p!(n-p)!}}$$
$$=\frac{\dfrac{(n-m)!}{(p-k)!((n-m)-(p-k))!}\dfrac{m!}{k!(m-k)!}}{\dfrac{n!}{p!(n-p)!}} \tag{5.7.2706}$$

and therefore:

$$P(n,p,m,k)=P(n,p,n-m,p-k) \tag{5.7.2707}$$

and so on...

Anyway, that being said, so we have in the upper left cell the value 8 while the theoretical effective is 6. The first thing we can answer is whether this value of 8 is unusually large or not compared the theoretical effective. For this, we calculate by example the unilateral cumulative probability of being less than or equal to 8. We have then with Microsoft® Excel® 14.0.6123 and later (the last parameter of 1 - equivalent to `TRUE` - of the function indicate to the software we want the cumulative probability):

```
=HYPGEOM.DIST(8,12,9,18,1)=0.995475113
```

It therefore appears with a threshold of 5% in unilateral that this value is unusually large. We are then in an extreme situation.

By cons, even if the probabilities are equal for all the cells, the cumulative probability is not! Thus we have for example for the value of the lower left cell (to check if it is abnormally small compared to the theoretical effective of 6):

```
=HYPGEOM.DIST(4,12,9,18,1)=0.06561086
```

So this is a value that is not abnormally small. However, we would like to have a test to conclude if the entire table is or is not an extreme configuration. However, by making the calculation cell by cell, we will not get too much...

The idea then is (at least on the "paper") to build all tables whose marginal frequencies are $9;9$ and $12;6$ and to calculate the probability of a given cell (the advantage of this technique is that the conclusion will be the same regardless the chosen cell as reference for the calculations):

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	9	0	9
Deadlines not met	3	6	9
Total	12	6	18

`=HYPGEOM.DIST(9,12,9,18)=0.004524887`

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	8	1	9
Deadlines not met	4	5	9
Total	12	6	18

`=HYPGEOM.DIST(8,12,9,18)=0.06108597`

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	7	2	9
Deadlines not met	5	4	9
Total	12	6	18

`=HYPGEOM.DIST(7,12,9,18)=0.244343891`

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	6	3	9
Deadlines not met	6	3	9
Total	12	6	18

`=HYPGEOM.DIST(6,12,9,18)=0.380090498`

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	5	4	9
Deadlines not met	7	2	9
Total	12	6	18

`=HYPGEOM.DIST(5,12,9,18)=0.244343891`

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	4	5	9
Deadlines not met	8	1	9
Total	12	6	18

`=HYPGEOM.DIST(4,12,9,18)=0.061085973`

Projects	**Certified Project Manager**	**Non-Certified Project Manager**	**Total**
Deadlines met	3	6	9
Deadlines not met	9	0	9
Total	12	6	18

`=HYPGEOM.DIST(3,12,9,18)=0.004524887`

To summarize with the values of k (corresponding to the top left cell):

k	**Probability**
9	0.00452489
8	0.06108597
7	0.24434389
6	0.3800905
5	0.24434389
4	0.06108597
3	0.00452489
Sum:	1

Table 5.109: **Probability of the hypergeometric law corresponding to the combination**

As in the column of the original table which we just worked with the smallest value is 4 and the biggest 8, we will take the tail probabilities to get what is the p-value to be greater or equal 8 and less than or equal 4 (this is therefore a bilateral test). Then we have:

k	**Probability**
9	0.00452489
8	0.06108597
4	0.06108597
3	0.00452489
Sum:	0.131221719

Table 5.110: **Selection of values of interest**

Therefore the p-value is 13.12%. We can therefore not say that our original table is in an extremal configuration if we chose an empirical threshold value of 5%. Many softwares only communicate the p-value.

Remark

The choice of the bounds in this test are subject to debate. Indeed, if we chose for example to focus on the probability to be in the closed bounded interval of 4 and 8 (inclusive!), we would have a result of 99.09% and then we should consider that we are in an extreme configuration if we made the 5% empirical threshold choice. Therefore the choice of the bounds with a discrete distribution like the Hypergeometric law many times something not obvious at the opposite of a test based on a continuous distribution that suffers absolutely not of this kind of problems. The majority of softwares that we know at this date take an open bounder interval (this corresponds therefore to the first calculation we made with the p-value of 13.12%.

Finally, to close this subject, the reader can check that he will find the same results whatever he takes for reference cell.

Let us also indicate that the Fisher exact test can obviously be used in Machine Learning to measure the performance of a binary classification!!!!!

5.7.15.6 Cohen's kappa agreement

If our judgements reflect our thinking, they are rarely in agreement with those of others.

This inter-individual variability beneficial to humans, however, is disadvantageous in many scientific disciplines, where it is often necessary to assess and improve the agreement between similar information applied to the same object in the context of a quality control requirement or in sensory analysis.

The nonparametric Cohen's kappa test allows for example to quantify the binary (dichotomous) agreement between two or more researchers or technicians when the judgements are qualitative.

This kappa statistic is frequently used to test "inter-rater reliability". The importance of rater reliability lies in the fact that it represents the extent to which the data collected in the study are correct representations of the variables measured. Measurement of the extent to which data collectors (raters) assign the same score to the same variable is named "interrater reliability". While there have been a variety of methods to measure interrater reliability, traditionally it was measured as percent agreement, calculated as the number of agreement scores divided by the total number of scores. In 11960 (holocene calendar), Jacob Cohen critiqued use of percent agreement due to its inability to account for chance agreement. He introduced the Cohen's kappa, developed to account for the possibility that raters actually guess on at least some variables due to uncertainty. Like most correlation statistics, the kappa can range from -1 to $+1$. While the kappa is one of the most commonly used statistics to test interrater reliability, it has limitations. Judgements about what level of kappa should be acceptable for health research are questioned. Cohen's suggested interpretation may be too lenient for health related studies because it implies that a score as low as 0.41 might be acceptable. Kappa and percent agreement are compared, and levels for both kappa and percent agreement that should be demanded in healthcare studies are suggested.

Many situations in the healthcare industry rely on multiple people to collect research or clinical laboratory data. The question of consistency, or agreement among the individuals collecting data immediately arises due to the variability among human observers. Well-designed research studies must therefore include procedures that measure agreement among the various data collectors. Interrater reliability is a concern to one degree or another in most large studies due to the fact that multiple people collecting data may experience and interpret the phenomena of interest differently.

Remark

There are a number of statistics that have been used to measure interrater and intrarater reliability. A partial list includes percent agreement, Cohen's kappa (for two raters), the Fleiss kappa (adaptation of Cohen's kappa for three or more raters) the contingency coefficient, the Pearson R and the Spearman rho, the intra-class correlation coefficient, the concordance correlation coefficient, and Krippendorff's alpha (useful when there are multiple raters and multiple possible ratings). Use of correlation coefficients such as Pearson's R may be a poor reflection of the amount of agreement between raters resulting in extreme over or underestimates of the true level of rater agreement.

Let us take the case in the medical field where two or more practitioners examining the same patient or even offer different diagnoses or different therapeutic decisions. In the absence of a reference, this proliferation of advices does not bring the expected security of a perfect diagnostic or therapeutic agreement for the physician and the patient. It is therefore important that the agreement in a team or between teams is the best possible guarantee for the quality and continuity of care.

One solution here is to realize a session of "concordance experiment" between physicians to estimate their rate of agreement using the kappa coefficient and study their disagreements to address them.

To illustrate the concepts, let us consider the very important case of two quality managers that analysed 11 pieces to reject or accept them. They get:

		Bob		
		Rejected	**Accepted**	**Total**
Alice	**Rejected**	3	2	5
	Accepted	1	5	6
	Total	4	7	11

Table 5.111: **Dichotomous example of table of contingencies**

The theoretical frequencies being obtained always by a rule of three (same calculation of rule of three that for the chi-square and Fisher test of independence exact seen above):

		Bob		
		Rejected	**Accepted**	**Total**
Alice	**Rejected**	$(4/11)\cdot 5=1.82$	$(7/11)\cdot 5=3.18$	5
	Accepted	$(4/11)\cdot 6=2.18$	$(7/11)\cdot 6=3.82$	6
	Total	4	7	11

Table 5.112: **Theoretical frequencies**

Cohen's kappa is defined by the ratio:

$$\boxed{\kappa_C=\frac{\text{Observed}_{\text{According}}-\text{Expected}_{\text{According}}}{\text{Trials}-\text{Expected}_{\text{According}}}} \tag{5.7.2708}$$

Therefore in our example:

$$\kappa_C=\dfrac{(3+5)-\left(\dfrac{4\cdot 5}{11}+\dfrac{7\cdot 6}{11}\right)}{11-\left(\dfrac{4\cdot 5}{11}+\dfrac{7\cdot 6}{11}\right)}=\dfrac{(3+5)-(1.82+3.82)}{11-(1.82+3.82)}=0.441 \qquad (5.7.2709)$$

This value of 0.441 indicates a moderate agreement between the two individuals (Alice and Bob).

If instead of having the frequencies, we work in percentages (proportions) of the total, the Kappa is then:

$$\kappa_C=\dfrac{\%\text{Observed}_{\text{According}}-\%\text{Expected}_{\text{According}}}{1-\%\text{Expected}_{\text{According}}}=\dfrac{p_{o,a}-p_{e,a}}{1-p_{e,a}} \qquad (5.7.2710)$$

Which will give obviously in our example:

$$\kappa_C=\dfrac{\dfrac{3+5}{11}-\dfrac{1}{11^2}(4\cdot 5+7\cdot 6)}{1-\dfrac{1}{11^2}(4\cdot 5+7\cdot 6)}=0.441 \qquad (5.7.2711)$$

That it is usage to write in the following condensed form:

$$\boxed{\kappa_C=\dfrac{\sum\limits_i p_{ii}-\sum\limits_i p_{i+}p_{i+}}{1-\sum\limits_i p_{i+}p_{i+}}=\dfrac{(p_{00}+p_{11})-(p_{0+}p_{0+}+p_{1+}p_{1+})}{1-(p_{0+}p_{0+}+p_{1+}p_{1+})}} \qquad (5.7.2712)$$

with:

$$-1\leq\kappa_C\leq+1 \qquad (5.7.2713)$$

where $+1$ corresponds to a perfect agreement and -1 to a perfect non-agreement. Obviously to have a perfect agreement, we must have the cells (Rejected, Rejected) and (Accepted, Accepted) that are equal and that the other cells are zero.

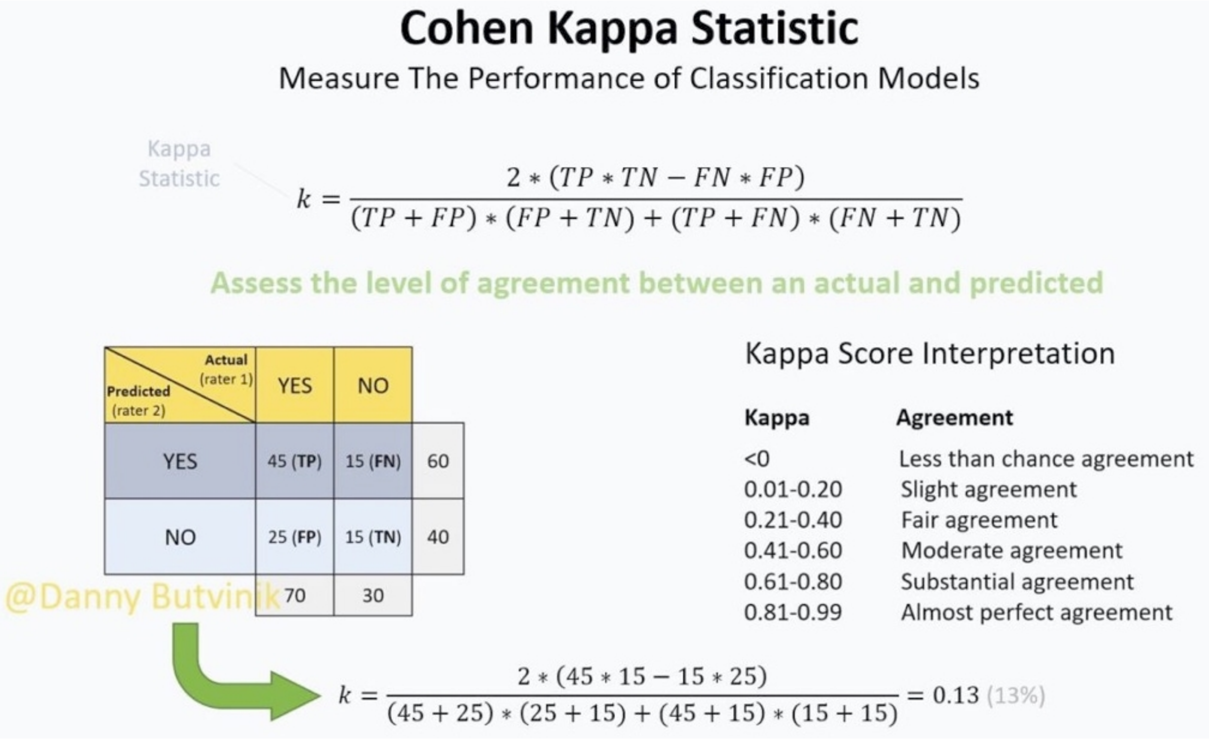
The following table of interpretation of the positive part of the κ_C is of common usage (the negative one having not too much interest...):

Interval	Interpretation
$0.8\leq\kappa\leq 1$	Very good agreement
$0.6\leq\kappa<0.8$	Good agreement
$0.4\leq\kappa<0.6$	Moderated agreement
$0.2\leq\kappa<0.4$	Poor agreement
$0.0\leq\kappa<0.2$	No agreement

Table 5.113: κ_C **usage interpretation table**

However, the practitioner must be very critical (as always!) by using this type of tool. Understanding its construction also helps - also as always - to identify its weaknesses and assumptions that are quite questionable.

Let us finally indicate that the Cohen's Kappa can obviously be used in Machine Learning to measure the performance of a binary classification! A quite well known example in that field is given by the following illustration made by Danny Butvinik:



Cohen Kappa Statistic

Measure The Performance of Classification Models

Kappa Statistic

$$k=\frac{2*(TP*TN-FN*FP)}{(TP+FP)*(FP+TN)+(TP+FN)*(FN+TN)}$$

Assess the level of agreement between an actual and predicted

Predicted (rater 2) \ Actual (rater 1)	YES	NO	
YES	45 (TP)	15 (FN)	60
NO	25 (FP)	15 (TN)	40
	70	30	

@Danny Butvinik

Kappa Score Interpretation

Kappa	Agreement
<0	Less than chance agreement
0.01-0.20	Slight agreement
0.21-0.40	Fair agreement
0.41-0.60	Moderate agreement
0.61-0.80	Substantial agreement
0.81-0.99	Almost perfect agreement

$$k=\frac{2*(45*15-15*25)}{(45+25)*(25+15)+(45+15)*(15+15)}=0.13\ (13\%)$$

Figure 5.247: **Cohen Kappa statistics in binary classification models (author: Danny Butvinik)**

How do we get the relation visible in the figure above?:

$$\kappa=\frac{2(\text{TP}\cdot\text{TN}-\text{FN}\cdot\text{FP})}{(\text{TP}+\text{FP})(\text{FP}+\text{TN})+(\text{TP}+\text{FN})(\text{FN}+\text{TN})} \tag{5.7.2714}$$

where TP are the true positives, FP are the false positives, TN are the true negatives, and FN are the false negatives[89]. It's quite simple (but boring)!

So based on the above table we see that:

$$p_{o,a}=\frac{\text{TP}+\text{TN}}{\text{TP}+\text{TN}+\text{FP}+\text{FN}} \tag{5.7.2715}$$

and:

$$p_{e,a}=\frac{(\text{TP}+\text{FN})(\text{TP}+\text{FP})+(\text{FP}+\text{TN})(\text{FN}+\text{TN})}{(\text{TP}+\text{TN}+\text{FP}+\text{FN})^2} \tag{5.7.2716}$$

Injecting that into:

$$\kappa_C=\frac{p_{o,a}-p_{e,a}}{1-p_{e,a}} \tag{5.7.2717}$$

---

[89] In this case, Cohen's Kappa is equivalent to the Heidke skill score known in Meteorology. The measure was first introduced by Myrick Haskell Doolittle in 11888 (holocene calendar).

we get the expected result visible in the figure above! Indeed, let us put TP$=a$, TN$=b$, FP$=c$, FN$=d$. Then (on request of reader...):

$$\begin{aligned}
\kappa_C=\frac{p_{o,a}-p_{e,a}}{1-p_{e,a}}&=\frac{\dfrac{a+b}{a+b+c+d}-\dfrac{(a+d)(a+c)+(c+b)(d+b)}{(a+b+c+d)^2}}{1-\dfrac{(a+d)(a+c)+(c+b)(d+b)}{(a+b+c+d)^2}}\\
&=\frac{\dfrac{a+b}{a+b+c+d}-\dfrac{(a^2+ac+ad+cd)+(b^2+bc+bd+cd)}{(a+b+c+d)^2}}{1-\dfrac{(a^2+ac+ad+cd)+(b^2+bc+bd+cd)}{(a+b+c+d)^2}}\\
&=\frac{\dfrac{a+b}{a+b+c+d}-\dfrac{a^2+ac+ad+b^2+bc+bd+2cd}{(a+b+c+d)^2}}{1-\dfrac{a^2+ac+ad+b^2+bc+bd+2cd}{(a+b+c+d)^2}}\\
&=\frac{\dfrac{a+b}{a+b+c+d}-\dfrac{a^2+ac+ad+b^2+bc+bd+2cd}{a^2+2ab+2ac+2ad+b^2+2bc+2bd+c^2+2cd+d^2}}{1-\dfrac{a^2+ac+ad+b^2+bc+bd+2cd}{a^2+2ab+2ac+2ad+b^2+2bc+2bd+c^2+2cd+d^2}}\\
&=\frac{\dfrac{((a+b)\cdot(a+b+c+d))-(a^2+ac+ad+b^2+bc+bd+2cd)}{(a+b+c+d)\cdot(a+b+c+d)}}{\dfrac{(a^2+2ab+2ac+2ad+b^2+2bc+2bd+c^2+2cd+d^2)-(a^2+ac+ad+b^2+bc+bd+2cd)}{a^2+2ab+2ac+2ad+b^2+2bc+2bd+c^2+2cd+d^2}}\\
&=\frac{\dfrac{2ab-2cd}{a^2+2ab+2ac+2ad+b^2+2bc+2bd+c^2+2cd+d^2}}{\dfrac{2ab+ac+ad+bc+bd+c^2+d^2}{a^2+2ab+2ac+2ad+b^2+2bc+2bd+c^2+2cd+d^2}}\\
&=\frac{2ab-2cd}{2ab+ac+ad+bc+bd+c^2+d^2}=\frac{2(ab-cd)}{(a+c)(c+b)+(a+d)(d+b)}
\end{aligned}\tag{5.7.2718}$$

That's it!

5.7.15.7 McNemar's test

McNemar's test may well be calculated along the Cohen's Kappa (the first being a statistical hypothesis test and the second one only an empirical point estimator of concordance). The idea is that under the null hypothesis H_0 (in this case named "symmetry hypothesis"), one of the diagonals of the table should have equal values. In other words in the form of proportions and only by focusing on one of the two diagonals:

$$H_0: p_{11}=p_{22}\tag{5.7.2719}$$

or of frequencies:

$$H_0: n_{11}=n_{22}\tag{5.7.2720}$$

Knowing that:

$$n_{11}+n_{22}=n\tag{5.7.2721}$$

and under the condition that n is large enough, we can write based on a binomial law whose behaviour is asymptotically Normal:

$$Z=\frac{\dfrac{n_{11}}{n}-0.5}{\sqrt{\dfrac{0.5(1-0.5)}{n}}} \tag{5.7.2722}$$

We can realize that this is equivalent to write:

$$Z=\frac{\dfrac{n_{11}}{n}-\dfrac{1}{2}\dfrac{n_{11}+n_{22}}{n}}{\sqrt{\dfrac{\left(\dfrac{n_{11}+n_{22}}{4n}\right)}{n}}}=\frac{n_{11}-\left(\dfrac{n_{11}+n_{22}}{2}\right)}{\dfrac{\sqrt{n_{11}+n_{22}}}{2}} \tag{5.7.2723}$$

In the literature, we often find this last relation in the form:

$$Z=\frac{b-\left(\dfrac{b+c}{2}\right)}{\dfrac{\sqrt{b+c}}{2}}=\frac{b-c}{\sqrt{b+c}} \tag{5.7.2724}$$

To return to our original relation, some take the square and then approximate the square of Z as a chi-square law (... !) with one degree of freedom (but good in reality approximate a Normal centered reduced distribution by the chi-square law with one degree of freedom is bulls... in our point of view...):

$$\boxed{Z^2=\frac{\left(\dfrac{n_{11}}{n}-0.5\right)^2}{\dfrac{0.5(1-0.5)}{n}}=\frac{(b-c)^2}{b+c}\cong\chi_1^2} \tag{5.7.2725}$$

which is often the relation defined in the books (without proof...) as the "McNemar test".

The test is normally conducted bilaterally. The advantage of the McNemar test is the ease with which we can build a confidence interval of the difference in the diagonal. Indeed, starting from the estimator of the difference:

$$\hat{d}=p_{11}-p_{22}=\frac{n_{11}}{n}-\frac{n_{22}}{n} \tag{5.7.2726}$$

Therefore using the variance (and covariance) proved at page 667, we get:

$$\begin{aligned}\text{V}(\hat{d})&=\text{V}\left(\frac{n_{11}}{n}-\frac{n_{22}}{n}\right)=\frac{1}{n^2}\text{V}(n_{11}-n_{22})=\frac{1}{n^2}\left[\text{V}(n_{11})+\text{V}(n_{22})-2\text{cov}(n_{11},n_{22})\right]\\&=\frac{1}{n^2}\left[np_{11}(1-p_{11})+np_{22}(1-p_{22})-2(-np_{11}p_{22})\right]\\&=\frac{1}{n}\left[p_{11}(1-p_{11})+p_{22}(1-p_{22})+2p_{11}p_{22}\right]\\&=\frac{1}{n}\left[\frac{n_{11}}{n}\left(1-\frac{n_{11}}{n}\right)+\frac{n_{22}}{n}\left(1-\frac{n_{22}}{n}\right)+\frac{n_{11}}{n}\frac{n_{22}}{n}\right]\end{aligned} \tag{5.7.2727}$$

and therefore we can do an approximate confidence intervals of the following if the usual conditions are met:

$$\hat{d}-Z_{\alpha/2}\sqrt{\text{V}(\hat{d})}\leq d\leq\hat{d}+Z_{\alpha/2}\sqrt{\text{V}(\hat{d})} \tag{5.7.2728}$$

That is to say a little bit more explicitly:

$$\boxed{\left(\frac{\hat{n}_{11}}{n}-\frac{\hat{n}_{22}}{n}\right)-Z_{\alpha/2}\sqrt{\text{V}(\hat{d})}\leq\frac{n_{11}}{n}-\frac{n_{22}}{n}\leq\left(\frac{\hat{n}_{11}}{n}-\frac{\hat{n}_{22}}{n}\right)+Z_{\alpha/2}\sqrt{\text{V}(\hat{d})}} \tag{5.7.2729}$$

with as we just proved it:

$$\text{V}(\hat{d})=\frac{1}{n}\left[\frac{n_{11}}{n}\left(1-\frac{n_{11}}{n}\right)+\frac{n_{22}}{n}\left(1-\frac{n_{22}}{n}\right)+\frac{n_{11}}{n}\frac{n_{22}}{n}\right] \tag{5.7.2730}$$

✍**Example:**

During a social audit, a survey is conducted on 200 employees about the work organization. After reorganization, the same question is asked. Can we consider that there has been real changes?

	Yes (before)	**No (before)**
Yes (after)	55	38
No (after)	38	82

Table 5.114: **Paired before/after simple survey**

We then have taking arbitrarily the diagonal $(25,38)$ the for analysis:

$$Z^2=\frac{\left(\dfrac{n_{11}}{n}-0.5\right)^2}{\dfrac{0.5(1-0.5)}{n}}=\frac{(b-c)^2}{b+c}=2.684$$

The majority of statistical software will not give you 2.683 as they apply an empirical correction due to the rough approximation of that is the chi-square law. You will then have on the softwares display the value of 2.285 for Z^2.

The p-value it is given (without correction) with a spreadsheet software like the Microsoft® Excel® 14.0.6123:

`= 1-CHISQ.DIST(2.683, 1, 1)` $=10.14\%$

and with the correction use by statistical software we would get about 13%. So in both cases the p-value is greater than the traditional 5% threshold, we therefore can not reject the null hypothesis H_0 as the difference is large.

We will not calculate in this example the confidence interval of the difference because almost all statistical softwares have different methods for calculating this value.

Finally, to close the subject on the McNemar test, let us indicate an empirical indicator often used that is named the "Yule coefficient" or "Yule's Q" and defined by:

$$Q=\frac{P\,(X \text{ and } Y \text{ are concordant})-P\,(X \text{ and } Y \text{ are discordant})}{P\,(X \text{ and } Y \text{ are concordant})+P\,(X \text{ and } Y \text{ are discordant})}=\frac{ad-bc}{ad+bc}$$

Where a,b,c,d must be positive non null integers corresponding to position values of contingency tables similar to:

	Yes	**No**
Positive	a	b
Negative	c	d

Remark

Yule's Q is just the a 2×2 version of the Goodman and Kruskal's gamma coefficient. We can also obviously calculate an odds ratio using $(a\cdot d)/(b\cdot c)$ (and then calculate its confidence interval according to the derivation at page 6496). We can convert also this odds ratio to a -1 to $+1$ scale using $(\text{OR}-1)/(\text{OR}+1)$.

Yule's Q is always a number between -1 and $+1$. Here is a table with possible interpretation of the values of Yule's Q:

Interval	Interpretation
$Q=0$	No association between the variables
$0\leq \lvert Q\rvert \leq 0.29$	A negligible or very small association
$0.30\leq \lvert Q\rvert \leq 0.49$	A moderate association between the variables
$0.50\leq \lvert Q\rvert \leq 0.69$	A substantial association between the variables
$0.70\leq \lvert Q\rvert < 1$	A very strong association
$\lvert Q\rvert = 1$	A perfect association between the events

Table 5.115: **Yule's Q usage interpretation table**

The "Cochran-Armitage test for trend" (see just below), also named "Chi-square test for trend" in many statistical softwares, is used in categorical data analysis when the aim is to assess for the presence of an association between a variable with 2 categories and a variable with k categories. It modifies the Pearson chi-squared test to incorporate a suspected ordering in the effects of the k categories of the second variable. For example, doses of a treatment can be ordered as 'low', 'medium', and 'high', and we may suspect that the treatment benefit cannot become smaller as the dose increases. The trend test is often used as a genotype-based test for case-control genetic association studies.

5.7.15.7.1 Derivation for Cochran-Armitage's trend test for the 2×3 genotype table

We will derive here a special case as the general one is out of the scope of this textbook. Consider for this that we have sampled R cases and S controls:

	Number of disease alleles			
	0	1	2	**Totals**
Cases	r_0	r_1	r_2	R
Controls	s_0	s_1	s_2	S
Totals	n_0	n_1	n_2	N

We want to test H_0 against H_1. The idea is:

- H_0: All entries in the table are proportional, vs.
- H_1: Within a column, the absolute value of the difference between the probability of an observation being classified as "Case" or "Control" increases monotonically across the table.

We'll work with the difference between the values in the column so we first standardize the rows to have the same sums:

	Number of disease alleles			
	0	1	2	**Totals**
Cases	$S\cdot r_0$	$S\cdot r_1$	$S\cdot r_2$	$R\cdot S$
Controls	$R\cdot s_0$	$R\cdot s_1$	$R\cdot s_2$	$R\cdot S$

We choose a set of scores x_1, x_2, and x_3 and form the test statistics:

$$U=\sum_{i=0}^{2}x_i(Sr_i-Rs_i) \tag{5.7.2731}$$

Under H_0:

$$P(\text{Case}|\text{Count}=i)=P(\text{Control}|\text{Count}=i)=\frac{n_i}{N}\qquad\text{and}\qquad \text{E}(U)=0 \tag{5.7.2732}$$

Letting $S=N-R$, $s_i=n_i-r_i$, and choosing scores $x_0=0$, $x_1=1$, and $x_2=2$, the test statistic becomes:

$$U=N(r_1+2r_2)-R(n_1+2n_2) \tag{5.7.2733}$$

Returning to generic scores x_i, we calculate the variance of U as:

$$\begin{aligned}\text{V}(U)=\text{V}\left(\sum_{i=0}^{2}x_i(Sr_i-Rs_i)\right)&=\text{V}\left(S\sum_{i=0}^{2}x_ir_i-R\sum_{i=0}^{2}x_is_i\right)\\ =&S^2\text{V}\left(S\sum_{i=0}^{2}x_ir_i\right)+R^2\text{V}\left(\sum_{i=0}^{2}x_is_i\right)\\ =&S^2\left[\sum_{i=0}^{2}x_i^2\text{V}(r_i)+2\sum_{i=0}^{1}\sum_{j=i+1}^{2}x_ix_j\text{cov}(r_i,r_j)\right]+R^2\left[\sum_{i=0}^{2}x_i^2\text{V}(s_i)+2\sum_{i=0}^{1}\sum_{j=i+1}^{2}x_ix_j\text{cov}(s_i,s_j)\right]\end{aligned} \tag{5.7.2734}$$

Under H_0 (we use the variance and covariance[90] of the Hypergeometric distribution ignoring the finite population correction factor):

$$\begin{aligned}\text{V}(U)\cong S^2&\left[\sum_{i=0}^{2}x_i^2R\left(\frac{n_i}{N}\right)\left(\frac{N-n_i}{N}\right)-2\sum_{i=0}^{1}\sum_{j=i+1}^{2}x_ix_jR\left(\frac{n_i}{N}\right)\left(\frac{n_j}{N}\right)\right]\\ &+R^2\left[\sum_{i=0}^{2}x_i^2S\left(\frac{n_i}{N}\right)\left(\frac{N-n_i}{N}\right)-2\sum_{i=0}^{1}\sum_{j=i+1}^{2}x_ix_jS\left(\frac{n_i}{N}\right)\left(\frac{n_j}{N}\right)\right]\\ &=\frac{S}{N^2}\left[\sum_{i=0}^{2}x_i^2SRn_i(N-n_i)-2\sum_{i=0}^{1}\sum_{j=i+1}^{2}x_ix_jSRn_in_j\right]\\ &+\frac{R}{N^2}\left[\sum_{i=0}^{2}x_i^2SRn_i(N-n_i)-2\sum_{i=0}^{1}\sum_{j=i+1}^{2}x_ix_jSRn_in_j\right]\\ &=\frac{SR}{N}\left[\sum_{i=0}^{2}x_i^2n_i(N-n_i)-2\sum_{i=0}^{1}\sum_{j=i+1}^{2}x_ix_jn_in_j\right]\end{aligned} \tag{5.7.2735}$$

---

[90] If the reader is not able to find where was our proof of that covariance, you can find it here at page 667

Let $S=N-R$. Choose scores $x_0=0$, $x_1=1$, and $x_2=2$ and the latter relation reduces to:

$$\text{V}(U)\cong\frac{(N-R)R}{N}\left[N(n_1+4n_2)-(n_1+2n_2)^2\right] \tag{5.7.2736}$$

For N large (this justifies the fact that we ignored the finite population correction factor earlier), we then have:

$$\frac{U}{\sigma_U}\cong\frac{N(r_1+2r_2)-R(n_1+2n_2)}{\sqrt{\dfrac{(N-R)R}{N}\left[N(n_1+4n_2)-(n_1+2n_2)^2\right]}}\sim\mathcal{N}(0,1) \tag{5.7.2737}$$

So, using Sasieni's (11997 according to holocene calendar) notation:

$$\boxed{\chi_G^2=\frac{N\left[N(r_1+2r_2)-R(n_1+2n_2)\right]^2}{(N-R)R\left[N(n_1+4n_2)-(n_1+2n_2)^2\right]}\sim\chi_1^2} \tag{5.7.2738}$$

Again we notice that the Cochran-Armitage test for trend use a Wald statistics and therefore belongs to the family of Wald tests.

Remark

For a practical example and implementation of that test our reader can refer to the `R` companion book.

5.7.16 Survival Statistics

Survival analysis is a branch of statistics for analysing the expected duration of time until one or more events happen, such as death in biological organisms, failure in mechanical systems, time to product reorder of customers, etc.

This topic is named "reliability theory" or "reliability analysis" in engineering (see section Industrial Engineering page 8716), "duration analysis" or "duration modelling" in economics, and "event history analysis" in sociology. Survival analysis attempts to answer questions such as: what is the proportion of a population which will survive past a certain time? Of those that survive, at what rate will they die or fail? Can multiple causes of death or failure be taken into account? How do particular circumstances or characteristics increase or decrease the probability of survival?

To answer such questions, it is necessary to define "lifetime". In the case of biological survival, death is unambiguous, but for mechanical reliability, failure may not be well-defined, for there may well be mechanical systems in which failure is partial, a matter of degree, or not otherwise localized in time. Even in biological problems, some events (for example, heart attack or other organ failure) may have the same ambiguity. The theory outlined below assumes well-defined events at specific times; other cases may be better treated by models which explicitly account for ambiguous events.

More generally, survival analysis involves the modelling of time to event data; in this context, death or failure is considered an "event" in the survival analysis literature – traditionally only a single event occurs for each subject, after which the organism or mechanism is dead or broken.

In practice we consider:

- The life tables (see section of Population Dynamics page 7299) to describe the survival times of members of a group.
- The Kaplan-Meier method to also describe the survival times of members of a group (see just below).
- The Cochran-Mantel-Haenzel test (Log-Rank test) to compare the survival times of two or more groups (see just below).
- The Cox's proportional[91] hazard model (Cox regression) to describe the effect of categorical or quantitative variables on survival (see just below).
- The Threshold Regression Models in that also describe the effect of categorical or quantitative variables on survival however without the proportional hazard assumption of the Cox model!

Here is a more exhaustive (i.e. however still incomplete) taxonomy of survivals analysis methods:

---

[91] The Cox proportional regression assumes hazards are proportional (PH), which means that the relative hazard remains constant!

5.7.16.1 Kaplan-Meier Survival Rate

OK... we don't like to do this in this textbook!!! But for the comfort of our readers and because of some readers feedback let us copy/paste here the theory about the Kaplan-Meier Survival Rate as introduced initially in the section of Industrial Engineering at page 8763.

In areas such as high-level industry, high-level medicine or high-level biology, we are often interested in the:

1. Survival duration after a serious event
2. Duration of remission after treatment or surgery
3. Duration of symptoms after an abnormality
4. Duration of a symptom-less infection

We seek very often to distinguish at least "the event of interest":

1. System shutdown after serious event
2. End of remission
3. End of a symptom after anomaly
4. Beginning of a symptom during an infection

of the variable to explain "duration before the event of interest":

1. Elapsed duration before shutdown
2. Elapsed duration before the end of remission
3. Elapsed duration before the end of the symptom
4. Elapsed duration without symptoms

Definitions (#5.7.159):

D1. We name "remission", the reduction of a disease or a temporarily malfunction.

D2. The "survival time" or "lifetime" T means the time which elapses from an initial time (start of treatment, diagnosis or failure, etc.) until the occurrence of a final event of interest (patient death, relapse, remission, cure, repair, etc.). We say that the object of the study "survives at time t" if at this moment the final interest event has not yet occurred.

Remark

Although this type of study can be associated with preventive maintenance (see section Industrial Engineering page 8716), statisticians associate this type of study rather to the domain of "survival analysis".

We will focus in this textbook on a particular context but that can be easily generalized:

- Cohort/Clinical trial where we study the survival time of each patient (machine).
- All patients (machines) do not have the same observation time (different instants of entry into the study).
- We have information on the survival time of each patient (machine) but we do not know exactly when it happens.

From the last two points, we conclude that the survival time can be censored. So the usual statistical techniques does not apply directly as censored data require special treatment (of course, if we remove the censored data we lose information). It goes without saying that this situation is extremely common and therefore the study of the Kaplan-Meier estimator is very important.

Definition (#5.7.160): The duration T is said to be censored if the duration is not observed completely. The different types of censoring are:

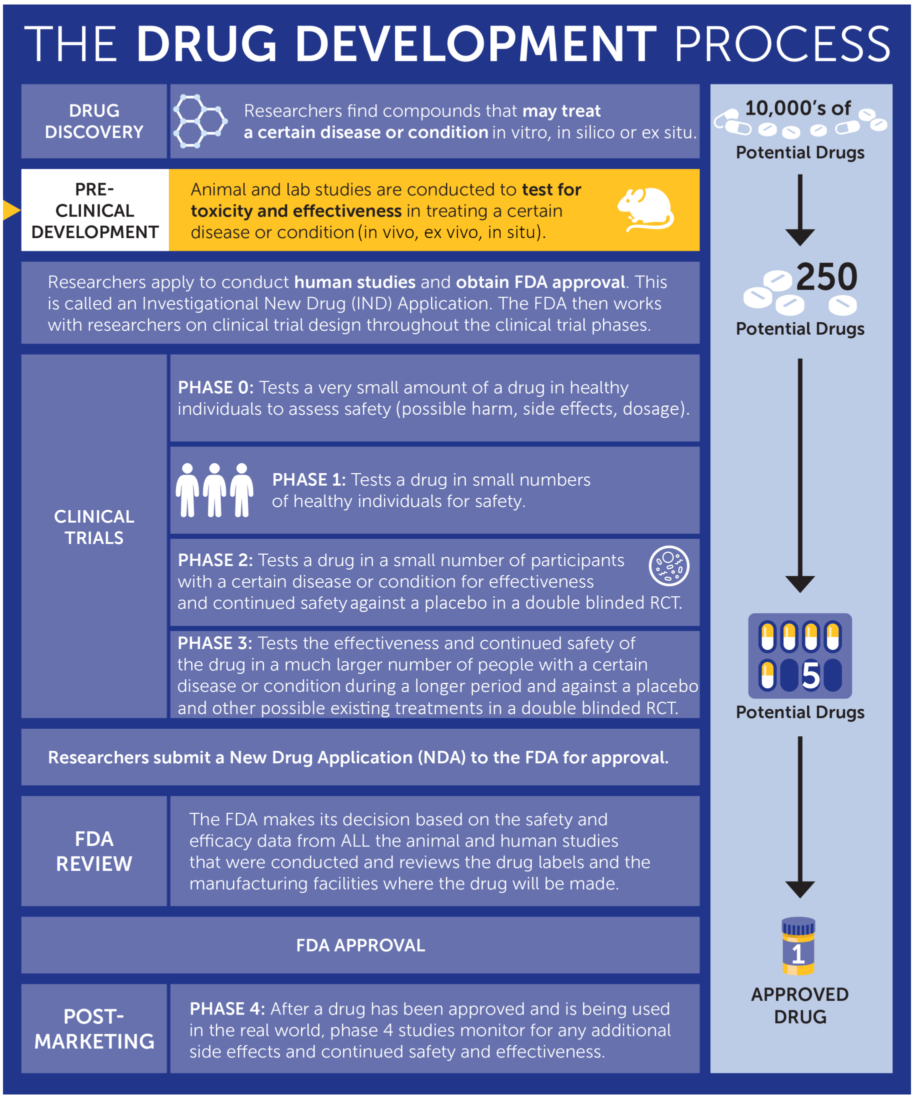
- Type I censoring: fixed right (right censored). In this situation, the time is not observable beyond a maximum, fixed, named "fixed-censoring" and imposed. So either we have the opportunity to observe the real duration of the event of interest for the item if it occurs before the fixed-censoring, or we limit ourselves to the fixed-censoring time if the vent of interest has not occurred before.
- Type I censorship: fixed left (left censored). In this situation, the study duration is not observable before a known date named "waiting censorship" and imposed. So either the event of interest takes place at the time of the wait censorship or after. If applicable later, we will consider the length of time between the date of censorship and the date of the event of interest.
- Type II censoring: wait. In this situation, we observe the lives of n individuals until $m \leq n$ individuals have seen the event to occur (deceased). The duration considered is therefore that of the beginning of the experiment until the event of interest for the m-th.
- Type III censoring: random left. In this situation, we do not know when the event of interest has occurred (because we started to observe the subject of study too late). We can not then deal with "durations" in the measurable sense and we have to limit ourselves to a simple count.
- Type III censoring: random right. In this situation, we do not know when the event will take place (because we stopped to observe the subject before it occurs for any reason). We can not then deal with "durations" in the measurable in the measurable sense and we must limit ourselves to a simple count.

- Type IV censoring: random intervals. In this situation, we have a mixture of random left and right censoring. That is to say that for some study subjects, we do not know when the event of interest has begun, and for others we do not know when it will occur (if any...).

In the machinery industry, we often deal with the type I censoring: fixed right. In the medical field, in clinical trials, we often deal with a type III censoring: random right. In the case of pandemics, we are dealing with type III censoring: random left.

To introduce this subject, rather than doing obscure theory, as always in this textbook we prefer at pragmatic approach. Suppose that the study is a clinical trial involving two groups of patients receiving two types of treatments. Two important questions raised to the physicians in a Phase II clinical trial (phase I is for non-toxicity approval to human and phase 0 for animals):

1. Is one of the two treatments more effective than the other in terms of improving patient survival?
2. Can we highlight prognostic factors, that is to say that improve / deteriorate survival?



THE **DRUG DEVELOPMENT** PROCESS

DRUG DISCOVERY — Researchers find compounds that **may treat a certain disease or condition** in vitro, in silico or ex situ.

PRE-CLINICAL DEVELOPMENT — Animal and lab studies are conducted to **test for toxicity and effectiveness** in treating a certain disease or condition (in vivo, ex vivo, in situ).

Researchers apply to conduct **human studies** and **obtain FDA approval**. This is called an Investigational New Drug (IND) Application. The FDA then works with researchers on clinical trial design throughout the clinical trial phases.

CLINICAL TRIALS

PHASE 0: Tests a very small amount of a drug in healthy individuals to assess safety (possible harm, side effects, dosage).

PHASE 1: Tests a drug in small numbers of healthy individuals for safety.

PHASE 2: Tests a drug in a small number of participants with a certain disease or condition for effectiveness and continued safety against a placebo in a double blinded RCT.

PHASE 3: Tests the effectiveness and continued safety of the drug in a much larger number of people with a certain disease or condition during a longer period and against a placebo and other possible existing treatments in a double blinded RCT.

Researchers submit a New Drug Application (NDA) to the FDA for approval.

FDA REVIEW — The FDA makes its decision based on the safety and efficacy data from ALL the animal and human studies that were conducted and reviews the drug labels and the manufacturing facilities where the drug will be made.

FDA APPROVAL

POST-MARKETING — **PHASE 4:** After a drug has been approved and is being used in the real world, phase 4 studies monitor for any additional side effects and continued safety and effectiveness.

Figure 5.249: **Drug development and clinical trials**

To answer the first question we can develop statistical methods that will allow us to compare the two groups of patients who receive both types of treatment.

To answer the second question we propose a model that links patient survival time for explanatory variables and highlight the prognostic factors.

Let us as always assist the theory with an example. For this consider the following table where two cohorts of patients (we move from mechanical engineering to human engineering...) of same initial size with acute leukemia drug test (6-MP) against a placebo[92] (of course blindly).

We have the following remission times for 21 patients (the table of 21 lines therefore indicates the number of weeks for where patient is considered cured after treatment before falling again ill):

6-mercaptopurine (6-MP) Group	**Placebo Group**
6	1
6	1
6	2
6+	2
7	3
9+	4
10	4
10+	5
11+	5
13	8
16	8
17+	8
19+	8
20+	11
22	11
23	12
25	12
32+	15
32+	17
34+	22
35+	23

Table 5.116: **Two cohort survival analysis with right censoring**

The "+" sign corresponds to patients who left the study for that week. They are therefore censored! For example, the fourth patient was lost of view for any reason after 6 weeks of treatment with 6-MP: it has therefore a duration of remission greater than 6 weeks! So in the study 6-MP, there are 21 patients and 11 of them are censored data.

---

[92] Let us recall that in the science of drugs, a "pure placebo" is a treatment without any active substance; an "impure placebo" is a pharmacologically active product but has no effect on the pathology treated, or whose efficacy has not been sufficiently demonstrated.

Remark

The theoretical model assumes that censoring is independent of the survival time (not informative censoring). But if censoring is due to the discontinuation of treatment, the independence assumption is not valid anymore!

For the placebo group it is simple to make a survival curve. It is sufficient to produce the following table (for the omitted weeks, obviously we impose the number of remission as constants):

Week i	**Total # remission at week i**	**Proportion (probability) of remission at week i**
0	21	100%
1	19	$19/21=90\%$
2	17	$17/21=81\%$
3	16	$16/21=76\%$
4	14	$14/21=67\%$
5	12	$12/21=57\%$
8	8	$8/21=38\%$
11	6	$6/21=29\%$
12	4	$4/21=19\%$
15	3	$3/21=14\%$
17	2	$2/21=10\%$
22	1	$1/20=0.05\%$
23	0	0%

Table 5.117: **Two cohort survival analysis with right censoring**

So if the data are not censored, the survival $S(t)$ can be estimated by the proportion of individuals surviving at time t, that is customary to write under the following mathematical form:

$$\hat{S}_k(t)=P_k(T_k>t)=\frac{1}{n}\sum_{i=1}^{k}1_{T_i>t} \tag{5.7.2739}$$

The idea is therefore to estimate:

$$P(T>t)=P(\text{probability to survive until time } t) \tag{5.7.2740}$$

by the proportion of patients who survived until time t.

If the data are censored, the estimated survival function requires specific tools. Kaplan and Meier have proposed in this particular case the following calculation:

$$\begin{aligned}&P(\text{be in remission a the } i\text{-th week})\\&=P(\text{to not relapse at the } i\text{-th week})\cdot P(\text{be in remission a the } i-1\text{-th week})\end{aligned} \tag{5.7.2741}$$

Let's see it in a slightly more mathematical form. If we denote by $X(1)\leq X(2)\leq\ldots\leq X(n)$ the moments (sorted) where an event occurred (death or censored), then we have:

$$P(T>X(k))=P(T>X(k)|T>X(k-1))P(T>X(k-1)) \tag{5.7.2742}$$

With of course:

$$P(T>0)=1 \tag{5.7.2743}$$

We estimate:

$$\hat{P}_k = \left(1 - \frac{d_k}{R_k}\right) \qquad (5.7.2744)$$

where d_k is the number of deaths (failures) observed in the time corresponding to the event $X(k)$ and R_k is the number of individuals at risk (at risk of death/failure) just before $X(k)$.

We define the "Kaplan-Meier estimator" for any $X(0) \leq t < X(k)$ by:

$$\boxed{\hat{S}_{\text{KM}}(t) = \prod_{k=1}^{n} \hat{P}_k = \prod_{k=1}^{n} \left(1 - \frac{d_k}{R_k}\right) = \prod_{k=1}^{n} \left(1 - \hat{\lambda}_k\right)} \qquad (5.7.2745)$$

where $\hat{\lambda}_k$ is the discrete hazard (i.e. conditional probability of death).

Remark

There is a much simpler estimator named "Nelson-Aalen estimator" and simply defined as:

$$\hat{S}_{\text{NA}} = \sum_{k=1}^{n} \frac{1}{R_k} \qquad (5.7.2746)$$

That latter estimator is just a sum over the observed survival times.

Therefore we get doing now for 6-MP group (not the placebo group!!!!!) the following:

Remission duration (uncensored) observed	**Items in remission at the beginning of k**	**Probability of not relapse at k knowing that we are at at $k-1$ ($\hat{P}_k$)**	**Survival probability of Kaplan-Meier**
0	21	$21/21 = 100\%$	100%
6	21	$18/21 = 1 - 3/21 = 85.7\%$	$100\% \cdot 85.7\% = 85.7\%$
7	17	$16/17 = 1 - 1/17 = 94.1\%$	$85.7\% \cdot 94.1\% = 80.7\%$
10	15	$14/15 = 1 - 1/15 = 93.3\%$	$80.7\% \cdot 93.3\% = 75.3\%$
13	12	$11/12 = 1 - 1/12 = 91.7\%$	$75.3\% \cdot 91.7\% = 69\%$
16	11	$10/11 = 1 - 1/11 = 90.9\%$	$69\% \cdot 90.9\% = 62.7\%$
22	7	$6/7 = 1 - 1/7 = 85.7\%$	$62.7\% \cdot 85.7\% = 53.8\%$
23	6	$5/6 = 1 - 1/6 = 83.3\%$	$53.8\% \cdot 83.3\% = 44.8\%$

Table 5.118: **6-MP survival analysis**

With the corresponding survival curves (including the confidence interval):

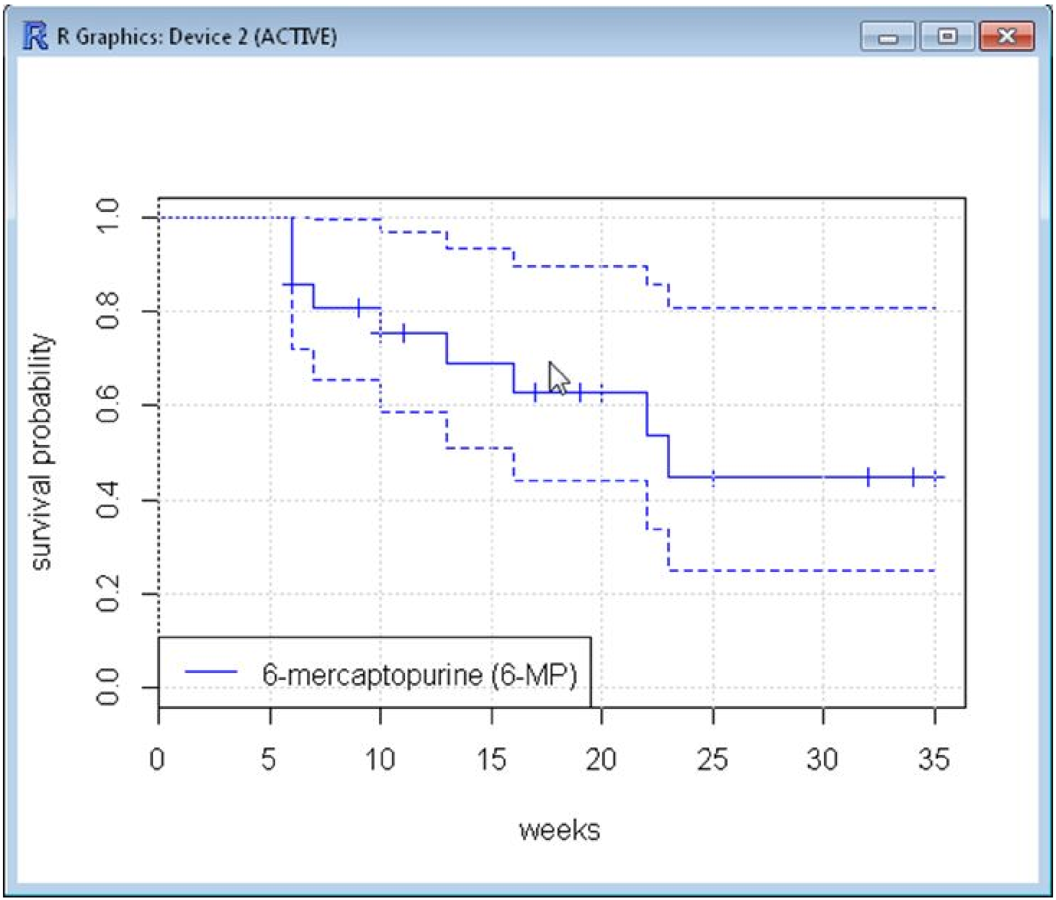


Figure 5.250: Kaplan-Meier Typical survival curves in R software

We thus find the same values as those given for example by Minitab Statistical Software 15.1.1 and R (see the companion books on Minitab or R for the details).

If we assume that the $\hat{\lambda}_k$'s are just binomial proportions given the R_k's we have the following normalized variance and mean of binomial random variable (see page 663):

$$\mathrm{E}(\hat{\lambda}_k) = \hat{\lambda}_k \qquad \mathrm{V}(\hat{\lambda}_k) = \frac{\hat{\lambda}_k(1-\hat{\lambda}_k)}{R_k} \tag{5.7.2747}$$

Remark

Sadly it is a tradition in survival analysis to denote the normalized variance of $\hat{\lambda}_k$ by $\mathrm{V}(\hat{\lambda}_k)$ instead of $\mathrm{V}(\hat{\lambda}_k/r_k)$...

And we will assume also that the $\hat{\lambda}_k$'s are asymptotically independent (...).

Since $\hat{S}_{\text{KM}}(t)$ is a function of the $\hat{\lambda}_k$'s, we can estimate its variance using the univariate Delta method (see section Numerical Methods page 6504) that has for important result for recall that:

$$g(X_n) \underset{n\to+\infty}{\cong} \mathcal{N}\left(0, g'(\mu)^2\sigma^2\right) \tag{5.7.2748}$$

with:

$$\mathrm{V}(g(X_n)) \cong g'(\mu)^2\sigma^2 \tag{5.7.2749}$$

Therefore instead of dealing with $\hat{S}_{\text{KM}}(t)$ directly, we will look at its natural logarithm:

$$\ln(\hat{S}_{\text{KM}}(t))=\sum_{k=1}^{n}\ln(1-\hat{\lambda}_k) \tag{5.7.2750}$$

Thus, by the approximate independence of the $\hat{\lambda}_k$'s and keeping in mind that we just choose $g()$ as the natural logarithm and using the univariate delta method:

$$\begin{aligned}\hat{\text{V}}\left[\ln(\hat{S}_{\text{KM}}(t))\right]&\cong\sum_{k=1}^{n}\hat{\text{V}}\left[\ln(1-\hat{\lambda}_k)\right]\underset{\text{delta method}}{\cong}\sum_{k=1}^{n}\left(\frac{1}{1-\hat{\lambda}_k}\right)^2\hat{\text{V}}(\hat{\lambda}_k)\\&=\sum_{k=1}^{n}\left(\frac{1}{1-\hat{\lambda}_k}\right)^2\frac{\hat{\lambda}_k(1-\hat{\lambda}_k)}{R_k}=\sum_{k=1}^{n}\frac{\hat{\lambda}_k}{(1-\hat{\lambda}_k)R_k}=\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}\end{aligned} \tag{5.7.2751}$$

And applying on it the univariate delta method:

$$\text{V}(g(X_n))\cong g'(\mu)^2\sigma^2=g'(\mu)^2\text{V}(X_n)\Rightarrow\text{V}\left(\ln(\hat{S}_{\text{KM}}(t)\right)\cong\frac{1}{\hat{S}^2_{\text{KM}}(t)}\hat{\text{V}}\left(\hat{S}_{\text{KM}}(t)\right) \tag{5.7.2752}$$

then rearranging and injecting the previous result we get:

$$\hat{\text{V}}\left(\hat{S}_{\text{KM}}(t)\right)\cong\hat{S}^2_{\text{KM}}(t)\text{V}\left(\ln(\hat{S}_{\text{KM}}(t)\right)=\hat{S}^2_{\text{KM}}(t)\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k} \tag{5.7.2753}$$

The following approximation:

$$\boxed{\hat{\text{V}}\left(\hat{S}_{\text{KM}}(t)\right)\cong\hat{S}^2_{\text{KM}}(t)\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}} \tag{5.7.2754}$$

is named the "Greenwood's relation". If we take the square root then the result is associated to the standard error (because of the division by R_k):

$$\text{SE}\left(\hat{S}_{\text{KM}}(t)\right)\cong\hat{S}_{\text{KM}}(t)\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}=\hat{S}_{\text{KM}}(t)\frac{\sqrt{\sum_{k=1}^{n}\dfrac{d_k}{(R_k-d_k)}}}{\sqrt{R_k}}=\hat{S}_{\text{KM}}(t)\frac{\sigma_{\hat{S}_{\text{KM}}(t)}}{\sqrt{R_k}} \tag{5.7.2755}$$

In order to construct an error bar for $\hat{S}_{\text{KM}}(t)$ we need to make some sort of distributional assumption. The simplest is to assume that $\hat{S}_{\text{KM}}(t)$ is normally distributed such that we can write:

$$\hat{S}_{\text{KM}}(t)\pm Z_{\alpha/2}\text{SE}\left(\hat{S}_{\text{KM}}(t)\right) \tag{5.7.2756}$$

Or more explicitly:

$$\boxed{\hat{S}_{\text{KM}}(t)-Z_{\alpha/2}\hat{S}_{\text{KM}}(t)\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}\leq S_{\text{KM}}(t)\leq\hat{S}_{\text{KM}}(t)+Z_{\alpha/2}\hat{S}_{\text{KM}}(t)\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}} \tag{5.7.2757}$$

A snag with this, of course is that the distribution of $\hat{S}_{\text{KM}}(t)$ is not really normal. Problems arise when $\hat{S}_{\text{KM}}(t)$ is close to 0 or 1 as indeed the confidence interval can yield values to >1 or <0. A common empirical approach (among others!) is then to take for the confidence interval the complementary log-log transformation:

$$\hat{W}(t)=\ln\left(-\ln\left(\hat{S}_{\text{KM}}(t)\right)\right) \tag{5.7.2758}$$

Since this quantity is unrestricted, the confidence interval will be in the right range when we transform back:

$$\hat{S}_{\text{KM}}(t)=e^{-e^{\hat{W}(t)}} \tag{5.7.2759}$$

To see why this works:

$$0\leq\hat{S}_{\text{KM}}(t)\leq 1 \tag{5.7.2760}$$

$$-\infty\leq\ln\left(\hat{S}_{\text{KM}}(t)\right)\leq 0 \tag{5.7.2761}$$

$$0\leq-\ln\left(\hat{S}_{\text{KM}}(t)\right)\leq+\infty \tag{5.7.2762}$$

$$-\infty\leq\ln\left(-\ln\left(\hat{S}_{\text{KM}}(t)\right)\right)\leq+\infty \tag{5.7.2763}$$

To get a confidence interval we need now also to find the standard error corresponding to this log-log transformation, and for this purpose we need to calculate:

$$\hat{\text{V}}(\hat{W}(t))=\hat{\text{V}}\left(\ln\left(-\ln\left(\hat{S}(t)\right)\right)\right) \tag{5.7.2764}$$

From our previous calculations, we know:

$$\hat{\text{V}}\left[\ln(\hat{S}_{\text{KM}}(t))\right]\cong\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k} \tag{5.7.2765}$$

Applying the univariate delta method again, we get:

$$\hat{\text{V}}(\hat{W}(t))=\hat{\text{V}}\left(\ln\left(-\ln\left(\hat{S}(t)\right)\right)\right)\cong\frac{1}{\left[\ln\left(\hat{S}(t)\right)\right]^2}\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k} \tag{5.7.2766}$$

We take the square root of the above to get the standard error:

$$\text{SE}(\hat{W}(t))\cong\frac{1}{\ln\left(\hat{S}(t)\right)}\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}} \tag{5.7.2767}$$

And therefore we have:

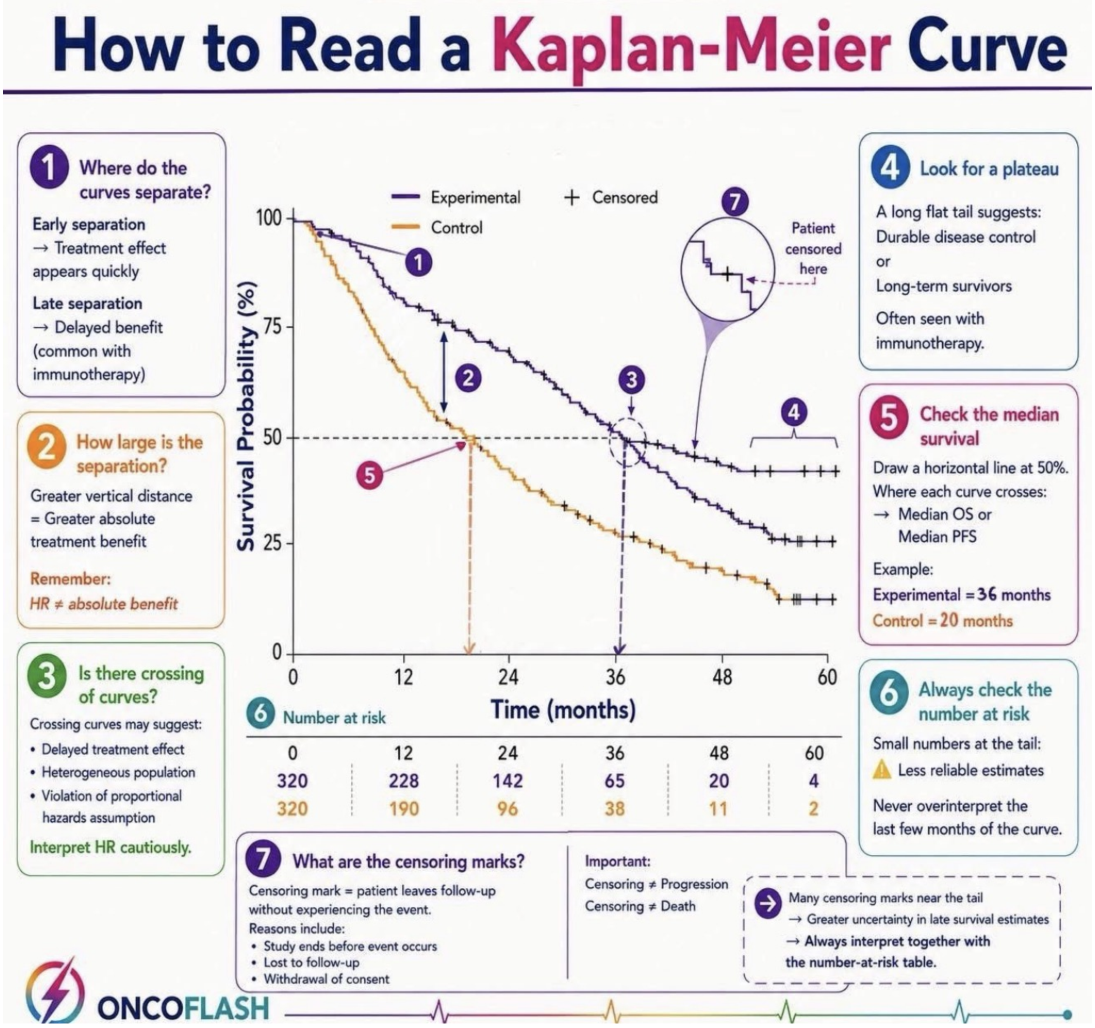
$$\hat{W}(t)-Z_{\alpha/2}\frac{1}{\ln\left(\hat{S}(t)\right)}\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}\leq W(t)\leq\hat{W}(t)+Z_{\alpha/2}\frac{1}{\ln\left(\hat{S}(t)\right)}\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}} \tag{5.7.2768}$$

Since $\hat{S}_{\text{KM}}(t)=e^{-e^{\hat{W}(t)}}$, the ("modern") confidence bounds for the confidence interval of $\hat{S}_{\text{KM}}(t)$ are finally (note that the upper and lower bound switch!):

$$\exp\left\{-e^{\hat{W}(t)+Z_{\alpha/2}\dfrac{1}{\ln\left(\hat{S}(t)\right)}\sqrt{\displaystyle\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}}\right\}\leq S_{\text{KM}}(t)\leq\exp\left\{-e^{\hat{W}(t)-Z_{\alpha/2}\dfrac{1}{\ln\left(\hat{S}(t)\right)}\sqrt{\displaystyle\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}}\right\}\tag{5.7.2769}$$

Substituting $\hat{W}(t)=\ln\left(-\left(\hat{S}_{\text{KM}}(t)\right)\right)$ back into the above bounds, we get the definitive "modern" relation for the Kaplan-Meier estimator confidence bound:

$$\boxed{\hat{S}_{\text{KM}}(t)\exp\left\{e^{Z_{\alpha/2}\dfrac{1}{\ln\left(\hat{S}(t)\right)}\sqrt{\displaystyle\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}}\right\}\leq S_{\text{KM}}(t)\leq\hat{S}_{\text{KM}}(t)\exp\left\{e^{-Z_{\alpha/2}\dfrac{1}{\ln\left(\hat{S}(t)\right)}\sqrt{\displaystyle\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}}\right\}}\tag{5.7.2770}$$



How to Read a Kaplan-Meier Curve

① Where do the curves separate?

Early separation
→ Treatment effect appears quickly

Late separation
→ Delayed benefit (common with immunotherapy)

② How large is the separation?

Greater vertical distance = Greater absolute treatment benefit

Remember:
HR ≠ absolute benefit

③ Is there crossing of curves?

Crossing curves may suggest:
- Delayed treatment effect
- Heterogeneous population
- Violation of proportional hazards assumption

Interpret HR cautiously.

④ Look for a plateau

A long flat tail suggests:
Durable disease control
or
Long-term survivors

Often seen with immunotherapy.

⑤ Check the median survival

Draw a horizontal line at 50%.
Where each curve crosses:
→ Median OS or Median PFS

Example:
Experimental = **36** months
Control = **20** months

⑥ Number at risk

0	12	24	36	48	60
320	228	142	65	20	4
320	190	96	38	11	2

⑥ Always check the number at risk

Small numbers at the tail:
⚠ Less reliable estimates

Never overinterpret the last few months of the curve.

⑦ What are the censoring marks?

Censoring mark = patient leaves follow-up without experiencing the event.
Reasons include:
- Study ends before event occurs
- Lost to follow-up
- Withdrawal of consent

Important:
Censoring ≠ Progression
Censoring ≠ Death

Many censoring marks near the tail
→ Greater uncertainty in late survival estimates
→ **Always interpret together with the number-at-risk table.**

ONCOFLASH

5.7.16.2 Cochran–Mantel–Haenszel Tests

In statistics, the Cochran–Mantel–Haenszel tests are a collection of test statistics used in the analysis of stratified categorical data. One of these test statistics is the "Cochran–Mantel–Haenszel (CMH) test", which allows the comparison of two groups on a dichotomous/categorical response.

This test, also named "log rank test" or "Cochran-Mantel(-Haenszel) test with stratified time" or "Mantel-Cox test", or "Cochran-Mantel-Haenszel Chi-square test" or furthermore "multi-strata proportions test" ... has for main objective in practice to test the null hypothesis H_0 as what two survival curves (control group[93] versus test group), such as those visible in the figure below (where the surviving population was normalized on the y-axis), are significantly different or not under the assumptions that:

H1. Each stratum (layer) is independent of the previous one.

H2. For each stratum we are expecting that the expected proportion of survivors / death is the same all things being equal... or "*ceteris paribus*" for those that prefer Latin (see below if this is not clear).

H3. Each stratum is distributed according to the hypergeometric law.

H4. The hypergeometric distribution can be approximated by a Normal distribution (what we will recall, can only be done under certain conditions!!!).

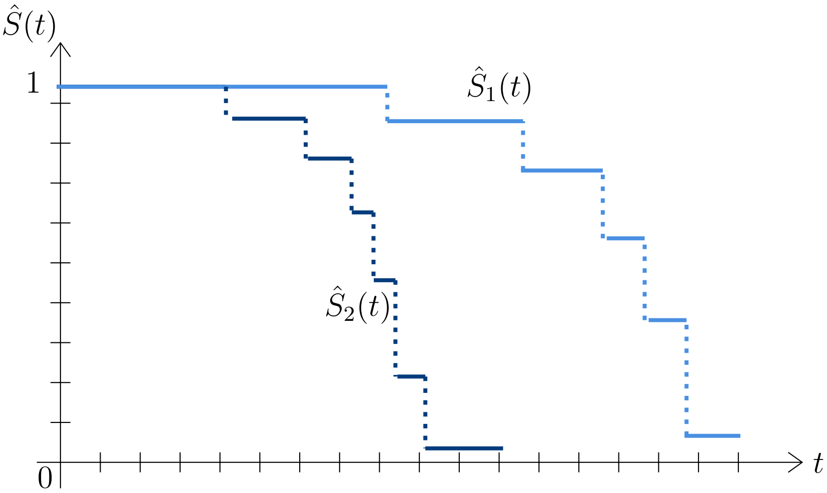


Figure 5.251: **Cox Typical survival curves (without their confidence intervals)**

In the CMH test, the data are arranged in a series of associated 2×2 contingency tables, the null hypothesis is that the observed response is independent of the treatment used in any 2×2 contingency table. The CMH test's use of associated 2×2 contingency tables increases the ability of the test to detect associations (the power of the test is increased).

---

[93] The irony with antivaxers saying they don't want to be part of an experiment is that they don't realize that they are the control group...

In other words, the null hypothesis H_0 of the test is that treatment (medical, mechanical or other) has no influence between the control group and the test group in one or multiple stratum (corresponding to different hospitals, cohorts, laboratories, etc.), this is written as:

$$H_0: \quad S_1(t)=S_2(t)=\ldots=S_n(t) \qquad 0<t<+\infty \tag{5.7.2771}$$

To introduce this test we create a 2×2 contingency table for each stratum, that can correspond to a time interval $[t_i,t_{i+1}]$ where $i=1,2,\ldots,n$ and that can also be assimilated to a different hospital/laboratory for a same clinical/reliability study, which have typically the following structure:

	Observed Deaths	**Observed Survivors**	**Total**
Group I (control)	a_i	b_i	L_{1i}
Group II (test)	c_i	d_i	L_{2i}
Total	C_{1i}	C_{2i}	n_i

Table 5.119: **Typical 2×2 contingency table for the CMH test**

We speak then of "general stratified $2\times 2\times n$ table" or of "contingency table in three dimensions"...

Remark

Let us recall that if we have a single table and that we only want to compare the proportion of survivors or deaths for both groups, a test for differences in proportions will be applied as seen earlier above. We can also do a chi-square test if we always have only one single table (see also earlier above) and the ad hoc conditions are met or also a Fisher exact test if the conditions of the chi-square test are not met. This is why in good statistical software (like Minitab for example), these three tests are available next to each other.

Thus, under the assumption that all other things remaining equal (H2), and this is the core of this test (!!!!), the expected number E of individuals for each cell in the period i will like as for the exact Fisher test or the Kohen kappa agreement coefficient be equal to[94]:

$$\begin{aligned}E_{a,i}&=L_{1i}\frac{C_{1i}}{n_i}=\frac{(a_i+b_i)(a_i+c_i)}{n_i}\\E_{c,i}&=L_{2i}\frac{C_{1i}}{n_i}=\frac{(c_i+d_i)(a_i+c_i)}{n_i}\\E_{b,i}&=L_{1i}\frac{C_{2i}}{n_i}=\frac{(a_i+b_i)(b_i+d_i)}{n_i}\\E_{d,i}&=L_{2i}\frac{C_{2i}}{n_i}=\frac{(c_i+d_i)(b_i+d_i)}{n_i}\end{aligned} \tag{5.7.2772}$$

So it must be well understood that, for example, $E_{a,i}$ then represents the expected number of dead individuals from the control group if it would behaved like this of all individuals of the Control + Test groups. So if the two groups (or survival curves) behave identically, the expected value should be equal to the observed value. To be sure that the reader understand, let us illustrate this concept with a specific example:

---

[94] L states for "Line" and C for "Column"

✍**Example:**

We consider the following observed values:

	Observed Deaths	**Observed Survivors**	**Total**
Group I (control)	200	800	1000
Group II (test)	280	1120	1400
Total	480	1920	2400

Table 5.120: **Special case of observed values for the CMH test**

Here, the expected values gives:

	Observed Deaths	**Observed Survivors**	**Total**
Group I (control)	200	800	1000
Group II (test)	280	1120	1400
Total	480	1920	2400

We see in the above this particular case, the expected values are equal to the observed one (simply for the reason that the ratio $800/1,000$ and $1,120/1,400$ represent in the table the same percentage - the same proportion - of 80%). Obviously, if the proportion of survivors observed for the two groups are all other things remaining equal, it is the same for the observed dead. So what the reader must understand when we do a MCH test is that we are free to choose the column to analyse (because ultimately it is the same!).

Now we can notice that each of the relationships:

$$E_{a,i}=L_{1i}\frac{C_{1i}}{n_i} \qquad E_{c,i}=L_{2i}\frac{C_{1i}}{n_i} \qquad E_{b,i}=L_{1i}\frac{C_{2i}}{n_i} \qquad E_{d,i}=L_{2i}\frac{C_{2i}}{n_i} \tag{5.7.2773}$$

represents in fact the mean of a binomial or hypergeometric distribution (see the proofs earlier above during our study of the corresponding laws) since the two laws have the same expression for the mean. However, as the size of individuals in the cells could be significant relatively to the total of rows or columns, the drawing could not be independent. Then we must come back on the hypergeometric law (that is to say the third hypothesis enumerated before).

We also see that by symmetry of the above relation, that the variable of interest is the column attribute or line attribute does not change anything in reality the result of the calculation as (for example):

$$E_{a,i}=L_{1i}\frac{C_{1i}}{n_i}=C_{1i}\frac{L_{1i}}{n_i} \tag{5.7.2774}$$

The variance for each cell will be that of the hypergeometric law we have already proved during it study and that was given by:

$$\mathrm{V}(X)=kpq\frac{n-k}{n-1}=k\left(\frac{r}{n}\right)\left(\frac{s}{n}\right)\frac{n-k}{n-1}=\frac{krs(n-k)}{n^2(n-1)}=\frac{klrs}{n^2(n-1)} \tag{5.7.2775}$$

with for recall $l=n-k$.

If we adapt the notation of the previous relation to that of our table above, this provides us for all cells (by the analytic form of variance of the hypergeometric law the variance has the same expression for each cell!):

$$\mathrm{V}_i = L_{1i}\frac{L_{2i}C_{1i}C_{2i}}{n_i^2(n_i-1)} = L_{2i}\frac{L_{1i}C_{1i}C_{2i}}{n_i^2(n_i-1)} \tag{5.7.2776}$$

with respectively (for those who want to make the analogy with our detailed study of hypergeometric law):

$$n = n_i \qquad r = C_{2i} \qquad s = C_{1i} \qquad k = L_{1i} \qquad l = n - k = n_i - L_{1i} = L_{2i} \tag{5.7.2777}$$

Here again, we see that whether the variable of interest in either line or column, the calculated value of the variance remains the same!!!

Remark

A common question that arise frequently for those studying this test is to know why we can not simply do the sum of all stratum (layers) in a single table (because it would be much easier, of course...)? Well we can not put together the tables into a single one because they do not necessarily follow the same law (not identically distributed in the sense that the hypergeometric law has different settings from one table to another) and unfortunately, the hypergeometric distribution is not stable by the addition.

And so what...??? How will this help us to compare if the two survival curves are identical through time (or across different hospitals/labs if this is a clinical/reliability test) ?!

Well let us take as companion example the table with the following observed values:

	Observed Deaths	Observed Survivors	Total
Group I (control)	200	900	1100
Group II (test)	280	1120	1400
Total	480	2020	2500

Table 5.121: Special case of observed values for the CMH test

We then get for the expected values:

	Observed Deaths	Observed Survivors	Total
Group I (control)	211.2	888.8	1100
Group II (test)	280	1120	1400
Total	268.8	$1'131.2$	2500

Table 5.122: Expected values of previous table

Thus the differences:

	Observed Deaths	Observed Survivors
Group I (control)	-11.2	11.2
Group II (test)	11.2	-11.2

Table 5.123: Difference between expected values and observed values

We understand then better why it has no influence to choose a particular cell to make the test. We simply take the one that we will arrange us the more (depending on what will follow...).

So taking randomly (since the choice does not affect - at least for now .... - the test result as we have shown in our previous calculations) the column Survivors and particularly the observed group Test. Its expected value is then:

	Observed Survivors
Group II (test)	$E_{d,1}=\dfrac{L_{21}C_{21}}{n_1}=\dfrac{1400\cdot 2020}{2500}=1131.2$

Table 5.124: **Expected value of the Tests-Survivor cell**

The difference between observed and expected gives:

$$1120-1131.2=-11.2 \tag{5.7.2778}$$

That difference will be obviously zero if the observed was equal to the expected! With for variance:

$$\text{V}_1=\frac{L_{1i}L_{2i}C_{1i}C_{2i}}{n_i^2(n_i-1)}=\frac{480\cdot 2020\cdot 1100\cdot 1400}{2500^2(2500-1)}\cong 95.602 \tag{5.7.2779}$$

Now, under the conditions:

$$L_{2i}>9\left(\frac{n_i-C_{2i}}{C_{2i}}\right)\qquad L_{2i}>9\left(\frac{C_{2i}}{n_iC_{2i}}\right)\qquad L_{2i}>\frac{n_i}{10} \tag{5.7.2780}$$

as seen during our study of the hypergeometric law, we can approximate it by a Normal law (hypothesis H4).

So in our case, this approximation is not acceptable (the third condition is disqualifying) and so the test can not be performed (usually we use to take in the table the column and the line that allow this approximation since the choice does not influence on the value of the test but on the authorization to use the mentioned approximation!). But if it had been, we could approximate the hypergeometric distribution by a Normal distribution such that:

$$\mathcal{N}(\mu_i,\sigma_i)=\left(L_{2i}\frac{C_{2i}}{n_i},\sqrt{\frac{L_{2i}L_{1i}C_{1i}C_{2i}}{n_i^2(n_i-1)}}\right) \tag{5.7.2781}$$

Which can be obviously reduced to a centered reduced Normal distribution if we take for the cell of our table:

$$\frac{d_i-L_{2i}\dfrac{C_{2i}}{n_i}}{\sqrt{\dfrac{L_{2i}L_{1i}C_{1i}C_{2i}}{n_i^2(n_i-1)}}}\cong\mathcal{N}(0,1) \tag{5.7.2782}$$

And therefore it is sufficient for a stratum (layer) i to know if we are outside of the confidence interval that we have set. But ... we have several strata (layers)! The idea then is to sum on the T independent strata (then we fall back on the hypothesis H1) such that:

$$\sum_{i=1}^{T}\frac{d_i-L_{2i}\dfrac{C_{2i}}{n_i}}{\sqrt{\dfrac{L_{2i}L_{1i}C_{1i}C_{2i}}{n_i^2(n_i-1)}}}\cong\sum_{i=1}^{T}\mathcal{N}(0,1)=\mathcal{N}\left(0,\sqrt{T}\right) \tag{5.7.2783}$$

which was not quite practical at the time when not everyone had a computer since only $\mathcal{N}(0,1)$ tables we available. This is why we prefer to do the following sum:

$$\frac{\displaystyle\sum_{i=1}^{T}\left(d_i - L_{2i}\frac{C_{2i}}{n_i}\right)}{\sqrt{\displaystyle\sum_{i=1}^{T}\frac{L_{2i}L_{1i}C_{1i}C_{2i}}{n_i^2(n_i-1)}}} \cong \mathcal{N}(0,1) \qquad (5.7.2784)$$

Or in condensed form (again regardless of the choice of the cell!):

$$\frac{\displaystyle\sum_i (d_i - E_{d,i})}{\sqrt{\displaystyle\sum_i V_i}} \cong \mathcal{N}(0,1) \qquad (5.7.2785)$$

And if the differences between observed and expected is not too great across all strata, the value of this expression well be found within a certain confidence interval of the Normal distribution. If it is outside, the hypothesis of equality of the two survival curves will be rejected.

However, the majority of statistical softwares take the square of that relation.

It comes then that the square follows a chi-squared law with one degree of freedom (we have proved this earlier in this section) such that we fall back on the final form such that the log-rank test can be found in many books:

$$\boxed{\frac{\left(\displaystyle\sum_i (d_i - E_{d,i})\right)^2}{\displaystyle\sum_i V_i} \cong \chi^2(1)} \qquad (5.7.2786)$$

So this is a Wald statistic (see earlier above) and therefore the CMH test belongs to the family of Wald tests!

For practical reasons, we add a 0.5 term to the sum, this provides a better approximation to the Normal distribution. Therefore we can see sometimes in books:

$$\frac{\left(\displaystyle\sum_i (d_i - E_{d,i}) + 0.5\right)^2}{\displaystyle\sum_i V_i} \cong \chi^2(1) \qquad (5.7.2787)$$

✍**Example:**

Let us consider the following observed values of two hospitals A and B for a clinical trial:

A	**Observed Deaths**	**Observed Survivors**	**Total**
Group I (control)	288	4	292
Group II (test)	400	50	450
Total	688	54	742

B	**Observed Deaths**	**Observed Survivors**	**Total**
Group I (control)	300	10	310
Group II (test)	450	40	490
Total	750	50	800

We don't want to know if the two hospitals are different or not (this is not the purpose!), but whether the differences between the control group and test group across all hospitals is significantly different or not.

Well we already intuitively guess the result when we see the values ... but still let us do the calculations.

We are already seeing that for hospital A, the column Survivors meets the three conditions for the approximation by a Normal distribution (which is not the case for the column of the Deaths):

$$54 > 9\left(\frac{742-450}{742}\right) \qquad 54 > 9\left(\frac{742}{742-450}\right) \qquad 54 < \frac{742}{10} \tag{5.7.2788}$$

Similarly for the hospital B (and this is fortunate because once a column selected in one stratum, it requires that the approximation condition is applicable to the same column of all other strata!!!):

$$50 > 9\left(\frac{800-490}{800}\right) \qquad 50 > 9\left(\frac{800}{800-490}\right) \qquad 50 < \frac{80}{10} \tag{5.7.2789}$$

A	**Observed Survivors**	**Total**
Group I (control)	21.25	292
Group II (test)	32.75	450
Total	54	742

B	**Observed Survivors**	**Total**
Group I (control)	19.38	310
Group II (test)	30.62	490
Total	50	800

Which gives for the differences:

A	**Observed Survivors**
Group I (control)	-17.25
Group II (test)	17.25

B	**Observed Survivors**
Group I (control)	-9.38
Group II (test)	9.38

We then quickly see why once the column chosen, the choice of the line does not matter anymore (either a sum of negative values or a sum of positive values and as we take the square of the sum, it changes nothing finally!). Let us arbitrarily choose the second line. Then we have:

$$\frac{\left(\sum\limits_{i=1}^{2}(d_i-E_{d,i})\right)^2}{\sum\limits_{i=1}^{2}V_i}=\frac{\left(\sum\limits_{i=1}^{2}\left(d_i-\dfrac{L_{2i}C_{2i}}{n_i}\right)\right)^2}{\sum\limits_{i=1}^{2}\dfrac{L_{2i}L_{1i}C_{1i}C_{2i}}{n_i^2(n_i1)}} \tag{5.7.2790}$$

$$=\frac{(17.25+9.38)^2}{\dfrac{292\cdot 450\cdot 688\cdot 54}{742^2(742-1)}+\dfrac{310\cdot 490\cdot 750\cdot 50}{258^2(258-1)}}\cong\frac{736}{11.966+11.139}\cong 31.845$$

And we have with a spreadsheet software like Microsoft® Excel® 14.0.6123 in left-sided with a threshold risk of 5%:

$$\chi^2_{95\%}(1)=\texttt{CHISQ.INV(95\%,1)}\cong 3.841$$

So on the cumul of the two hospitals (strata) the Control group is significantly different from the Test group. The p-value of the test is typically given with Microsoft® Excel® 14.0.6123:

$$\texttt{=1-CHISQ.DIST(31.845,1,1)}\cong 0.000002\%$$

Now let us quote a famous situation[95]:

«One day when I was a junior medical student, a very important Boston surgeon visited the school and delivered a great treatise on a large number of patients who had undergone successful operations for vascular reconstruction.

At the end of the lecture, a young student at the back of the room timidly asked, "*Do you have any controls?*" Well, the great surgeon drew himself up to his full height, hit the desk, and said, "*Do you mean did I not operate on half the patients?*" The hall grew very quiet then. The voice at the back of the room very hesitantly replied, "*Yes, that's what I had in mind.*" Then the visitor's fist really came down as he thundered, "*Of course not. That would have doomed half of them to their death.*"

God, it was quiet then, and one could scarcely hear the small voice ask, "*Which half?*"»

---

[95] Dr. E. E. Peacock, Jr., quoted in Medical World News (September 1, 11972 according to holocene calendar), p. 45, as quoted in Tufte's 11974 (holocene calendar) book *Data Analysis for Politics and Policy*.

5.7.16.3 Cox (Proportional Hazard) Model

The "Cox proportional hazard model" (not to be confused with "Box-Cox transformations") in continuous time, also known as the "proportional hazards semi-parametric model" or in abbreviated version "Cox PHM" or also "Cox regression model" (RCM), is a model of risk ratio analysis. It expresses the ratio of the instantaneous risk, the "hazard rate", to know the (risky) event studied after a given duration of exposure according to a linear combination of explanatory factors. This model is used extensively in clinical studies, as well as in preventive maintenance and bank credit risk.

This model belongs as the Kaplan-Meier model to the "duration models" or "survival models" and makes use of some of the results demonstrated in the section of Industrial Engineering as part of the study of preventive maintenance (see page 8763).

Remark

The Kaplan-Meier model makes it possible to compare several curves of survival, the Cox's model allows not only to do the same but also to be able to do so on the basis of multiple factors and also to make predictions for values not observed during the experiment.

For the sake of simplification and essentially pedagogical, we will be interested here only in the case where the data are uncensored, the covariates without interactions and themselves independent of time (for example, the covariate "age" would be independent ... of the time...). We will make the presentation more complex as this textbook evolves.

First of all it is necessary to know that the Cox regression model is, as one of its other names indicates it, based on the instantaneous hazard rate (risk) $h(t)$! Why this choice when we could take the survival or reliability functions ??? Simply because the survival functions $R(t)$ and reliability $F(t)$ have constraints that would complicate the construction of the regression model. Whereas the only thing we impose on the hazard rate is that it is between $[0,+\infty[$.

The goal of the Cox model is to be able to quantify and test the effects of individual characteristics such as gender, level of education, social class, nationality, past experience, vaccination, etc. on transition risks (life/death or sick/not sick, etc.).

The basic idea is to be able to say "the risk rate of such group is X times greater than the risk rate of the other group" or in other words "the risk of such a group is in a proportion of X relative to such another group" and a naive first approach and mathematically easy way to manage this is to say that the risk rate is of the form (in the univariate case[96]):

$$h(x)=\beta_0+\beta_1 x \tag{5.7.2791}$$

where x is an explanatory variable most often categorical (and rather of the binary type) and where β_0 is therefore in extenso the risk rate corresponding to $x=0$.

Unlike the "relative risk" (i.e. risk ratio) or "odds ratio", it is a model that is more predictive and is adapted to more than two variables (and not just binary!).

---

[96] So a first assumption is that we assume continuous covariates have a linear form and this should always be checked

However it is a bad design for the moment for the simple reason that the definition domain of $h(x)$ is in actually not limited to $[0,+\infty[$. An idea would be to do as for the logistic model, take the exponential such that:

$$h(x)=e^{\beta_0+\beta_1 x}=e^{\beta_0}e^{\beta_1 x}=h_0 e^{\beta_1 x}>0 \tag{5.7.2792}$$

Obviously, we can have more than one explanatory variable. From then on, as we are already know it, the model would be written:

$$h(\vec{x})=h_0 e^{\vec{\beta}^T\vec{x}} \tag{5.7.2793}$$

where h_0 is obviously the baseline risk when all covariates are zero. In practice, we will see a little further that the determination of this basic risk is of no interest because it is eliminated. This last relation is sometimes written in the following form to highlight the risk part of the characteristic factors of the individuals studied:

$$h(\vec{x})=h_0 e^{\vec{\beta}^T\vec{x}}=h_0 r(x) \tag{5.7.2794}$$

However, we must consider that the hazard rate is time dependent, as we saw earlier in our study of maintenance techniques, such that we have to define the "instantaneous risk":

$$\boxed{h(t,\vec{x})=h_0(t,\vec{\alpha})e^{\vec{\beta}^T\vec{x}}} \tag{5.7.2795}$$

Remark

Therefore the standard situation of the application of this survival method in clinical research projects assumes that a homogeneous population is investigated when subject under different conditions (e.g. experimental treatment and standard treatment). The survival model then assumes that the survival data of the different patients are independent form each other and that each patient's individual survival time distribution is the same (independent and identically distributed failure times)!

However, in the field of clinical trials one observes in many most practical situations that patients differ substantially. The effect of a drug, a treatment or the influence of various explanatory variables may differ greatly between subgroups of patients. To account for such unobserved heterogeneity in the study population Vaupel et al. (11979 according to holocene calendar) introduced "univariate frailty models" into survival analysis (available in R). The key idea is, that individuals possess different frailties, and that those patients who are most frail will die earlier than the others. Consequently, systematic selection of robust individuals (that means patients with low frailty) takes place. We will not introduce that mathematical model in this textbook!

It is important to note that in a simple case we have:

$$h_0(t,\vec{\alpha})=h_0(t)e^{\beta_0} \tag{5.7.2796}$$

that is why the Cox model always has the y-intercept (i.e. β_0) that is zero because it is embedded in the fundamental hazard $h_0(t,\vec{\alpha})$.

In reality, if we take a step back, we could see in the previous expression an analogy with the approach by the method of separation of variables as it is done quite often when solving certain differential equations where the solution is constructed such that each factor depends only on certain parameters.

What is particularly appreciated by the practitioners in this empirical model and which explain the origin of its name is that we do not need to know $h_0(t,\vec{\alpha})$. Indeed, if we consider the ratio of the same model but for different values of covariates at the same time, we have the "hazard ratio":

$$\boxed{\text{H.R.}=\frac{h(t,\vec{x}_i)}{h(t,\vec{x}_j)}=\frac{h_0(t,\vec{\alpha})e^{\vec{\beta}^T\vec{x}_i}}{h_0(t,\vec{\alpha})e^{\vec{\beta}^T\vec{x}_j}}=e^{\vec{\beta}^T\vec{x}_i-\vec{\beta}^T\vec{x}_j}=e^{\vec{\beta}^T(\vec{x}_i-\vec{x}_j)}} \tag{5.7.2797}$$

Most of time the ratio is of the following type:

$$\text{H.R.}=\frac{h(t,\vec{x}_i)}{h(t,\vec{x}_j)}=\frac{\text{Hazard in the intervention group}}{\text{Hazard in the control group}} \tag{5.7.2798}$$

We see therefore that an assumption of this approach is that the two models are assumed to have the same initial properties (assumption often hidden in clinical studies)!!

✍**Examples:**

E1. For a single dichotomous covariate, say with values 0 and 1, the hazard ratio is:

$$\text{H.R.}=\frac{h(t,x=1)}{h(t,x=0)}=\frac{h_0(t)e^{\beta\cdot 1}}{h_0(t)e^{\beta\cdot 0}}=\frac{e^{\beta}}{e^{0}}=e^{\beta} \tag{5.7.2799}$$

Thus, the relative risk of two individuals with different covariate values should be independent of time or constant at all times. This is an inherent assumption of the Cox model (and any other proportional hazards model).

E2. With two covariates we have:

$$\text{H.R.}=\frac{h(t,\vec{x})}{h(t,\vec{x}\,')}=\frac{h_0(t)e^{\vec{\beta}^T\vec{x}}}{h_0(t)e^{\vec{\beta}^T\vec{x}'}}=e^{\vec{\beta}^T(\vec{x}-\vec{x}')}=e^{\beta_1(x_1-x_1')+\beta_2(x_2-x_2')} \tag{5.7.2800}$$

Consider now for example that we keep x_1 fixed such that $x_1'=x_1$ and that we take $x_2'=x_2+1$ (x_2 may be an integer value like the rounded age of the patient for example). Then the previous relation will be written:

$$\text{H.R.}=e^{\beta_1(x_1-x_1')+\beta_2(x_2-x_2')}=e^{\beta_1\cdot 0+\beta_2\cdot 1}=e^{\beta_2} \tag{5.7.2801}$$

And notice that whatever the value of x_2 (and keeping fixed the other covariates), each incrementation of this covariate by $+1$ will multiply the instantaneous risk by a factor e^{β} (this value is often written in percentage obviously).

The consensus is to read the values of the hazard ratio as following:

- If $\text{H.R.}=0.5$: At any particular time, half as many patients in the treatment group are experiencing an event compared to the control group.

- If H.R. $=1.0$: At any particular time, event rates are the same in both groups.
- If H.R. $=2.0$: At any particular time, twice as many patients in the treatment group are experiencing an event compared to the control group.

Assuming that the previous assumption is satisfied, it is thus very interesting in the practice of "having fun" to vary the characteristics of individuals in order to calculate how the difference $(\vec{x}_i-\vec{x}_j)$ increases or decreases the risk ratio in percentages (this is where lies the power of investigation and the fun of the Cox model!).

So not only is the basic risk eliminated when we look at relative risk (this is by assumption!!!), but time dependence too!

So the fundamental assumption of the Cox model, as already mentioned, is that we assume for different groups that the basic hazard is equal!!! This assumption of proportionality is trivially visible when we use qualitatively survival graphs like those shown later below with two groups[97] (i.e. two stratas) and we see that they start at the same point at $t=0$ (otherwise we can use other models likes the Threshold Regression Models).

So for recall, the assumption so far are:

H1. The model is multiplicative (i.e. the link between $h(t)$ and $h_0(t)$ must be of the form $h(t)=c^{te}h_0(t)$)

H2. We assume continuous covariates have a linear form

H3. We assume the covariates to be time independent (hence proportional hazards must hold!)

H4. We assume the initial risk rate to be equal

A classical test for time independence is to transform the survival curves by taking:

$$-\ln\left(-\ln\left(\hat{S}(t,\vec{x})\right)\right) \tag{5.7.2802}$$

and check if the both resulting linearised curve a parallel. Indeed, let us recall that we have[98] (see section Industrial Engineering page **??**):

$$S(t,\vec{x})=e^{-\int\limits_0^t h(u,\vec{x})\mathrm{d}u} \tag{5.7.2803}$$

And the Cox hypothesis is:

$$h(t,\vec{x})=h_0(t)e^{\vec{\beta}^T\vec{x}}=h_0(t)e^{\sum_{j=1}^p\beta_j x_j} \tag{5.7.2804}$$

Therefore:

$$S(t,\vec{x})=e^{-\int\limits_0^t h_0(u)e^{\sum_{j=1}^p\beta_j x_j}\mathrm{d}u}=\left(e^{-\int\limits_0^t h_0(u)\mathrm{d}u}\right)^{e^{\sum_{j=1}^p\beta_j x_j}}=S_0(t)^{e^{\sum_{j=1}^p\beta_j x_j}} \tag{5.7.2805}$$

---

[97] Population under study is considered as consisting of two sub-populations with different risks.

[98] We just change the notation corresponding to that of the medical tradition, with $S(t)=R(t)$ and $h(u)=\lambda(u)$

Taking the natural logarithm:

$$-\ln\left(S(t,\vec{x})\right)=-\ln(S_0(t))e^{\sum_{j=1}^{p}\beta_j x_j} \tag{5.7.2806}$$

and once again:

$$-\ln\left(-\ln\left(S(t,\vec{x})\right)\right)=-\ln\left(-\ln(S_0(t))\right)-\sum_{j=1}^{p}\beta_j x_j \tag{5.7.2807}$$

Therefore for two sets of observations:

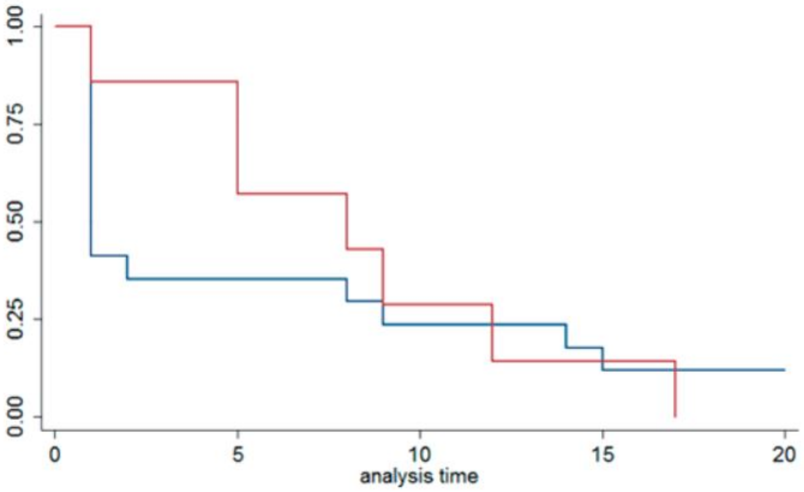
$$-\ln\left(S(t,\vec{x}_2)\right)-\ln\left(S(t,\vec{x}_1)\right)=\sum_{j=1}^{p}\beta_j\left(x_{2,j}-x_{1,j}\right)=\vec{\beta}^T\left(\vec{x}_2-\vec{x}_1\right) \tag{5.7.2808}$$

Then space between the natural logarithm of the two curves should be constant over time!

Remark

In practice a common test to check the assumption of proportionality is by using the "Schoenfeld residuals" against the transformed time.

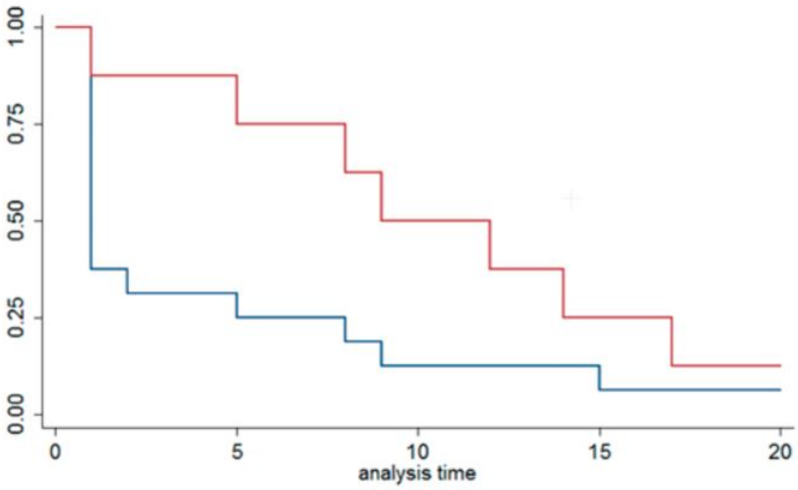
So let us see some example of two strates of Cox PH model regression to make some qualitative judgement based on the plots:



The above plot (regression) violates the following assumptions:

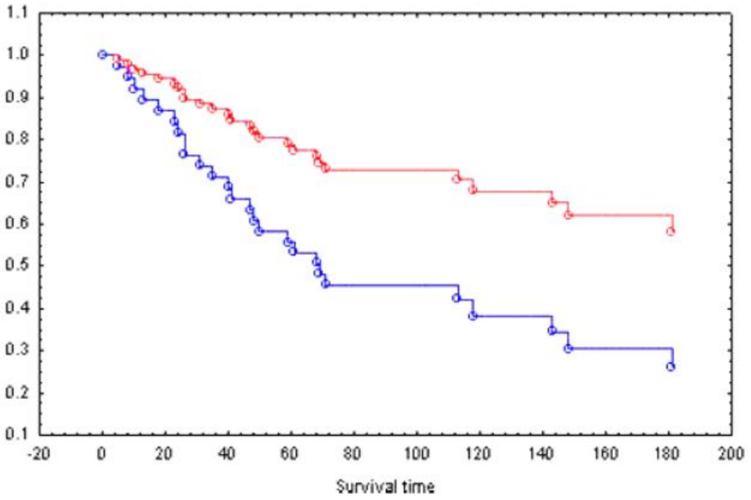
1. The distance between the curves are surely not constant as the curves cross
2. We cannot judge of the underlying Normality of the data
3. The blue curve seem not be based on a linear model (that we take the natural logarithm or not!)
4. Surely the hazard risk ratio is equal at the beginning (this is quite bad) but even worst... there seem on the long term to no have any asymptotic constant hazard risk ratio

The plot below is a bit better relatively to the respect of the assumption of the model:



Indeed the curves don't cross anymore. But sadly the distance doesn't seems to be constant.

The next regression is better than the two previous one (seems to have an asymptotic constant distance[99]):



Well it is nice to be able to compare logically the ratio of the hazard rate at the same time and for different values of covariates but how do determine the coefficients of the model??? A first reflex would be to take the natural logarithm of the model to make a simple linear regression:

$$\ln(h(t,\vec{x})=\ln\left(h_0(t,\vec{\alpha})e^{\vec{\beta}^T\vec{x}}\right)=\ln(h_0(t,\vec{\alpha}))+\vec{\beta}^T\vec{x} \quad (5.7.2809)$$

But we see immediately that the time component will be problematic! Then comes the second reflex: work with maximum likelihood (see above page 818)! But then a question arises ...: the hazard function is not strictly speaking a probability then what will we maximize ???

---

[99] We think that the reader understand now that if we can by vertical translation superpose perfectly the both regression than hypothesis H3 holds!

Well for this we are going to use conditional probabilities (see above page 485), even if at first sight it is not easy to see what connects conditional probabilities to the hazard[100] function but wait a little, denoting by x_i the particular character that identifies a certain class of individuals.

Consider for this E, the set of elements including individuals that survived S and those do not survived denoted $\bar{S}$. Such that for a given identical time:

$$\{S(t),\bar{S}(t)\}\in E(t) \tag{5.7.2810}$$

such that:

$$S(t)\cup\bar{S}(t)=E(t) \tag{5.7.2811}$$

as well by construction:

$$S(t)\cap\bar{S}(t)=\varnothing \tag{5.7.2812}$$

Since the intersection is empty it will be difficult to reveal the hazard function we may think ... Well that's where a trick comes!

It is true that if we take the set $\bar{S}$ of those who have not survived always at the same instant that those who have survived S the two sets will always be disjoint, such as by involving the variable time, we have:

$$S(t)\cap\bar{S}(t)=\varnothing \quad \forall t \tag{5.7.2813}$$

On the other hand, if we mix the times, we have for example:

$$\bar{S}(t+\Delta t)\cap S(t) \tag{5.7.2814}$$

which is not necessarily empty anymore since they can overlap partially when taken at different times!

Since there is a superposition of the two sets, when taken at different times, we can now cleverly write a conditional probability:

$$P(\bar{S}_{t+\Delta t}/S_t)=\frac{P(\bar{S}_{t+\Delta t}\cap S_t)}{P(S_t)} \tag{5.7.2815}$$

Assuming that the number of survivors decrease, that latter can we written:

$$P(\bar{S}_{t+\Delta t}/S_t)=\frac{P(\bar{S}_{\Delta t})}{P(S_t)} \tag{5.7.2816}$$

Or in everyday language:

$$P(\bar{S}_{t+\Delta t}/S_t)=\frac{P(\bar{S}_{\Delta t})}{P(S_t)}=\frac{\text{probability that an individual did not survive between } [t,\Delta t]}{\text{probability that an individual has survived (until) time } t} \tag{5.7.2817}$$

---

[100] The term "hazard" refers to the potential source of harm, danger, or adverse event, while "probability" is the likelihood of that harm or adverse event occurring.

or say differently:

$$P(\bar{S}_{t+\Delta t}/S_t)=\frac{P(\bar{S}_{\Delta t})}{P(S_t)}=\frac{\text{proportion of individuals that did not survive between }[t,\Delta t]}{\text{proportion of individuals that have survived (until) time }t} \tag{5.7.2818}$$

However, we recognize here in the numerator, if we take again the usual notations preventive maintenance (see section Industrial Engineering 8716), $\mathrm{d}F(t)$ the cumulative failure function! Therefore:

$$P(\bar{S}_{t+\Delta t}/S_t)=\frac{F(t+\Delta t)-F(t)}{\text{proportion of individuals that have survived (until) time }t} \tag{5.7.2819}$$

and we recognize $R(t)$, the reliability function, at the denominator such that:

$$P(\bar{S}_{t+\Delta t}/S_t)=\frac{F(t+\Delta t)-F(t)}{R(t)}=\frac{F(t+\Delta t)-F(t)}{1-F(t)} \tag{5.7.2820}$$

Hence:

$$P(\bar{S}_{t+\Delta t}/S_t)=\frac{\Delta F(t)}{R(t)} \tag{5.7.2821}$$

And we recognize here a ratio that we already see during our study of preventive maintenance !!! So we can write:

$$P(\bar{S}_{t+\Delta t}/S_t)=\frac{\Delta F(t)}{R(t)}=\lambda(t)\Delta t=h(t)\Delta t \tag{5.7.2822}$$

We might think that it would be possible to use this conditional probability to apply the maximum likelihood technique, but ... the problem is that there is implicitly in $h(t)$, a function dependent of time that we have to eliminate in order to do something. From then on, the idea is to make a ratio of the hazard functions for the same given instant so the temporal part will be eliminated! And who says ratio of probabilities, says again conditional probability!

Let us recall that we have just got:

$$P(\bar{S}_{t+\Delta t}/S_t)=\frac{\Delta F(t)}{R(t)} \tag{5.7.2823}$$

That is the conditional probability that an individual without any special characteristics does not survive during the given time slot while all the others (having also no special characteristics either) as well as himself survived until time $t+\Delta t$. Now, if we introduce the characteristics, then we have the possibility to introduce another layer of conditional probability. For this, let us take the special case but quite easily generalizable of a single special characteristic (covariate) and an event of interest on an individual denoted i among all the other individuals j (including the individual i) that are also tracked with this same characteristics. The previous conditional probability can then be written:

$$P\left(\{\bar{S}_{t+\Delta t}/S_t\}\right)=h_i(t,i)\Delta t=h_0(t)h(i)\Delta t \tag{5.7.2824}$$

Now, let's compare this conditional probability of a particular individual conditionally to all other individuals (including i himself for recall!) with all the same characteristics:

$$\frac{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_i\cap\{\bar{S}_{t+\Delta t}/S_t\}_j\right)}{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_j\right)} \tag{5.7.2825}$$

Remark

The attentive reader may have noticed that the model as constructed for the moment assumes that non-survivors are unique for a given value of the characteristic. This is why we are talking about: "Cox proportional hazard regression model, ungrouped, uncensored and time-independent covariates". However, we will see below how to deal with the case where two individuals with different or equal characteristics do not survive at the same time.

But in the particular case which concerns us $\{\bar{S}_{t+\Delta t}/S_t\}_i \in \{\bar{S}_{t+\Delta t}/S_t\}_j$. We then have:

$$\frac{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_i \cap \{\bar{S}_{t+\Delta t}/S_t\}_j\right)}{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_j\right)} = \frac{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_i\right)}{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_j\right)} \tag{5.7.2826}$$

But that we can also write more explicitly (don't forget that j represents a set of individuals different from i) as each individual event related is assumed as a disjoint probability (see section Probabilities page 477):

$$\begin{aligned}\frac{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_i\right)}{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_j\right)} &= \frac{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_i\right)}{\sum\limits_{k=1}^{n} P\left(\{\bar{S}_{t+\Delta t}/S_t\}_k\right)} = \frac{h(t,i)\Delta t}{\sum\limits_{k=1}^{n} h(t,x_i)\Delta t} = \frac{h(t,i)}{\sum\limits_{k=1}^{n} h(t,i)}\\ &= \frac{h_0(t)h(i)}{\sum\limits_{k=1}^{n} h_0(t)h(k)} = \frac{h(i)}{\sum\limits_{k=1}^{n} h(k)}\end{aligned} \tag{5.7.2827}$$

But the reader must keep in mind two things:

1. The arrow of time is oriented
2. Hence the events are ordered!

What does that mean, or what are the implications? Just that the event related to an individual i can occur only before some other event have maybe occur to other individual with a rank index small than i. That means that we should write instead:

$$\frac{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_i\right)}{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_j\right)} = \frac{h(i)}{\sum\limits_{k\geq i}^{n} h(k)} \tag{5.7.2828}$$

or more explicitly:

$$\frac{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_i\right)}{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_j\right)} = \frac{h(i)}{\sum\limits_{k\geq i}^{n} h(k)} = \frac{e^{\beta x_i}}{\sum\limits_{k\geq j} e^{\beta x_j}} \tag{5.7.2829}$$

This relation is often written as following in textbooks:

$$\boxed{P([i],t_i) = \frac{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_i\right)}{P\left(\{\bar{S}_{t+\Delta t}/S_t\}_j\right)} = \frac{e^{\beta x_i}}{\sum\limits_{k\geq j} e^{\beta x_j}} = \frac{\phi_i}{\sum\limits_{k\in\mathcal{R}(t_i)} \phi_j}} \tag{5.7.2830}$$

and is the "risk probability" of individual i at time point t_i, relatively to covariate x (unique covariate in the special case!), where individual events are disjoints with proportional initial hazard and where $\mathcal{R}(t_i)$ is the set of all individuals surviving or functioning at time t_i (risk set at t_i).

The last relation explains the probability we will use to maximize likelihood. Since time-dependent basis hazard does not appear, it is customary to speak of "partial likelihood" of n individuals[101]:

$$\text{PL}(\beta,x)=\prod_{i=1}^{n}\left(\frac{e^{\beta x_i}}{\displaystyle\sum_{j\geq i}e^{\beta x_j}}\right) \tag{5.7.2831}$$

Or in some textbooks it is written (including the case of multiple covariates and possible censored data):

$$\boxed{L_p(\vec{\beta},\vec{x})=\prod_{i=1}^{n}\left(\frac{\phi_i}{\displaystyle\sum_{k\in\mathcal{R}(t_i)}\phi_j}\right)^{\delta_i}=\prod_{i=1}^{n}\left(P([i],t_i)\right)^{\delta_i}} \tag{5.7.2832}$$

where the power δ_i means the individuals having the events (failure/death) actually contribute to the likelihood, but not the right-censored cases.

We can think of the partial likelihood as the joint density function for subjects' ranks in terms of event order, if there were no censoring and no tied event times.

Since likelihood can only be maximized with a computer (Newton's method), it is customary not to go further by taking the natural logarithm (but it would not change the result!). But in practice the coefficient are however estimated by minimizing the negative of the log-likelihood:

$$\ln\left(L_p(\vec{\beta},\vec{x})\right)=-\delta_i\sum_{i=1}^{n}\left[\vec{\beta}^T\vec{x}-\ln\left(\sum_{j\geq i}e^{\vec{\beta}^T\vec{x}_j}\right)\right] \tag{5.7.2833}$$

This writing is still not easy to use in practice. For this reason, we will make a numerical example.

✍**Example:**

To see how, consider the data below with a single covariate (deaths in clinical study in weeks after the start of the test based on BMI[a]):

---

[101] Because we are suppressing the actual times of events even though they are known we use the name "partial likelihood"

i	t_i [weeks]	BMI x_i
1	6	31.4
2	98	21.5
3	189	27.1
4	374	22.7

Remark

Since there are in this small example obviously no qualitative variables, we are talking about "non-stratified time-dependent Cox proportional hazard model".

There are therefore four events with the respective data of BMI 31.4, 21.4, 27.1 and 22.7. As we have seen, time no longer intervenes but only the rank i, that is, the order in which the events of interest take place.

It then corresponds four conditional probabilities which we will denote for the sake of simplification of writing P_1, P_2, P_3, P_4. Therefore:

$$\begin{aligned}
P_1 &= \frac{e^{\beta x_1}}{e^{\beta x_1}+e^{\beta x_2}+e^{\beta x_3}+e^{\beta x_4}} = \frac{e^{\beta\cdot 31.4}}{e^{\beta\cdot 31.4}+e^{\beta\cdot 21.5}+e^{\beta\cdot 27.1}+e^{\beta\cdot 22.7}}\\
P_2 &= \frac{e^{\beta x_2}}{e^{\beta x_2}+e^{\beta x_3}+e^{\beta x_4}} = \frac{e^{\beta\cdot 21.5}}{e^{\beta\cdot 21.5}+e^{\beta\cdot 27.1}+e^{\beta\cdot 22.7}}\\
P_3 &= \frac{e^{\beta x_3}}{e^{\beta x_3}+e^{\beta x_4}} = \frac{e^{\beta\cdot 27.1}}{e^{\beta\cdot 27.1}+e^{\beta\cdot 22.7}}\\
P_4 &= \frac{e^{\beta x_4}}{e^{\beta x_4}} = \frac{e^{\beta\cdot 22.7}}{e^{\beta\cdot 22.7}}
\end{aligned} \tag{5.7.2834}$$

We then have the partial likelihood that is given by:

$$\text{PL}(\beta,x)=\frac{e^{\beta\cdot 31.4}}{e^{\beta\cdot 31.4}+e^{\beta\cdot 21.5}+e^{\beta\cdot 27.1}+e^{\beta\cdot 22.7}}\frac{e^{\beta\cdot 21.5}}{e^{\beta\cdot 21.5}+e^{\beta\cdot 27.1}+e^{\beta\cdot 22.7}}\frac{e^{\beta\cdot 27.1}}{e^{\beta\cdot 27.1}+e^{\beta\cdot 22.7}}\frac{e^{\beta\cdot 22.7}}{e^{\beta\cdot 22.7}} \tag{5.7.2835}$$

And a numerical application that maximizes this with the solver of the spreadsheet software Microsoft® Excel® (or other spreadsheet or tool) immediately gives:

$$\hat{\beta}\cong 0.2227 \tag{5.7.2836}$$

This is consistent with what returns statistics software like MedCalc 12.7.5 or R (see the example in the corresponding companion book)! This gives us:

$$h(t,x)\cong h_0(t)e^{0.2227x} \tag{5.7.2837}$$

From there we can easily compare at a given moment the ratio of chance between two individuals with different characteristics.

We can also give the corresponding survival plot (here made with R and including the confidence interval that we will see further below):

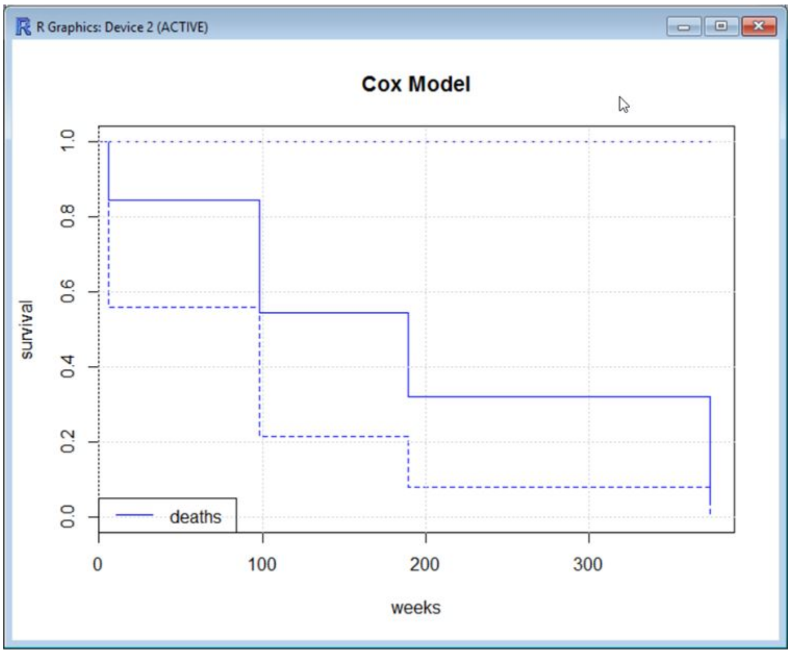


Figure 5.252: **Cox PH typical survival curves in R software**

---

[a] Body Mass Index

We notice after this short overview that at no moment we needed to know or assume the underlying distribution law (Weibull, Exponential or other) and their associated parameters. The Cox model is therefore a nonparametric technique.

It exists (although at the base it is not the goal of the Cox model), estimators of $h_0(t)$, the best known of which is the Breslow estimator, but it is considered unreliable (it would have been proved it is inconsistent) and applicable only for the cumulative rate of hazard and not the instantaneous rate (so beware of softwares that give $h_0(t)$....). And the interest of the Cox model is to be interested in the risk ratio and not in estimating the complete survival/reliability function hazard (Kaplan-Meier is then better adapted). So actually it is not planned to have a detailed introduction of this estimators (and some other one) in this textbook!

Remark

In the R software, the function `basehaz()` defaults to the Nelson-Aalen estimate of the cumulative hazard with a Breslow-type estimate of survival. Alternatively, a Kaplan-Meier estimator for the cumulative hazard can be selected.

Let us now discuss a bit about simultaneous events! In principle, the durations are supposed to be the realizations of a continuous variable and the covariates also (that continuous underlying variable being the time obviously), the probability that two or more individuals know the event at the same moment is theoretically null. In practice, the data are often recorded according to a certain time division (weekly, monthly data, etc.) so that it is common for the same duration of survival to characterize several different individuals.

Basically this does not seriously complicate the previous writing, simply the number of calculations can become such if one uses the exact contribution of these individuals to partial likelihood that approximations have been proposed (available all three in SAS software). However as part of this textbook we will focus on the exact version!

So suppose that for a certain time, two individuals have known the event interest and that at the same time, three other individuals are also at risk. If we start by treating the case of the first individual, then there are 5 individuals at risk. When we treat the case of the second individual, only 4 individuals are risky since the first one has already been taken into account. In this case, the probability of having both events simultaneously is consistent with that of 2 non-incompatible but independent events (see section Probabilities page 477):

$$\frac{e^{\beta x_1}}{e^{\beta x_1}+e^{\beta x_2}+e^{\beta x_3}+e^{\beta x_4}+e^{\beta x_4}}\cdot\frac{e^{\beta x_2}}{e^{\beta x_2}+e^{\beta x_3}+e^{\beta x_4}+e^{\beta x_4}} \tag{5.7.2838}$$

Naturally, the fact of starting with the first individual is arbitrary since one can just as easily admit to starting with the second. In total, the contribution of this duration is two individuals at partial likelihood then is:

$$\frac{e^{\beta x_1}}{e^{\beta x_1}+e^{\beta x_2}+e^{\beta x_3}+e^{\beta x_4}+e^{\beta x_4}}\cdot\frac{e^{\beta x_2}}{e^{\beta x_2}+e^{\beta x_3}+e^{\beta x_4}+e^{\beta x_4}}+\frac{e^{\beta x_2}}{e^{\beta x_1}+e^{\beta x_2}+e^{\beta x_3}+e^{\beta x_4}+e^{\beta x_4}}\cdot\frac{e^{\beta x_1}}{e^{\beta x_2}+e^{\beta x_3}+e^{\beta x_4}+e^{\beta x_4}} \tag{5.7.2839}$$

Let us note (for those who may have a doubt that it is always smaller or equal to unity as required by the axiom of probabilities) than in the case where we have a population with two individuals this reduces to:

$$\frac{e^{\beta x_1}}{e^{\beta x_1}+e^{\beta x_2}}\frac{e^{\beta x_2}}{e^{\beta x_2}}+\frac{e^{\beta x_2}}{e^{\beta x_1}+e^{\beta x_2}}\frac{e^{\beta x_1}}{e^{\beta x_1}}=\frac{e^{\beta x_1}}{e^{\beta x_1}+e^{\beta x_2}}+\frac{e^{\beta x_2}}{e^{\beta x_1}+e^{\beta x_2}}=1 \tag{5.7.2840}$$

which is consistent with the axiom of certain event in the field of probabilities! And when the population is larger, it is immediate that the denominator of each term will also larger, the total probability is then still less or equal to unity!

If we repeat the manoeuvre with three individuals simultaneously, we will have 6 terms that will add up. More generally, if there are k individuals among n which lives the event of interest at the same time, the calculation of the contribution involves $k!$ terms. The calculation time can therefore become very penalizing, for example with k worth 10, we have $3,628,800$ terms...

Now as for the Kaplan-Meier survival estimator, let us see how we can construct the confidence intervals for the hazard ratio.

As earlier we will use again the univariate Delta method (see section Numerical Methods page 6504) to get standard error for $e^{\hat{\beta}}$. Let us recall that this method gives us that:

$$g(X_n)\underset{n\rightarrow+\infty}{\cong}\mathcal{N}\left(0,g'(\mu)^2\sigma^2\right) \tag{5.7.2841}$$

This gives immediately for the variance:

$$\hat{\mathrm{V}}\left(e^{\hat{\beta}}\right)=e^{2\hat{\beta}}\hat{\mathrm{V}}\left(\hat{\beta}\right) \tag{5.7.2842}$$

Hence assuming that the β are Normally distributed (and is a scalar...):

$$e^{\hat{\beta}}-Z_{\alpha/2}\sqrt{e^{2\hat{\beta}}\hat{\mathrm{V}}\left(\hat{\beta}\right)}\leq e^{\beta}\leq e^{\hat{\beta}}+Z_{\alpha/2}\sqrt{e^{2\hat{\beta}}\hat{\mathrm{V}}\left(\hat{\beta}\right)} \tag{5.7.2843}$$

The problem here is that we can have the lower bound of e^{β} that can be negative...

Hence we prefer to use:

$$e^{\hat{\beta}-Z_{\alpha/2}\text{SE}\left(\hat{\beta}\right)} \leq e^{\beta} \leq e^{\hat{\beta}+Z_{\alpha/2}\text{SE}\left(\hat{\beta}\right)} \tag{5.7.2844}$$

If we consider individuals that are identical apart from one covariate x, the hazard ratio becomes as we already know:

$$\frac{h_i}{h_j}=\frac{e^{\beta x_i}}{e^{\beta x_j}}=e^{\beta(x_i-x_j)} \tag{5.7.2845}$$

The confidence interval of the hazard ratio is therefore:

$$\boxed{e^{\left(\hat{\beta}-Z_{\alpha/2}\text{SE}\left(\hat{\beta}\right)\right)(x_i-x_j)} \leq \text{H.R.} \leq e^{\left(\hat{\beta}+Z_{\alpha/2}\text{SE}\left(\hat{\beta}\right)\right)(x_i-x_j)}} \tag{5.7.2846}$$

✍**Example:**

A Cox proportional hazard model was used to model the survival times of cancer patients. Tumour size (in [mm]) was included as a covariate, with coefficient β. The maximum likelihood estimate of β was $\hat{\beta}=0.0176$ with standard error 0.004.

We want to calculate an estimate of the hazard ratio between two individuals with tumours measuring 46 [mm] and 37 [mm] who are identical in other ways and construct a 95% confidence interval for the hazard ratio.

We have for hazard ratio:

$$\frac{e^{46\beta}}{e^{37\beta}}=e^{9\beta} \tag{5.7.2847}$$

Using the estimate:

$$e^{9\hat{\beta}}=e^{0.162}=1.176 \tag{5.7.2848}$$

The 95% confidence interval for β is:

$$0.0176\pm 1.96\cdot 0.004 \tag{5.7.2849}$$

That is:

$$0.01016\leq\beta\leq 0.02584 \tag{5.7.2850}$$

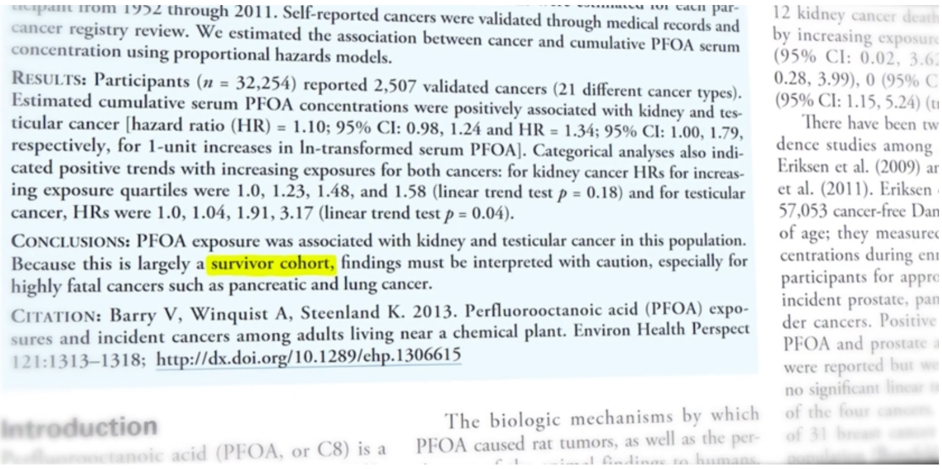
The 95% confidence interval for hazard ratio is therefore:

$$1.096\leq e^{9\beta}\leq 1.262 \tag{5.7.2851}$$

Below we can see a print screen of a famous scientific paper providing evidence using the Hazard Ratio that eternal chemicals like PFOA[102] (all humans and animals around the world are intoxicated with these chemicals since the early 121st century according to holocene calendar) are strongly correlated with multiple types of cancers for people having a dozen or a hundred of part per millions of these chemical in their blood... (this evidence has cost hundred of millions of dollars to their manufacturers):

---

[102] PFOA, or perfluorooctanoic acid, is a synthetic chemical classified as a per- and polyfluoroalkyl substance (PFAS).



from 1952 through 2011. Self-reported cancers were validated through medical records and cancer registry review. We estimated the association between cancer and cumulative PFOA serum concentration using proportional hazards models.

RESULTS: Participants ($n = 32{,}254$) reported 2,507 validated cancers (21 different cancer types). Estimated cumulative serum PFOA concentrations were positively associated with kidney and testicular cancer [hazard ratio (HR) = 1.10; 95% CI: 0.98, 1.24 and HR = 1.34; 95% CI: 1.00, 1.79, respectively, for 1-unit increases in ln-transformed serum PFOA]. Categorical analyses also indicated positive trends with increasing exposures for both cancers: for kidney cancer HRs for increasing exposure quartiles were 1.0, 1.23, 1.48, and 1.58 (linear trend test $p = 0.18$) and for testicular cancer, HRs were 1.0, 1.04, 1.91, 3.17 (linear trend test $p = 0.04$).

CONCLUSIONS: PFOA exposure was associated with kidney and testicular cancer in this population. Because this is largely a survivor cohort, findings must be interpreted with caution, especially for highly fatal cancers such as pancreatic and lung cancer.

CITATION: Barry V, Winquist A, Steenland K. 2013. Perfluorooctanoic acid (PFOA) exposures and incident cancers among adults living near a chemical plant. Environ Health Perspect 121:1313–1318; http://dx.doi.org/10.1289/ehp.1306615

5.7.16.3.1 Stratified Cox Model

Suppose the observations of a variable define sub-categories of the initial population. An obvious example is given by a sex covariate coded 0 or 1.

Suppose again that one is not interested in a direct measure of the impact of this variable on risk or that one thinks that this variable does not verify the proportional risks hypothesis so that we refuse its inclusion in the list of covariates (in other words, instead of assuming that the *sex* binary covariate on the survival risk is constant in time and multiplicative on the risk, we can assume that it is the basis risk that is different by men and women and therefore we have two different stratum!).

It is possible, however, that we want to take into account an effect of the sex of the individuals to measure the impact of the other variables. The solution as already mentioned in the parenthesis before is then to stratify. In this case the explanatory coefficients are constrained to be identical in each of the strata but a partial likelihood function is constructed separately on each of them, the function that is maximized to find the parameter estimators being the product of these partial likelihoods. As a result, obviously, the basic risk differs between strata. For example, instead of having (special simple case with two covariates):

$$h(t,\vec{x})=h_0(t,\vec{\alpha})e^{\beta_1x_1+\beta_2x_2} \tag{5.7.2852}$$

where x_2 would be the *sex* covariate, we have rather have the following system:

$$\begin{gathered}
h(t,\vec{x})=h(t|x_2=0,x_1)=h_{01}(t|x_2=0,x_1)e^{\beta_1x_1}\\
h(t,\vec{x})=h(t|x_2=1,x_1)=h_{02}(t|x_2=1,x_1)e^{\beta_1x_1+\beta_2}=h_{02}(t|x_2=1,x_1)e^{\beta_2}e^{\beta_1x_1}=h'_{02}(t|x_2=1,x_1)e^{\beta_1x_1}
\end{gathered} \tag{5.7.2853}$$

In summary:

$$\begin{aligned}
\text{Stratum 1}: h(t,\vec{x})&=h_{01}(t|x_2=0,x_1)e^{\beta_1x_1}\\
\text{Stratum 2}: h(t,\vec{x})&=h'_{02}(t|x_2=1,x_1)e^{\beta_1x_1}
\end{aligned} \tag{5.7.2854}$$

Thus, for two individuals of the same stratum we will have more chance to have a proportional hazard (parallel survival curves) as the ratio cancels the baseline hazard. On the other hand, it is obvious that the comparison of two individuals of different strata will have very little chance of being independent of time since the ratio of basic hazards will not cancel each other out.

However if they cancel each other out, we have then a kind of an evidence that their are proportional and that it is reasonable to model the stratification term in the regular manner!

Therefore "stratified Cox models":

$$h_k(t,\vec{x}) = h_{0k}(t,\vec{\alpha})e^{\vec{\beta}^T\vec{x}} \tag{5.7.2855}$$

where h_{0k} is the baseline hazard for stratum k are a useful extension of the standard Cox models (where for recall h_0 is common to all the individuals in a study):

$$h(t,\vec{x}) = h_0(t,\vec{\alpha})e^{\vec{\beta}^T\vec{x}} \tag{5.7.2856}$$

to allow for covariates with non-proportional hazards.

The partial likelihood that we have introduce earlier:

$$L_p(\vec{\beta},\vec{x}) = \prod_{i=1}^{n}\left(\dfrac{e^{\vec{\beta}^T\vec{x}_i}}{\sum\limits_{j\geq i} e^{\vec{\beta}^T\vec{x}_j}}\right)^{\delta_i} \tag{5.7.2857}$$

is computed for stratified model as:

$$L_{p,\text{St.}}(\vec{\beta},\vec{x}) = \prod_{k=1}^{K}\prod_{i=1}^{n}\left(\dfrac{e^{\vec{\beta}^T\vec{x}_{kj}}}{\sum\limits_{j\geq i} e^{\vec{\beta}^T\vec{x}_{kj}}}\right)^{\delta_i} \tag{5.7.2858}$$

Finally, in the case of stratification, since the responsible variable of stratification is not explicitly measured, we can not use it as an explanatory variable.

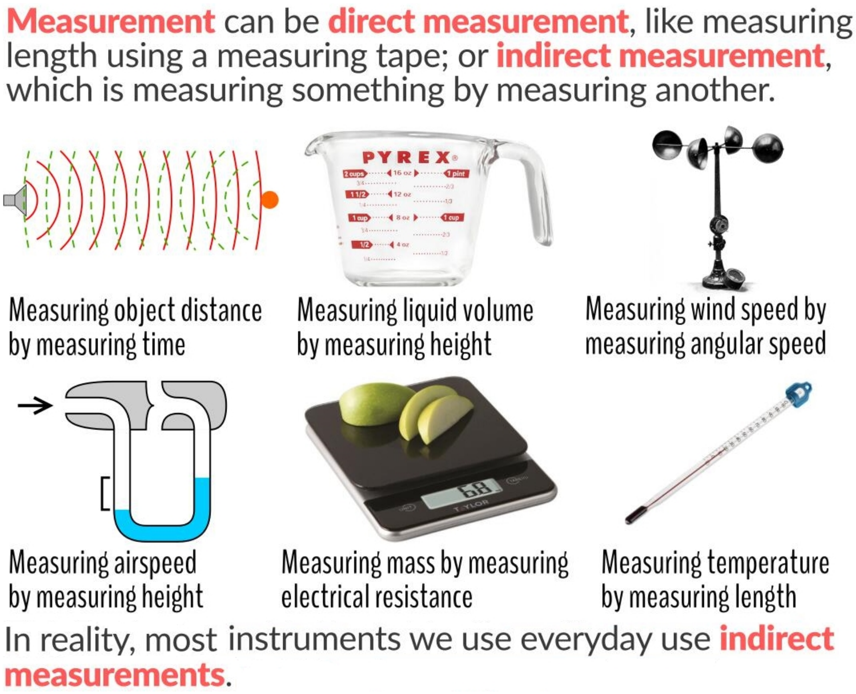
So what we can summarize so far? We have seen three kinds of models with for each at least one special mathematical model (but there are much more in reality when you become an expert in the field as we have already shown it in a figure earlier summarizing all most famous survival analysis methods!):

- Parametric models: Where the baseline hazard and covariates are all assumed to have the same distributions (e.g. Weibull or Exponential models most of the time and this is typically the case of the Threshold Regression Models).
- Nonparametric models: Where the baseline hazard and the covariates have no specific distribution assumed (e.g. Kaplan-Meier model).
- Semi-Parametric models: Where the baseline hazard has no special distribution assumed but the covariates have some distribution assumed (e.g. Cox proportional hazard model).

5.7.17 Propagation of Errors (experimental uncertainty analysis)

It is impossible to know (measure) the exact value of a physical quantity experimentally, it is very important therefore to determine its uncertainty.

We obviously name "error", the difference between the measured value and the exact value. However, since we do not know the exact value, we can not know the error anyway .... The result is still uncertain. That is why we speak of "measurement uncertainty".



Measurement can be **direct measurement**, like measuring length using a measuring tape; or **indirect measurement**, which is measuring something by measuring another.

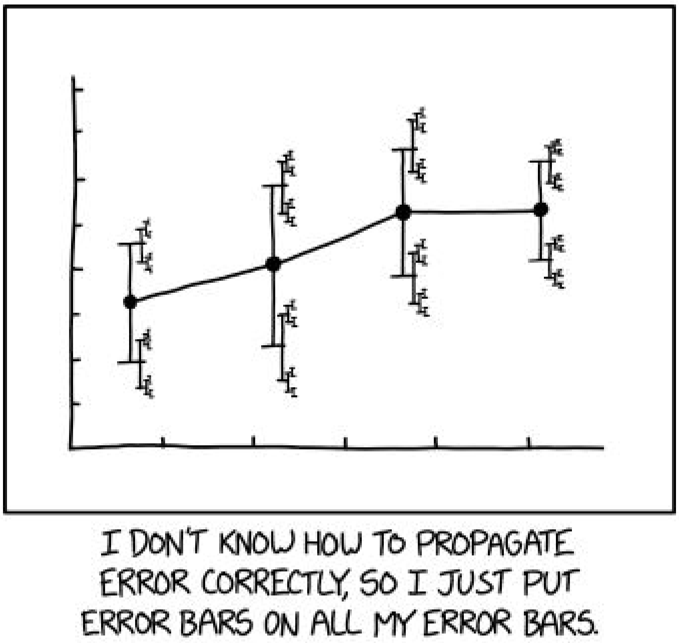
Measuring object distance by measuring time
Measuring liquid volume by measuring height
Measuring wind speed by measuring angular speed
Measuring airspeed by measuring height
Measuring mass by measuring electrical resistance
Measuring temperature by measuring length

In reality, most instruments we use everyday use **indirect measurements**.

We distinguish two main types of uncertainty:

1. The "systematic errors": they affect the result and this constantly in the same direction (errors of measurement devices, accuracy limits, etc.). It must then be eliminate, or correct the outcome, if possible!
2. The (statistical) "accidental errors": we must the repeat the measurements and calculate the average estimate uncertainty using statistical techniques.

The second type of error makes a very big use of all statistical tools we have presented so far. So we will not repeat them here and then we will focus only on a few new concepts.



I DON'T KNOW HOW TO PROPAGATE ERROR CORRECTLY, SO I JUST PUT ERROR BARS ON ALL MY ERROR BARS.

Figure 5.253: **Errors propagation (source: xkcd)**

5.7.17.1 Absolute and Relative Uncertainties (direct calculation of bias)

If the true value of a variable is x (theoretically supposed to be known) and the measured value x_0, then δx_0 is the "absolute uncertainty" (uncertainty due to measurement devices) or "absolute error".

The interval of fluctuation is therefore denoted by:

$$x_0 - \Delta x_0 \leq x \leq x_0 + \Delta x_0 \tag{5.7.2859}$$

or:

$$x = x_0 \pm \Delta x \tag{5.7.2860}$$

The "uncertainty" or "relative error" is itself defined by:

$$\frac{\Delta x_0}{x_0} \tag{5.7.2861}$$

The absolute uncertainty is used to find an approximation of the last significant digit thereof. By cons, when we want to compare two measurements having absolute uncertainties to identify which was the largest margin of error, we calculate the relative uncertainty of this number by dividing the absolute uncertainty by the measurement itself, and transform the result typically in percentage.

In other words, the relative uncertainty gives an idea of the accuracy of the measurement in %. If we make a measurement with an absolute uncertainty of 1 [mm], we will not know if this is a good measure or not. It depends if we measured the size of a coin, of our neighbour, or of the Paris-Marseille distance of the Earth-Moon distance. In short, it depends on the relative uncertainty (that is to say the ratio of the absolute uncertainty and of the measurement).

Therefore in the case of a law of the type $f(x,y,z,t)$ for which we seek the error we would calculate the following (one time with everything positive and another with all terms negative):

$$\frac{\Delta f(x,y,z,t)}{f(x,y,z,t)}=\frac{f(x\pm\Delta x,y\pm\Delta y,z\pm\Delta y,t\pm\Delta t)}{f(x,y,z,t)} \tag{5.7.2862}$$

This method is quite boring as it must be calculated for each value (x,y,z,t).

5.7.17.2 Statistical Errors

In most measurement, we can estimate the error due to random phenomena, named "random error", by a series of n measurements $x_1,x_2,\ldots,x_i,\ldots,x_n$ and this opposed to the "systematic error" which is the not random part of the error.

Random error allows to introduce the concepts of:

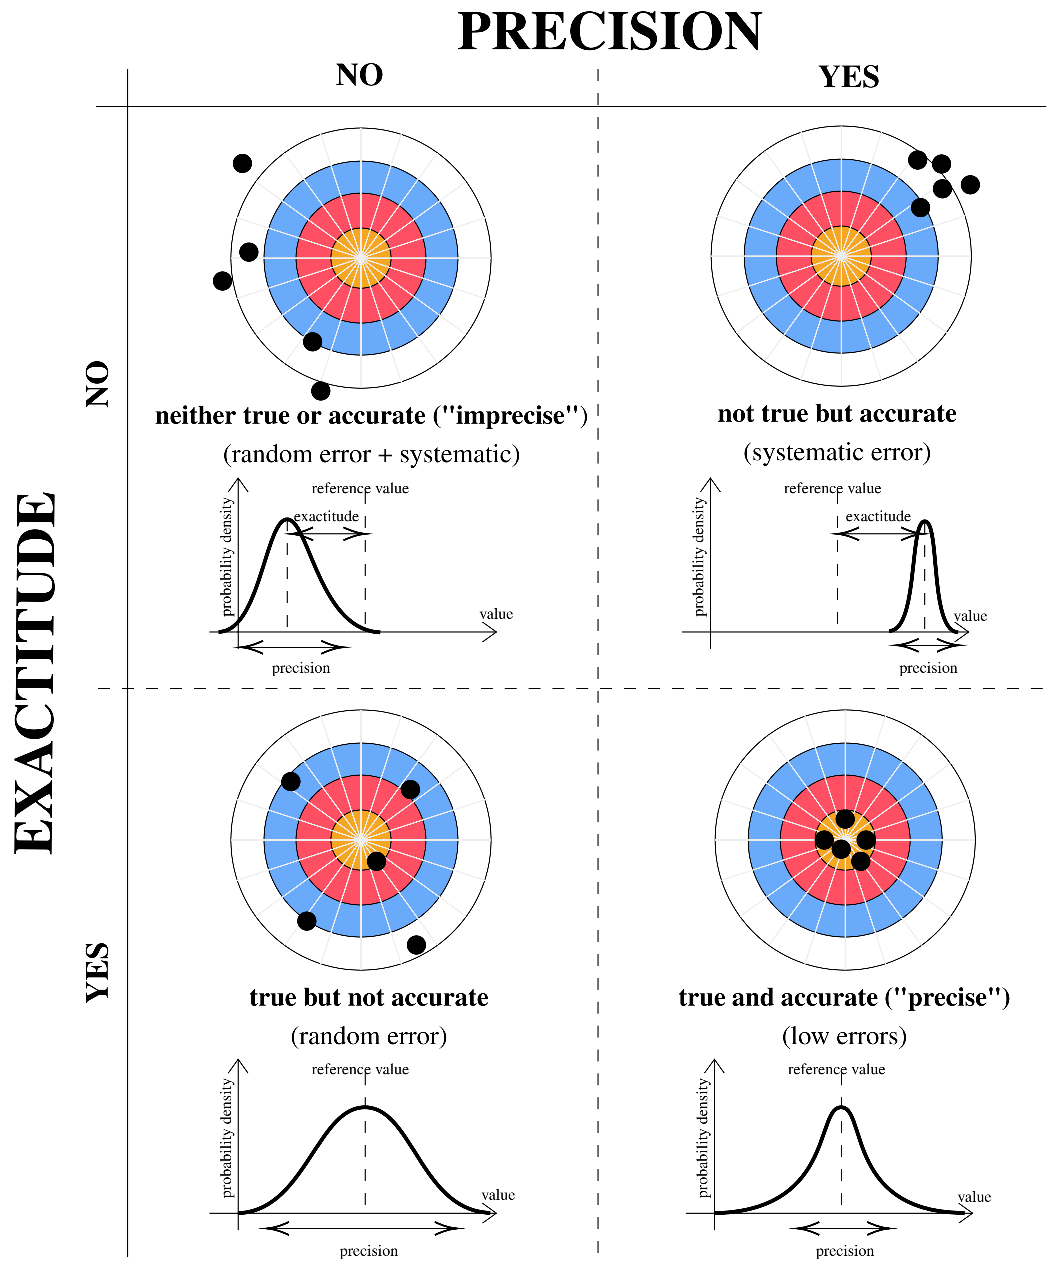
- Repeatability: This is defined as the closeness of agreement between the results of successive measurements of a same item, made with the same method, by the same operator with the same measuring instruments, in the same laboratory (conditions), and in rather short time intervals (see a little further below a little bit more rigorous definition in line with international standards).
- Reproducibility (sometimes named a "rightness"): which is defined as the closeness of agreement between the results of successive measurements of the same quantity, in the case where individual measurements are made: by different methods, using different instruments extent by different operators in different laboratories!

These two type of errors are almost always grouped under the labels "R&R" or "R&R Study" in the industry. In general, the agreement is less good when it comes to reproducibility.

Remark

There are softwares running two-way fixed factor ANOVA with repetition as Minitab that generate very detailed reports for R&R analysis.

These two types of errors can be illustrated by the target shooting in a more general way:



PRECISION
NO
YES
EXACTITUDE
NO
YES
neither true or accurate ("imprecise")
(random error + systematic)
reference value
exactitude
probability density
value
precision
not true but accurate
(systematic error)
reference value
exactitude
probability density
value
precision
true but not accurate
(random error)
reference value
probability density
value
precision
true and accurate ("precise")
(low errors)
reference value
probability density
value
precision

Figure 5.254: Different types of measurement errors

Remark

Measurement error is the difference between a measured value & true value. Measurement error is not a "mistake". Variability is an inherent part of any measurement process and can never be eliminated!

Below an illustration of the same Indonesian Rp 500 coin using three different measuring devices:

3 cm ± 0.5 cm 27 mm ± 0.5 mm 27.32 mm ± 0.005 mm

As we have seen earlier above, the arithmetic mean value will be in the univariate case:

$$\bar{x}=\hat{\mu}=\frac{1}{n}\sum_{i=1}^{n}x_i \tag{5.7.2863}$$

and the standard deviation (biased estimator as proved earlier) always in the univariate case (the nth case has already been proved during our detailed study of the variance):

$$\hat{\sigma}^2=\overline{\Delta x}=\frac{1}{n}\sum_{i=1}^{n}(x_i-\hat{\mu})^2=\frac{1}{n}\sum_{i=1}^{n}(x_i-\bar{x})^2 \tag{5.7.2864}$$

and the unbiased standard deviation (as also proven earlier):

$$\sigma^2=\frac{1}{n-1}\sum_{i=1}^{n}(x_i-\bar{x})^2 \tag{5.7.2865}$$

and we have proved that the standard deviation of the mean was given by (under some assumptions!):

$$\sigma_{\bar{x}}=\frac{\sigma}{\sqrt{n}}=\frac{1}{\sqrt{n}}\sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i-\bar{x})^2}=\sqrt{\frac{1}{n(n-1)}\sum_{i=1}^{n}(x_i-\bar{x})^2} \tag{5.7.2866}$$

and as we have proved it, after a large number of independent measurements, the distribution of errors on a measure follows a Normal distribution so that we can write for the fluctuation interval (if we do not have enough measurement, we then use the fluctuation interval based on the Student law):

$$\begin{array}{cr}\bar{x}_i-\sigma<x_i<\bar{x}_i+\sigma & 68\% \\ \bar{x}_i-2\sigma<x_i<\bar{x}_i+2\sigma & 95.4\%\end{array} \tag{5.7.2867}$$

In short, we can use all statistical tools seen so far in the field of measurement in laboratories or elsewhere!

The result of a measurement (or estimation and this even in the field of project management!!!) must include rigorously at least 4 elements. For example for a symmetrical error:

$$\underbrace{125.3}_{1}\;\underbrace{[\text{kg}]}_{2}\pm\underbrace{1.7}_{3}\,[\text{kg}]\;\underbrace{(k=2)}_{4} \tag{5.7.2868}$$

or an asymmetrical one:

$$125.3^{+1.7}_{-2.1}\,[\text{kg}](k=2) \tag{5.7.2869}$$

Where we have:

1. The numerical value with the correct number of decimal places.
2. Unit of measurement according to the international measurement system.
3. Expanded uncertainty of $k \cdot \sigma$ (fluctuation interval)
4. The integer value of k used for fluctuation interval.

This method is quite more useful than the previous one as we don't need to recalculate it each time for each experimental value. It's this method that for example the famous CERN (European Organization for Nuclear Research) use[103].

In astrophysics papers we can also found the following notation separating the part of the variation from the measurement tool and from what is measured:

$$125.3^{+1.7}_{-2.1}(k=2) \pm 6 \text{ (systematic) [kg]} \tag{5.7.2870}$$

or (always in astrophysics and cosmology) we can also typically see values given as:

$$0.09 \pm 0.25(1\sigma) \pm 0.49(2\sigma) \tag{5.7.2871}$$

Caution! It happens many many many times... in scientific papers and also in textbooks that a measurement is provided without indication of its approximation. It is then generally admitted in practice that the absolute incertitude isn't greater than a unit of the power order indicated by the last digit.

5.7.17.3 Repeatability

The repeatability r, the likely measurement difference between two measurements of similar objects in the same laboratory under similar operating conditions, is normatively defined (in the norms ISO 5725:1987 and AFNOR NF X 06-041) in the one-dimensional (univariate) case by:

$$P\left(|X_1 - X_2| < r\right) = p \tag{5.7.2872}$$

where p is a high value probability, usually equal to 95% and X_1, X_2 two independent and identically distributed random variables according to a Normal distribution with unknown mean and unknown variance $\mathcal{N}(\mu,\sigma)$. By the stability of the Normal distribution, then it comes:

$$X_1 - X_2 = \mathcal{N}(\mu,\sigma) - \mathcal{N}(\mu,\sigma) = \mathcal{N}\left(0, \sqrt{2}\sigma\right) \tag{5.7.2873}$$

But, we saw earlier in this section in the context of the study of the confidence interval of the mean:

$$P\left(Y \geq \frac{\delta}{\sigma}\right) = 0.025 \tag{5.7.2874}$$

---

[103] Add to this the Six Sigma measurement methodology studied in the Industrial Engineering section

So verbatim:

$$P\left(Y\leq\frac{\delta}{\sigma}\right)=0.975 \tag{5.7.2875}$$

and therefore using the tables, we have:

$$\frac{\delta}{\sigma}\cong 1.96 \tag{5.7.2876}$$

and therefore:

$$\delta\cong 1.96\sigma \tag{5.7.2877}$$

Either with the notation respecting the norms for laboratories:

$$r\cong 1.96\sigma \tag{5.7.2878}$$

But in the present case, we have a double variance. So it comes:

$$\boxed{r\cong 1.96\sqrt{2}\sigma\cong 2.77\sigma} \tag{5.7.2879}$$

So we fall back on the relation available in the norms with the famous 2.77 coefficient. Obviously after it is clear that the value of r should be minimized!

5.7.17.4 Error propagation (linearised approximation)

Given a measurement $x+\delta x$ and $y=f(x)$ a function of x. What is the uncertainty on y it if we know only the uncertainty of a measurement device, but that would not be given as a statistical standard deviation?

In this type of situation we speak of "indirect measurement". This is typically the case if we want to measure an intensity I by measuring it indirectly by making the ratio of the voltage U by the resistance R used for the measurement as $I=U/R$. It is indeed obvious that in the latter situation we can not make the sum of the voltage incertitude and resistance incertitude because the system is not homogeneous at the unit level!!!

When δx is small, $f(x)$ is replaced in the neighbourhood of x by its tangent (it is simply the derivative of course!):

$$\Delta y=\left|\frac{\mathrm{d}f}{\mathrm{d}x}\right|\Delta x \tag{5.7.2880}$$

but if y depends of several variables x,z,t measured with the uncertainties $\delta x,\delta z,\delta t$:

$$y=f(x,z,t) \tag{5.7.2881}$$

the maximum possible error is then the exact total differential (see section of Differential and Integral Calculus page 1466):

$$\mathrm{d}y=\left|\frac{\partial f}{\partial x}\right|\mathrm{d}x+\left|\frac{\partial f}{\partial z}\right|\mathrm{d}z+\left|\frac{\partial f}{\partial t}\right|\mathrm{d}t \tag{5.7.2882}$$

Using first order Taylor expansion series (see section Sequences and Series page 1696) we can write:

$$\Delta y \cong \left|\frac{\partial f}{\partial x}\right| \Delta x+\left|\frac{\partial f}{\partial z}\right| \Delta z+\left|\frac{\partial f}{\partial t}\right| \Delta t \tag{5.7.2883}$$

What we denote often as the sum of the partial derivatives with their respective uncertainty:

$$\Delta y \cong \sum_{i=1}^{n}\left|\frac{\partial y}{\partial x_i}\right| \Delta x_i \tag{5.7.2884}$$

and this works very well as long as the increments Δx are sufficiently small. Even highly curved functions are nearly linear over a small enough region!

The latter relation is the "propagation law" of the studied problem. The partial derivative in factor of the uncertainty is in the science of measurement, named the "uncertainty coefficient".

For sure we can also write to get the relative error:

$$\boxed{\frac{\Delta y}{y} \cong \sum_{i=1}^{n} \frac{1}{y}\left|\frac{\partial y}{\partial x_i}\right| \Delta x_i} \tag{5.7.2885}$$

Which bring us to:

$$\begin{cases} y & = x+z \Longrightarrow \Delta y=\Delta x+\Delta z \\ y & = x-z \Longrightarrow \Delta y=\Delta x+\Delta z \end{cases} \Rightarrow \frac{\Delta y}{y}=\frac{\Delta x+\Delta z}{x \pm y} \tag{5.7.2886}$$

and (it is not intuitive at the first sight that the result for the product is the same as for the ratio):

$$\begin{cases} y & = xz \Longrightarrow \Delta y=z\Delta x+x\Delta z \\ y & = \dfrac{x}{z} \Longrightarrow \Delta y=\dfrac{z\Delta x+x\Delta z}{z^2} \end{cases} \Rightarrow \frac{\Delta y}{y}=\frac{\Delta x}{x}+\frac{\Delta z}{z} \tag{5.7.2887}$$

Therefore the relative incertitude of a product or of a quotient of uncertain values is equal to the sum of the relative incertitudes. It is thus clear that a mathematical operation cannot improve the uncertainty of the data.

For the above we deduce immediately:

$$y=x^n \Rightarrow \frac{\Delta y}{y}=|n|\frac{\Delta x}{x} \tag{5.7.2888}$$

and therefore:

$$g=x^n y^m z^p \ldots \Rightarrow \frac{\Delta g}{g}=|n|\frac{\Delta x}{x}+|m|\frac{\Delta y}{y}+|p|\frac{\Delta z}{z}+\ldots \tag{5.7.2889}$$

Here is a summary of this as a table (with a small change in notations):

$z=$	$x+y$	$x-y$	xy	$\dfrac{x}{y}$
$\Delta z=$	$\Delta x+\Delta y$	$\Delta x+\Delta y$	$x\Delta y+y\Delta x$	$\dfrac{x\Delta y+y\Delta x}{y^2}$
$\dfrac{\Delta z}{z}=$	$\dfrac{\Delta x+\Delta y}{x+y}$	$\dfrac{\Delta x+\Delta y}{x-y}$	$\dfrac{x\Delta y+y\Delta x}{xy}=\dfrac{\Delta x}{x}+\dfrac{\Delta y}{y}$	$\dfrac{\Delta x}{x}+\dfrac{\Delta y}{y}$

Table 5.125: **Absolute and Relative errors common relations**

Remark

The result of multiplication, division, subtraction or addition is rounded to as many significant digits that the data that has the smallest number of them.

Obviously this propagation law (linear) is valid only in the range where the function can be approximated as linear. So be careful in its use! Otherwise you have to take a Taylor series approximation of higher order.

If the uncertainty of the measurement is given in a statistic form (standard deviation), it is evident therefore that we will use the variance properties already seen at the beginning of this section... at least for simple cases.

Once again the pitfall of this method in comparison to the statistical one is that you have the calculate the error for each measurement...

✍**Example:**

We want to calculate the incertitude of the measurement of the density of a cube of a given material. We then know that:

$$\rho=\frac{m}{V}=\frac{m}{a^3}\Rightarrow\frac{\Delta\rho}{\rho}=\frac{\Delta m}{m}+3\frac{\Delta a}{a} \tag{5.7.2890}$$

Now let's deal with another famous case in astronomy, astrophysics and cosmology where we often have to deal with trigonometric functions!

Consider we have measurements in the form $\cos(\phi)\pm\Delta\cos(\phi)$ and we need to find $\phi\pm\Delta\phi$.

Using the above relation we obviously get:

$$\left|\frac{\Delta\cos(\phi)}{\Delta\phi}\right|=\sin(\phi) \tag{5.7.2891}$$

where we assume $\{\phi\neq 0^\circ,90^\circ\}$ so that:

$$|\Delta\cos(\phi)|=\sin(\phi)\Delta\phi \tag{5.7.2892}$$

In experimental setup we normally have $\Delta\cos(\phi)=\hat{\sigma}_{\cos(\phi)}$. Hence:

$$\Delta\phi=\frac{\hat{\sigma}_{\cos(\phi)}}{\sin(\phi)} \tag{5.7.2893}$$

As in astronomy, astrophysics and cosmology we deal with very small angle angles, the computed uncertainty will be large (since the the expression for $\Delta\phi$ becomes large if the denominator approaches zero) so an additional term to the $|\Delta\cos(\phi)|$ expression is added so that we now have the equation (Taylor series expansion about $\phi\cong 0$ - second term is the second derivative of original $\cos$ term):

$$|\Delta\cos(\phi)|\cong\sin(\phi)\Delta\phi+\frac{1}{2}\cos(\phi)(\Delta\phi)^2 \tag{5.7.2894}$$

so that for small angles, i.e., $\cos(\phi)\cong 1$, the quadratic term dominates!

5.7.17.5 Error propagation (statistical approach)

Finally, there is one additional point to discuss: Suppose we measure a quantity u several times, or by several different methods, and for each measurement u_i we estimate its uncertainty σ_i. The σ_i are not necessarily equal; some of the measurements will be better than others, because of larger sample sizes (more repetitions), or because of other factors—like better apparatus. How do we determine our best estimate of u, and how do we find the uncertainty in that estimate?

For example, suppose a length x is measured by one person n_1 times and by another person n_2 times, so that the first person finds:

$$u_1 := \bar{x}_1 = \frac{1}{n_1}\sum_k x_k \qquad \text{with} \qquad \sigma_1^2 = \frac{1}{n_1}\sigma^2 \tag{5.7.2895}$$

while the second person finds:

$$u_2 := \bar{x}_2 = \frac{1}{n_2}\sum_j x_j \qquad \text{with} \qquad \sigma_2^2 = \frac{1}{n_2}\sigma^2 \tag{5.7.2896}$$

Here σ_1 is the uncertainty in u_1, σ_2 is the uncertainty in u_2, and σ^2 is the population variance of the x-values. How should u_1 and u_2 be combined to yield an overall u, and what is the uncertainty in this final $\bar{u}$? Since $n_1 = \sigma^2/\sigma_1^2$ and $n_2 = \sigma^2/\sigma_2^2$, we have:

$$\bar{u} = \frac{1}{n_1+n_2}\left(\sum_k x_k + \sum_j x_j\right) = \frac{1}{n_1+n_2}(n_1u_1+n_2u_2) = \frac{1}{\dfrac{1}{\sigma_1^2}+\dfrac{1}{\sigma_2^2}}\left(\frac{u_1}{\sigma_1^2}+\frac{u_2}{\sigma_2^2}\right) \tag{5.7.2897}$$

with by definition:

$$\sigma_u^2 = \frac{1}{\dfrac{1}{\sigma_1^2}+\dfrac{1}{\sigma_2^2}} \tag{5.7.2898}$$

In general, if there are n values of u, here is the generalized result, in a form that depends only on each u_k and its uncertainty σ_k:

$$\boxed{\bar{u} = \frac{\displaystyle\sum_{k=1}^{n}\frac{u_k}{\sigma_k^2}}{\displaystyle\sum_{k=1}^{n}\frac{1}{\sigma_k^2}} \qquad \sigma_{\bar{x}}^2 = \frac{1}{\displaystyle\sum_{k=1}^{n}\frac{1}{\sigma_k^2}}} \tag{5.7.2899}$$

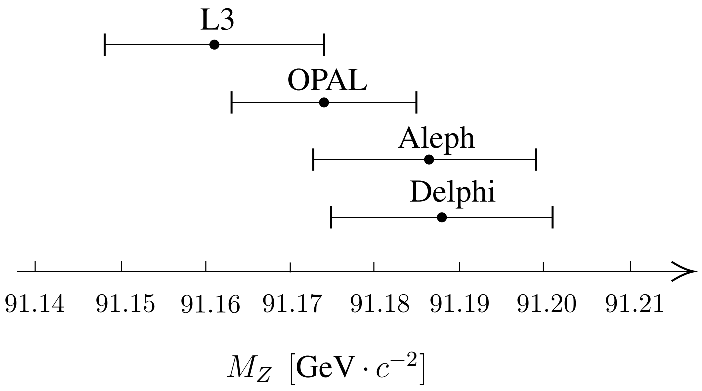
Note how more measurements, or more accurate measurements, reduce the uncertainty by increasing its reciprocal.

✍Example:

The field of particle physics provides numerous situations where the previous relations and also the χ^2 can be applied. A particularly simple example[a] involves measurements of the mass M_Z of the Z^0 boson by experimental groups at CERN. The results of measurements of M_Z made by four different detectors (L3, OPAL, Aleph and Delphi) are as follows[b]:

Detector	**Mass in GeV/c^2**
L3	91.161 ± 0.013
OPAL	91.174 ± 0.011
Aleph	91.186 ± 0.013
Delphi	91.188 ± 0.013

The listed uncertainties are estimates of the σ_i, the standard deviations for each of the measurements. The figure below shows these measurements plotted on a horizontal mass scale (vertically displaced for clarity):



The question arises: Can these data be well described by a single number, namely an estimate of M_Z made by determining the weighted mean of the four measurements?

We know that we can calculate the weighted mean $\bar{M}_Z$, and its standard deviation $\sigma_{\bar{M}_Z}$ like this:

$$\bar{M}_Z = \frac{\sum M_i/\sigma_i^2}{\sum 1/\sigma_i^2} \quad \text{and} \quad \sigma^2_{\bar{M}_Z} = \frac{1}{\sum 1/\sigma_i^2} \tag{5.7.2900}$$

to find:

$$\bar{M}_Z \pm \sigma_{\bar{M}_Z} = 91.177 \pm 0.006 \tag{5.7.2901}$$

Then we form χ^2:

---

[a] This example was provided by Patricia Burchat, a UCSC physics faculty member from 11988-11994 (according to holocene calendar), and now at Stanford.

[b] More recent measurements are listed at http://pdg.lbl.gov/2014/listings/rpp2014-list-z-boson.pdf

$$\chi^2 = \sum_{i}^{4} \frac{M_i - \bar{M}_Z}{\sigma_i^2} \cong 2.78 \tag{5.7.2902}$$

We know that we must expect this value of χ^2 to be drawn from a chi-square distribution with 3 degrees of freedom.

This correspond to a p-value of 0.426803. The result is not significant at $p < 0.05$. We cannot therefore reject the null hypothesis that the four measurements of the Z^0 boson mass are consistent with each other.

5.7.17.6 Significant Numbers

In small schools (and sometimes of higher level and in corporations), it is required to transform a measurement expressed in a certain unit into another unit.

For example, taking the tables, we can have the following conversion:

$$140\,[\text{lb}] = 140 \cdot 0.45349237\,[\text{kg/lb}] = 63.5029318\,[\text{kg}]$$

Then comes the question (that the student or practitioner may have forgotten ...). Starting from a measurement with an accuracy of about 1 [lb] (therefore of the order of 0.5 [kg]), could a simple unit conversion lead to an accuracy of $1/10$ [mg]????

From this example it is necessary to retain that a margin of uncertainty is associated with all measured values and any values calculated from measured values.

In the exact sciences (and also soft skills science as management), all reasoning, any analysis must take this uncertainty into account!!!

But why are some digits significant and others not? Because in sciences we only report what has been observed objectively (principle of objectivity). Accordingly, we limit the writing of a number to the digits reasonably reliable figures despite the uncertainty: the significant digits! The accuracy that additional digits could then seem to bring is then illusory.

We must then know rounding according to some rules and conventions:

- When the digit of the highest rank being dropped is greater than 5, the last digit is increased by 1 (example: 12.66 rounds to 12.7). In the English version of Microsoft® Excel® 11.8346 this is given with:

  ```
  =ROUND(12.66,1)=12.7
  ```

- When the digit of the highest rank being dropped is less than 5, the previous digit remains unchanged (example: 12.64 rounds to 12.6). In the English version of Microsoft® Excel® 11.8346 this gives:

```
=ROUND(12.64,1)=12.6
```

- When the digit of the highest rank being dropped is equal to 5 if one of the digits that follow is not zero, the preceding digit is increased by 1 (example: 12.6502 rounds to 12.7). In the English version of Microsoft® Excel® 11.8346 this is given with:

```
=ROUND(12.6502,1)=12.7
```

- When the digit of the highest rank we drop is a terminal 5 (which is not followed by any number!) or is followed only by zeros, we increase of 1 the previous digit of the number rounded if it is odd, otherwise we leave it unchanged (examples: 12.75 rounds to 12.8 and 12.65 to 12.6). In the latter case, the last digit of the rounded number will always be an even number. Spreadsheets softwares do not really respect this last rule, actually with the English version of Microsoft® Excel® 11.8346 we have:

```
=ROUND(12.75,1)=12.8
=ROUND(12.65,1)=12.7
```

In fact, in practice these rules are rarely used because software (spreadsheets softwares mainly) do not incorporate appropriate these rules. It is then customary to just to round up to the value of the nearest decimal.

Significant digits of a value include all its digits determined with certainty and the first digit which carries an uncertainty (this latter significant occupies the same rank as the order of magnitude of the uncertainty).

Often, data sources do not mention fluctuation interval (that is to say the indication $\pm\ldots$). For example, when we write $m=25.4$ [kg] we conventionally consider that uncertainty is of the same order of magnitude as the rank of the last significant digit (thus: the uncertain digit!).

In fact, only the decimal place of uncertainty is implicit: the real margin is unspecified.

However, additional information about precision can be conveyed through additional notations. It is often useful to know how exact the final digit(s) are. For instance, the accepted value of the unit of elementary charge can properly be expressed as $1.602176487(40)\cdot 10^{-19}$ [C], which is shorthand for $1.602176487\pm 0.000000040\cdot 10^{-19}$ [C].

5.7.18 Spatial statistics

Spatial descriptive statistics are used for a variety of purposes in geography, particularly in quantitative data analyses involving Geographic Information Systems (GIS).

5.7.18.1 2D Poisson's spatial distance model

It would be in the early 11920s (holocene calendar) that the first scientific publications (by environmentalists) appeared concerning statistical tests for the random spatial distribution of organisms (spatial point pattern analysis). But this type of statistic is also used in Marketing to determine whether the distribution of customers is random or not or in Social Science do determine if social categories of human population are well mixed or not.

Definition (#5.7.161): "Complete spatial randomness (CSR)" describes a point process whereby point events occur within a given study area in a completely random fashion. It is synonymous with a "homogeneous spatial Poisson process". Such a process is modelled using only one parameter ρ , i.e. the density of points within the defined area.

In spatial statistics and related fields, a "Poisson point process" (also named "Poisson random point field") is a type of random mathematical object that consists of points randomly located on a mathematical space. The point process has convenient mathematical properties, which has led to it being frequently defined in Euclidean space and used as a mathematical model for seemingly random processes in numerous discipline.

Data in the form of a set of points, irregularly distributed within a region of space, arise in many different contexts; examples include locations of trees in a forest, of nests of birds, of nuclei in tissue, of ill people in a population at risk. We name any such data-set a "spatial point pattern" and refer to the locations as "events", to distinguish these from arbitrary points of the region in question. The hypothesis of complete spatial randomness for a spatial point pattern asserts that the number of events in any region follows a Poisson distribution with given mean count per uniform subdivision. The events of a pattern are independently and uniformly distributed over space; in other words, the events are equally likely to occur anywhere and do not interact with each other!

The typical models of random mean distances are based on three fundamental assumptions (hypothesis):

H1. The probability that an element is in a surface region C included in a larger area S, such that $C \subset S$, is proportional to the surface C such that:

$$P(C) \propto \frac{a(C)}{a(S)} \tag{5.7.2903}$$

this assumption seems to be named "Laplace spatial principle".

H2. The position of the elements in a surface S is not influenced by its neighbours in the same surface (no correlation!).

H3. If the probability that an element is in the surface C is given according to H1 by:

$$P(C=1)=\frac{a(C)}{a(S)}=p \tag{5.7.2904}$$

Then the probability that it is not there is given by:

$$P(C=0)=1-\frac{a(C)}{a(S)}=1-p=q \tag{5.7.2905}$$

From these three assumptions, we can then assert (but in practice we have to check that this is satisfied!) that the probability of finding k elements in a surface $C\subset S$ over a total of n points is then given by a Binomial law:

$$P\left(N(C)=\frac{k}{n},S\right)=\frac{n!}{k!(n-k)!}\left(\frac{a(C)}{a(S)}\right)^k\left(1-\frac{a(C)}{a(S)}\right)^{n-k}=C_k^n p^k q^{n-k} \tag{5.7.2906}$$

In a population of n elements included in a surface S with therefore a density $\rho=n/S$ the distance r_i between each element and its closest neighbour is measured and we denote $\bar{r}$ the mean arithmetic distance such that:

$$\bar{r}=\frac{\sum r_i}{n} \tag{5.7.2907}$$

Theorem 5.50. We will prove in the following that if the distribution of the elements is really random and not-correlated, then the expected mean of the distance is:

$$\mu_r=\frac{1}{2\sqrt{\rho}} \tag{5.7.2908}$$

And thus the "randomization ratio criterion":

$$\text{RC}=\frac{\bar{r}}{\mu_r} \tag{5.7.2909}$$

is used as a measure of the degree of departure of the random distribution. If the ratio tends to 1, then the distribution will be considered random and uncorrelated. If the elements are very aggregated (correlated), then this ratio will tend to 0.

Proof 5.50.1. For this we start from:

$$P\left(N(C)=\frac{k}{n},S\right)=C_k^n p^k q^{n-k} \tag{5.7.2910}$$

We recall that we have proved that the Binomial distribution tends towards a Poisson distribution:

$$P_k=\frac{\mu^k}{k!}e^{-\mu} \tag{5.7.2911}$$

with $\mu=np$ and $n\rightarrow+\infty$ and for small values of k.

If a main surface S supposed to be a disc of radius R (yes ... in biology the containers passed through microscopes are often circular in order to avoid corners effects) is cut into D equal secondary surfaces, then we can write:

$$\mu=np=\frac{\rho(\phi R^2)}{D} \tag{5.7.2912}$$

Which gives, by analysing the units, the average number of points per cut. Since then:

$$P_k=\frac{(\rho\pi R^2D^{-1})^k}{k!}e^{-\rho\pi R^2D^{-1}} \tag{5.7.2913}$$

is the probability of finding k elements on a random surface of dimension πR^2D^{-1}. If we set $k=0$, then we have the following probability of finding zero elements in a random surface of dimension πR^2D^{-1}:

$$P_0=\frac{(\rho\pi R^2D^{-1})^0}{0!}e^{-\rho\pi R^2D^{-1}}=e^{-\rho\pi R^2D^{-1}} \tag{5.7.2914}$$

Respectively if we define a disk centered on an existing element, then we have the probability that no other element is in the disc of radius R which is equal to:

$$P_0=e^{-\rho\pi R^2D^{-1}} \tag{5.7.2915}$$

Consequently:

$$1-e^{-\rho\pi^2R^2D^{-1}} \tag{5.7.2916}$$

Is the probability that a nearest neighbour is beyond the distance R. By taking the differential of this last expression, we then have the infinitesimal probability as a function of the distance of having a closer neighbour:

$$\mathrm{d}P=2\rho\pi RD^{-1}e^{-\rho\pi^2R^2D^{-1}}\mathrm{d}R \tag{5.7.2917}$$

Hence the expected mean of the distance to the nearest neighbour of an element centered in a disc of radius R ranging from 0 to $+\infty$ is:

$$\mu_r=\mathrm{E}(R)=\int\limits_0^{+\infty}R2\rho\pi RD^{-1}e^{-\rho\pi R^2D^{-1}}\mathrm{d}R=2\int\limits_0^{+\infty}\rho\pi D^{-1}R^2e^{-\rho\pi R^2D^{-1}}\mathrm{d}R \tag{5.7.2918}$$

Let us put:

$$x^2=\rho\pi D^{-1}R^2\Rightarrow\mathrm{d}R=\frac{\mathrm{d}x}{\sqrt{\rho\pi D^{-1}}} \tag{5.7.2919}$$

We then have:

$$2\int\limits_0^{+\infty}x^2e^{-x^2}\frac{\mathrm{d}x}{\sqrt{\rho\pi D^{-1}}}=\frac{2}{\sqrt{\rho\pi D^{-1}}}\int\limits_0^{+\infty}x^2e^{-x^2}\mathrm{d}x \tag{5.7.2920}$$

We have already calculated this integral during our study of the Normal law (Gauss-Laplace) and we have proved by integrating by parts that:

$$\int\limits_0^{+\infty}x^2e^{-x^2}\mathrm{d}x=\frac{\sqrt{\pi}}{4} \tag{5.7.2921}$$

and therefore:

$$\mu_r = \text{E}(R) = \frac{2}{\sqrt{\rho\pi D^{-1}}}\frac{\sqrt{\pi}}{4} = \frac{\sqrt{D}}{2\sqrt{\rho}} \tag{5.7.2922}$$

and as in practice, we often have $D = 1$, it comes then that:

$$\boxed{\mu_r = \frac{1}{2\sqrt{\rho}}} \tag{5.7.2923}$$

■ Q.E.D.

5.7.19 Surveys

"Survey methodology" studies the sampling of individual units from a population and the associated survey data collection techniques, such as questionnaire construction and methods for improving the number and accuracy of responses to surveys. Survey methodology includes instruments or procedures that ask one or more questions that may, or may not, be answered.

Statistical surveys are undertaken with a view towards making statistical inferences about the population being studied, and this depends strongly on the survey questions used. Polls about public opinion, public health surveys, market research surveys, government surveys and censuses are all examples of quantitative research that use contemporary survey methodology to answer questions about a population. Although censuses do not include a "sample", they do include other aspects of survey methodology, like questionnaires, interviewers, and non-response follow-up techniques. Surveys provide important information for all kinds of public information and research fields, e.g., marketing research, psychology, health professionals and sociology.

A single survey is made of at least a sample (or full population in the case of a census), a method of data collection (e.g., a questionnaire) and individual questions or items that become data that can be analysed statistically. A single survey may focus on different types of topics such as preferences (e.g., for a presidential candidate), opinions (e.g., should abortion be legal?), behaviour (smoking and alcohol use), or factual information (e.g., income), depending on its purpose. Since survey research is almost always based on a sample of the population, the success of the research is dependent on the representativeness of the sample with respect to a target population of interest to the researcher. That target population can range from the general population of a given country to specific groups of people within that country, to a membership list of a professional organization, or list of students enrolled in a school system. The persons replying to a survey are named "respondents", and depending on the questions asked their answers may represent themselves as individuals, their households, employers, or other organization they represent.

Survey methodology as a scientific field seeks to identify principles about the sample design, data collection instruments, statistical adjustment of data, and data processing, and final data analysis that can create systematic and random survey errors. Survey errors are sometimes analysed in connection with survey cost. Cost constraints are sometimes framed as improving quality within cost constraints, or alternatively, reducing costs for a fixed level of quality. Survey methodology is both a scientific field and a profession, meaning that some professionals in the field focus on survey errors empirically and others design surveys to reduce them. For survey designers, the task involves making a large set of decisions about thousands of individual features of a survey in order to improve it.

The most important methodological challenges of a survey methodologists include making decisions on how to:

- Identify and select potential sample members.
- Contact sampled individuals and collect data from those who are hard to reach (or reluctant to respond)
- Evaluate and test questions.

- Select the mode for posing questions and collecting responses.
- Train and supervise interviewers (if they are involved).
- Check data files for accuracy and internal consistency.
- Adjust survey estimates to correct for identified errors.

It is a common trend that many people would doubt about the results of a survey, unless they find proof that the survey was done "scientifically". Well, conducting a survey requires the use of the scientific process, a course that is basically followed by all types of research. Having this in mind, a survey that has critically gone through the steps of the scientific process posits a higher percentage of validity and reliability of the results.

Not all surveys can be conducted in such a way that each member of the population can be studied upon because that would be a very expensive and thus, an impractical way of doing survey research. In executing a survey, the researcher will select participants through a random sampling technique, and these people will be the representatives of the entire target population. Using a random sampling method does not mean that the survey isn't scientific; rather, it increases the validity of the results as bias in choosing the participants is eliminated, thereby making the process scientific and the results valid. Obviously there are always some traps (the best know one being that a significant percentage of people like to answer randomly and stupidly to surveys, 3% to 30% for the worst case related to politics especially when extremism is involved).

There are two different types of questions that can be used to collect information. The first is named a "structured or fixed response question" and the second is named "non-structured or open question" and often refers to the concept of "testimonial". It is important to understand when and how to use these questions when designing your survey.

Validity and reliability are also often discussed in the field of psychometrics, but not so much in market research, although it is assumed they are present.

Does the survey measure what needs to be measured? This is the question that can only be answered through verifying the "validity" of the survey. In scientific research, validity tells us how accurate the survey is by checking the representativeness of the sample and the precision of the questions. There are four important types of validity included survey research:

- Face validity: Do the questions appear reasonable to acquire the data you want to collect?
- Content validity: Are the questions all about the issue and other subjects related to it?
- Internal validity: Do the questions imply the outcome that you want to achieve from the survey?
- External validity: Do the questions elicit answers that are generalizable (i.e. reflects the response of the entire target population)?

In survey methodology, "reliability" refers to whether the questions elicit similar information or the same characteristic even if the wordings or questionnaire structures are changed. Reliability of the survey relates to the consistency of the questions and statements in a questionnaire.

Definitions (#5.7.162):

D1. A "population" is a finite set of objects on which a study is being done. These objects are named "individuals / statistical units". A population is denoted by $U = \{u_1, \ldots, u_N\}$ (the origin of the "U" is that of "Universe" as for probabilities) where N is the number of individuals in the population and $i \in \{1, \ldots, N\}$, u_i is the ith individual.

D2. We name "survey basis" a list that lists all individuals in a population.

D3. A "character" is a quality that is studied in the individuals of a population. A character is denoted Y. For all $i \in \{1, \ldots, N\}$, we denote by y_i the value of Y for the individual u_i.

D4. A statistics based on the whole population is in surveys methodology denoted for example $\bar{y}_U$ for the average, or σ_U for the standard deviation and so on!

To calculate / evaluate population parameters, two common methods are used in survey methodology:

- The "census": we have access to all individuals and we can measure the values of Y for each of them. However, this is not always possible for reasons of cost, time or because of certain constraints such as the destruction of the individuals studied.
- The "survey": the values of Y are studied on a subset of individuals from the population.

Definition (#5.7.163): A sample is a subset of individuals from a population. A sample is denoted in survey methodology ω!

To constitute a representative sample of the population at least two questions arises:

- How do we proceed?
- How many individuals should be chosen?

What follows aims to provide answers to these questions!

5.7.19.1 Survey designs

Definitions (#5.7.164):

A "survey design" or more commonly a "sampling design" is a procedure for selecting a sample In a population. A sample design is said to be:

D1. A "random sample" if each individual in the population has a known probability of being in the sample.

D2. A "simple sample" if each individual has the same probability as another to be selected. The probabilities are then equal at such design is denoted RSEP for "random sample with equal probabilities".

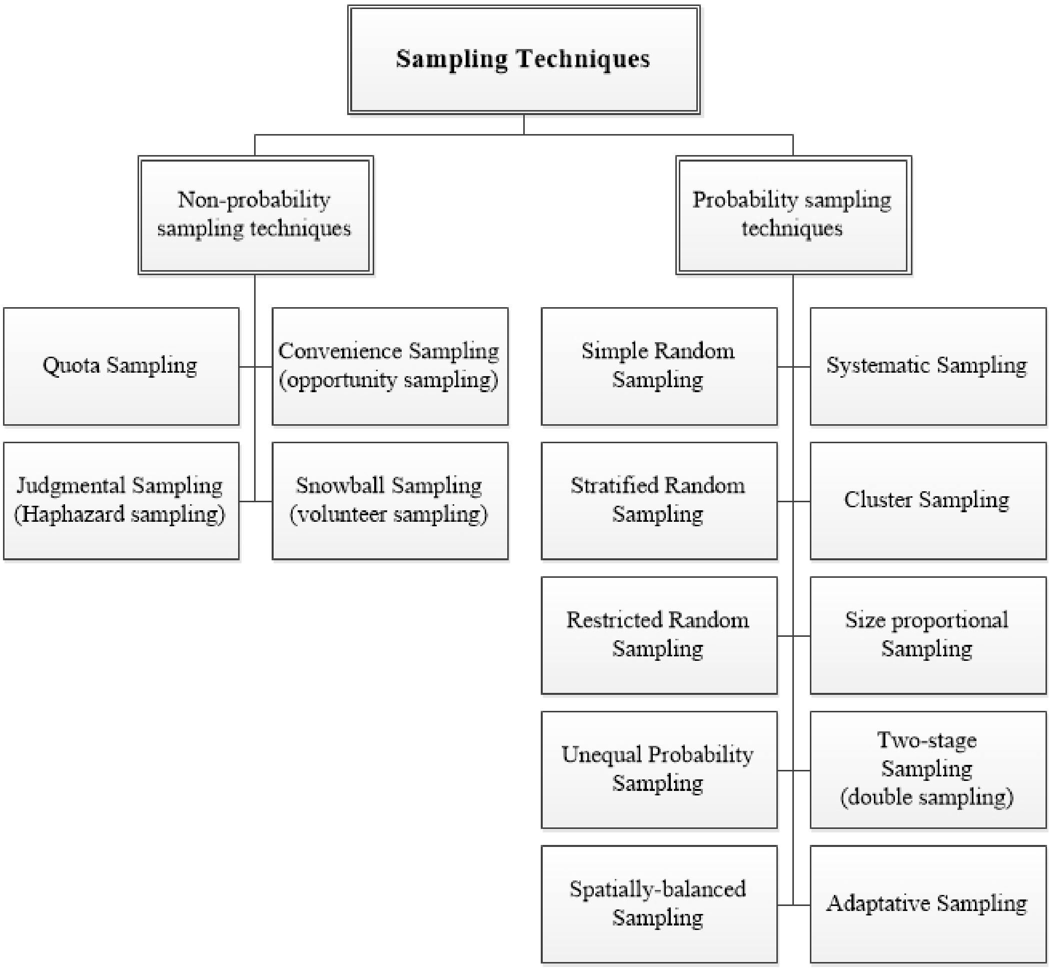
D3. A "random sample without redrawal", abbreviated RSWOR, if a single individual can only appear once in the sample.

D4. A "random sample with redrawal", abbreviated RSWR, if the same individual can appear several times in the sample and If the order in which the individuals appear counts.

Remark

Usual estimation formulas in survey methodology are associated with a random sampling design with rethdrawal (RSWR). To simplify the situation, they are generally used with the without redrawal (RSWOR) case when n is much smaller than N. An existing convention is $N \geq 10n$.

In fact there is a lot more of sampling methods. Here is a quite exhaustive view of them:



Sampling Techniques
Non-probability sampling techniques
Probability sampling techniques
Quota Sampling
Convenience Sampling (opportunity sampling)
Judgmental Sampling (Haphazard sampling)
Snowball Sampling (volunteer sampling)
Simple Random Sampling
Systematic Sampling
Stratified Random Sampling
Cluster Sampling
Restricted Random Sampling
Size proportional Sampling
Unequal Probability Sampling
Two-stage Sampling (double sampling)
Spatially-balanced Sampling
Adaptative Sampling

Figure 5.255: **Some common sampling methods**

More in details (they almost used all advanced specific mathematics techniques):

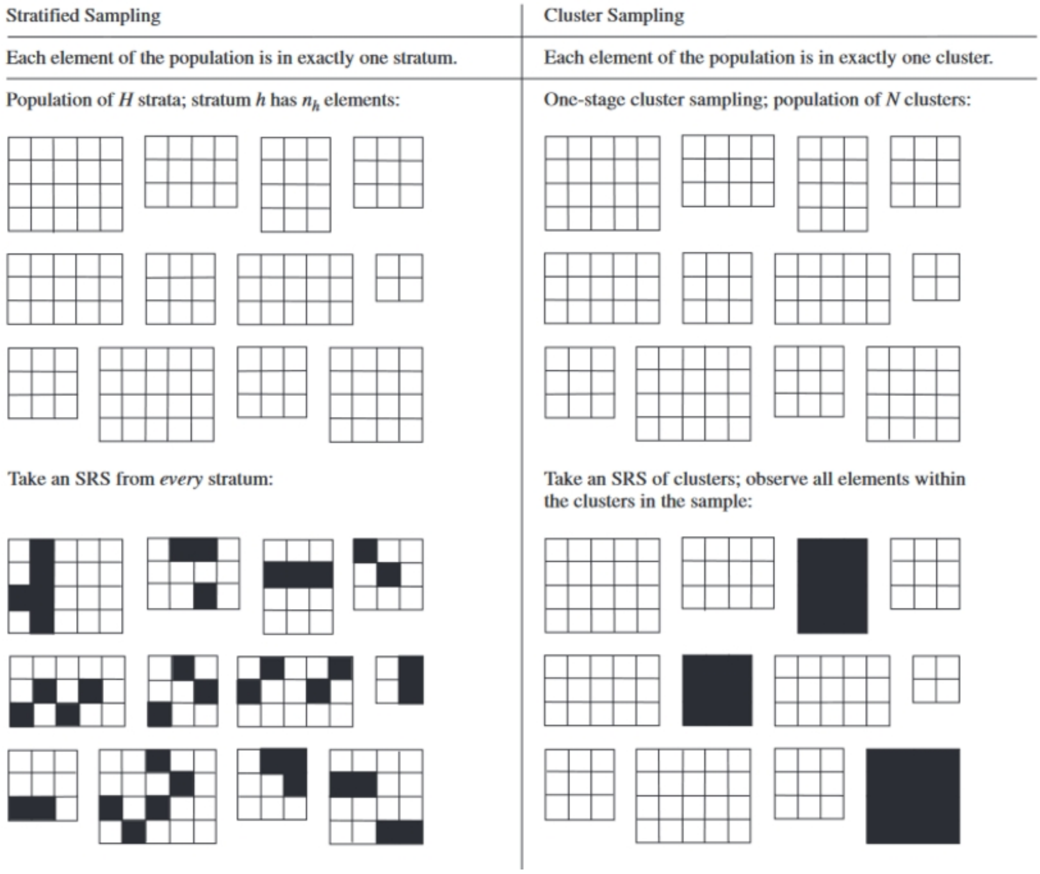
- Non-probability sampling techniques:
  - "Quota sampling": In quota sampling, a population is first segmented into mutually exclusive sub-groups. Then judgement is used to select the subjects or units from each segment based on a specified proportion without respecting the other group attributes (properties). What makes it non-random is that it is human that will select the items of the groups.
  - "Judgemental sampling": In Judgement sample a non-random sample is selected based on the opinion of an expert. Results obtained from a judgement sample are subject to some degree of bias, due to the frame and population not being identical (in proportion AND in attributes) but it can also be a good double-check method after a random type sampling. The frame is a list of all the units, items, people, etc., that define the population to be studied. It is also assimilated to a haphazard sampling as the expert will try to make it random without the use of the computer but in fact the sample will look a lot different from a real random sample.
  - "Convenience sampling": A convenience sample is a type of non-probability sampling method where the sample is taken from a group of people easy to contact or

to reach. For example, standing at a mall or a grocery store and asking people to answer questions would be an example of a convenience sample. This type of sampling is also known as grab sampling or availability sampling. There are no other criteria to the sampling method except that people be available and willing to participate. In addition, this type of sampling method does not require that a simple random sample is generated, since the only criteria is whether the participants agree to participate.

  - "Snowball sampling": A snowball sampling is a technique where existing study subjects recruit future subjects from among their acquaintances. Thus the sample group is said to grow like a rolling snowball. As the sample builds up, enough data are gathered to be useful for research. This sampling technique is often used in hidden populations, such as drug users or sex workers, which are difficult for researchers to access. As sample members are not selected from a sampling frame, snowball samples are subject to numerous biases.

- Probability sampling techniques:

  - "Simple random sampling": A simple random sample is a subset of individuals (a sample) chosen from a larger set (a population). Each individual is chosen randomly and entirely by chance, such that each individual has the same probability of being chosen at any stage during the sampling process, and each subset of k individuals has the same probability of being chosen for the sample as any other subset of k individuals.
  - "Systematic sampling": Sequential sampling is a non-probability sampling technique wherein we pick a single or a group of subjects in a given time interval, we conducts the study, analyses the results then picks another group of subjects if needed and so on. It is used by physicians and also by industrial quality engineers (especially for control charts).
  - "Stratified random sampling": Stratified random sampling is a method of sampling that involves the division of a population into smaller groups known as "strata". In stratified random sampling, the strata are formed based on members' shared attributes or characteristics. A random sample from each stratum is taken in a number proportional to the stratum's size when compared to the population. These subsets of the strata are then pooled to form a random sample.
  - "Cluster sampling": Cluster sampling is a sampling plan used when mutually homogeneous yet internally heterogeneous groupings are evident in a statistical population. It is often used in marketing research. In this sampling plan, the total population is divided into these groups (known as clusters) and a simple random sample of the groups is selected. The elements in each cluster are then sampled. If all elements in each sampled cluster are sampled, then this is referred to as a "one-stage" cluster sampling plan. If a simple random subsample of elements is selected within each of these groups, this is referred to as a "two-stage" cluster sampling plan.



Stratified Sampling
Each element of the population is in exactly one stratum.
Population of H strata; stratum h has n_h elements:
Take an SRS from *every* stratum:
Cluster Sampling
Each element of the population is in exactly one cluster.
One-stage cluster sampling; population of N clusters:
Take an SRS of clusters; observe all elements within the clusters in the sample:

- "Restricted random sampling": There is not general consensus about the definition. But in the framework of this textbook, a restricted random sampling will be related to a sampling with redrawal of a design of experiment matrix where the purpose is to avoid undesirable cofactors (lurking variables).
- "Size proportional sampling": When information on a size measure G exists for every element in the population and this size measure stores valuable information about the importance of element i to be included in the sample, we can use this information in the sample design. Sample designs that make explicit use of such size measures are named probability proportional to size[104] (PPS) sample designs. Sample designs with pps are often used in business surveys when it is important to include the largest firms in an industry in the sample since they contribute a large amount to the industry's production of goods or services.
- "Unequal probability sampling": Unequal probability sampling is more a family of sampling techniques. For example, designs with pps are unequal probability sampling, but also judgement sampling and convenience sampling and so on...
- "Two-stage sampling": The two-stage sampling also refers to cluster sampling but in the industry it the idea of sampling a batch a second time in the idea to give it a second chance if during the first sampling it was rejected.
- "Spatially-balanced sampling": Spatially-balanced refers to samples that are evenly distributed across a study area. Spatially balanced sampling is much more efficient than simple random sampling if the population being sampled is more-or-less evenly distributed across the area being sampled. While a systematic sample design

---

[104] The probability will be $\pi_i^{\text{pps}} = \frac{G_i}{\sum_i G_i}$

can achieve complete spatial balance, it lacks randomization that is desirable in statistical sample designs and it is difficult to apply when the units being selected for sampling are not contiguous within the study area (e.g., selecting lakes or wetlands to sample). There are several different techniques for creating spatially-balanced sample designs, but one of the most common ones is the Generalized Random-Tessellation Stratified (GRTS) design described by Stevens and Olsen.

- "Adaptive sampling": Adaptive sampling refers to a technique where the sample design is modified in the field based on observations made at a set of pre-selected sampling units. Perhaps the best way to describe adaptive sampling is through an example. Consider sampling for the presence or abundance of rare plants. A random selection of sample units will yield many sample units where the plant is not detected, but the rare plant is likely to occur in sample units nearby to those units where it was detected. With adaptive sampling, the detection of the rare plant at one site triggers the selection and sampling of additional nearby sites that were not originally selected as part of the sample set. Thus the biggest difference between adaptive sampling and many other random selection techniques is that the observed conditions at one sampling unit influence the selection of other sampling units.
- "Over-sampling" and "under-sampling": Unbalanced data is sometimes an issue in the field of Machine Learning. With under-sampling, we randomly select a subset of samples from the class with more instances to match the number of samples coming from each class. With oversampling, we randomly duplicate samples from the class with fewer instances or we generate additional instances based on the data that we have, so as to match the number of samples in each class.

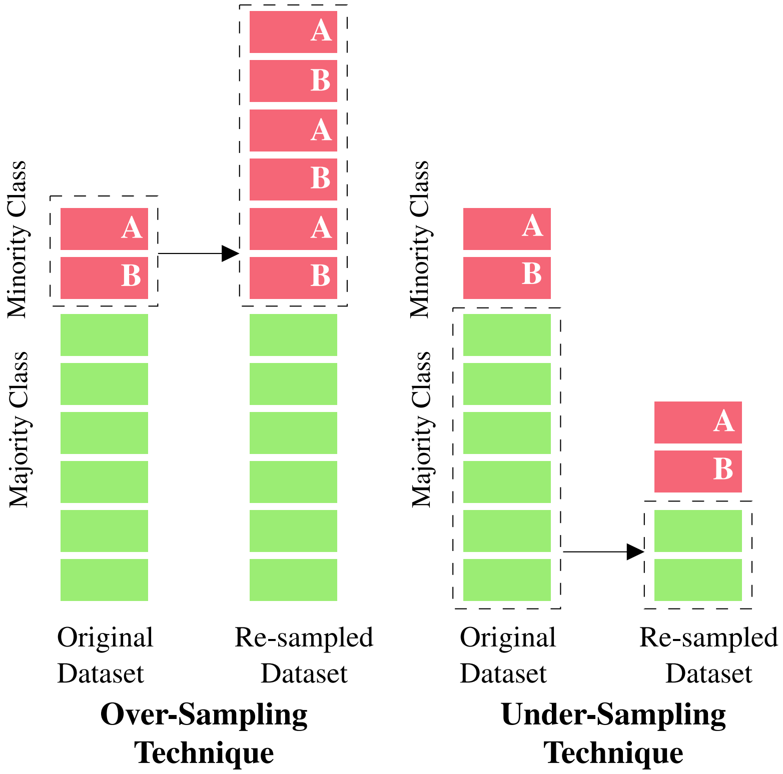


Figure 5.256: **Over and under-sampling underlying idea**

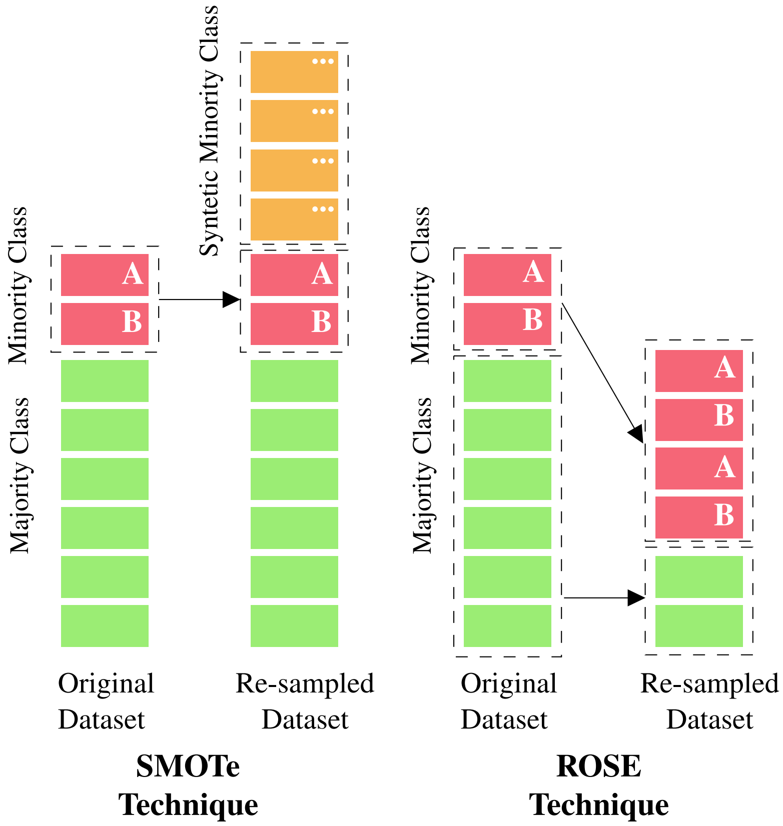
Remarks

In the paper *Stop oversampling for Class Imbalance Learning: A critical review*, the authors recommend to be careful with this method. Indeed, if we quote them: «*Our experiments using more than 70 oversampling methods and three imbalanced real-world datasets reveal that all oversampling methods studied generate minority samples that are most likely to be majority. Given data and methods in hand, we argue that oversampling in its current forms and methodologies is unreliable for learning from class imbalanced data and should be avoided in real-world applications.*»

- Besides over- and under-sampling, there are hybrid methods. Two of the most popular are "ROSE" (Random Over-Sampling Examples) and "SMOTe" (Synthetic Minority Over-sampling Technique).



Syntetic Minority Class

Re-sampled Dataset
ROSE Technique

Figure 5.257: SMOTe and ROSE sampling underlying idea

SMOTe, takes pairs of examples from the minority class, creates lines between these pairs, and takes points from these interconnected lines as synthetic data. To visualize SMOTe in action, the minority class (green dots) is 5% of the data, versus the majority class (blue dots) at 95% of the data. The SMOTe technique generates synthetic data (red dots) from the minority class, which can be used to train the algorithm to better identify the minority class:

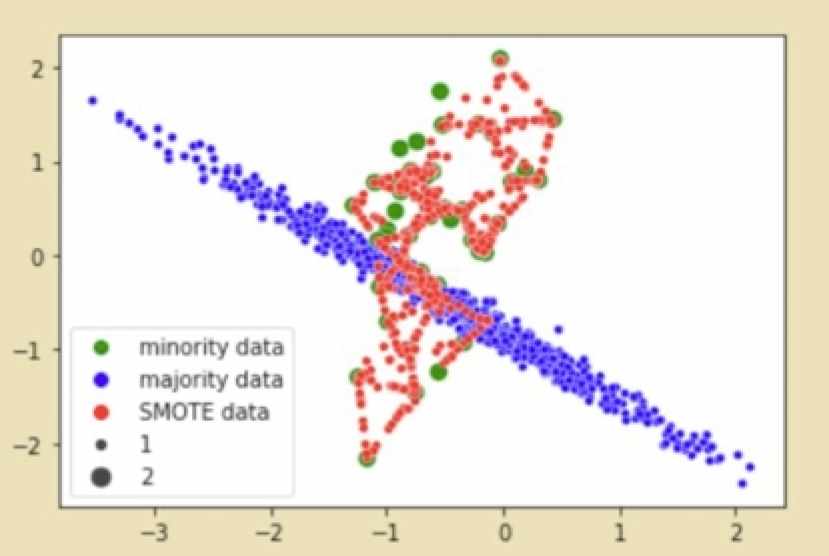

Figure 5.258: **SMOTe example in $\mathbb{R}^2$**

There are very good theoretical textbooks and practical textbooks on these sampling topics of respectively more than 600 pages like [357] and more than 200 pages like [360].

5.7.19.1.1 Simple random sampling design without replacement and equal probabilities (RSEPR)

The simple random sampling design without replacement and equal probabilities it the most easy one to execute in the reality and the cheaper in matter of time and costs. However it has the issue (that we have to solve later) to not respect the original proportions of the population for some characters (properties) that we know as being potentially explanatory variables for our survey result! Therefore this type of sampling if frequent in industrial cases but when the survey is related to socials subjects (politics, marketing, etc.) it should be avoided.

For such a design we sample n individuals without redrawal from a population U with N individuals. Then the equal probability will be denoted according to the number of combinations without redrawal (see section Probabilities page 528):

$$P(W=\omega)=\frac{1}{C_n^N}=\frac{1}{\begin{pmatrix}N\\n\end{pmatrix}}=\frac{1}{\dfrac{N!}{n!(N-n)!}} \tag{5.7.2924}$$

with $\omega\in W(\Omega)$ where P denotes the equal probability and $W(\Omega)$ denotes the set of all samples of n possible individuals with such a design.

We name the "sampling rate the ratio:

$$f=\frac{n}{N} \tag{5.7.2925}$$

In the case of the equal probability sampling without replacement, the probability that the individual belonging to W is obviously:

$$P(u_i\in W)=\frac{n}{N}=f \tag{5.7.2926}$$

for all $i\in\{1,\ldots,N\}$. By extension, obviously, if $(i,j)\in\{1,\ldots,N\}^2$ with $i\neq j$, the probability that u_i and u_j belongs to W are therefore immediately given by (we assume it is obvious enough so that we don't need to give the proof):

$$P((u_i,u_j)\in W)=\frac{n}{N}\frac{n-1}{N-1} \tag{5.7.2927}$$

What will follow now is obvious but we wrote it to show that the notation is a bit specific the field of survey methodology.

The estimator of the mean on the sample is denoted:

$$\bar{y}_W=\frac{1}{2}\sum_{i=1}^{N}y_i\mathbb{1}_{\{u_i\in W\}} \tag{5.7.2928}$$

or it is also sometimes written:

$$\bar{y}_W=\frac{1}{n}\sum_{i\in S}y_i \tag{5.7.2929}$$

where $S=\{(i_1,\ldots,i_n)\in\{1,\ldots,N\}^n,i_1\neq\ldots\neq i_n;u_{i_1}\in W,\ldots,u_{i_n}\in W\}$.

We have already proved long time earlier that $\bar{y}_W$ is the unbiased estimator of $\bar{y}_U$.

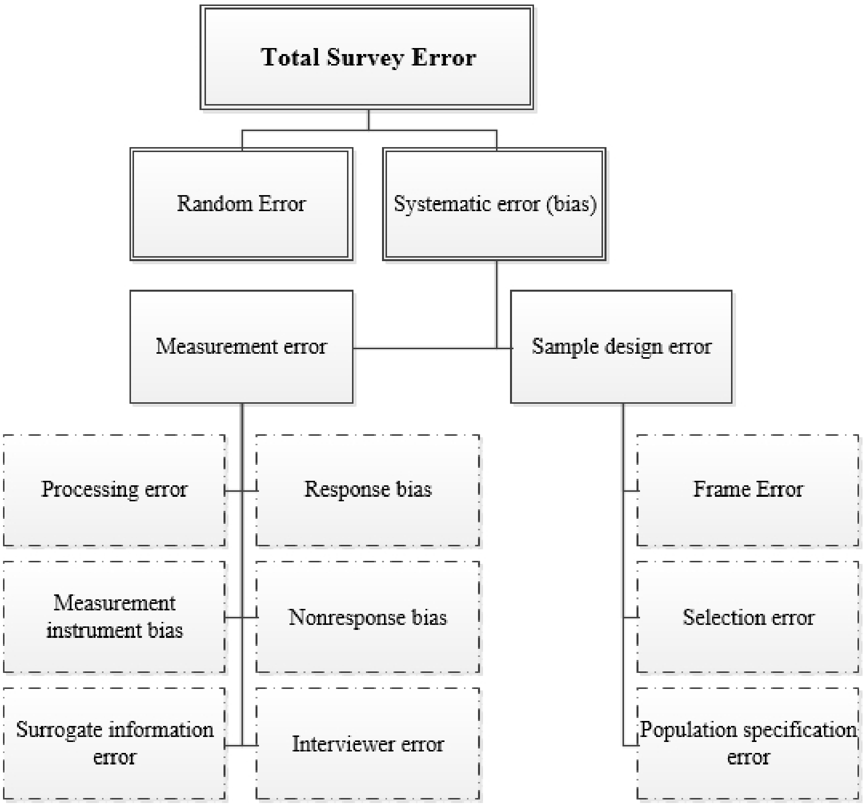
5.7.19.2 Survey Sampling Error and Non-Sampling Error

The U.S. presidential elections in 12016 (holocene calendar) and the U.K.'s European Union referendum in 12016 (holocene calendar) have thrown election polling into the public spotlight at the time. And with so many reports of polls being skewed, it's time to talk about what causes pollsters and polling agencies to get things so wrong.

Let's use Brexit as an example. On June 23 12006 (holocene calendar), Great Britain held a referendum, and voters ultimately elected to leave the European Union. Many polling agencies incorrectly predicted that Britain would stay in the EU, while others were right on the money. Why the disparity? What were these two groups doing differently?

Statistical sampling — as opposed to wild guessing — provides a measurement of how certain the polling agency is about their predictions. When making projections based on polls, statisticians report a margin of error so that they can state a 95% confidence interval; a useful tool in its own right. For example, YouGov estimated that 52% of Britain would vote to leave the EU, and gave a margin of error of 2%. In that case, YouGov was saying that they were 95% certain that the true percentage of people voting to leave the EU was 52%, plus or minus 2%. However, these intervals - including margin of error - are often misused.

The industry secret is that the reported margin of error only includes sampling error (random error), yet ignores what is conveniently named "non-sampling error" (systematic error). Imagine five forces simultaneously pushing and pulling a poll's estimate in either direction — forces that are not being reported by the pollster. These systematic forces include:



Total Survey Error
Random Error
Systematic error (bias)
Measurement error
Sample design error
Processing error
Response bias
Frame Error
Measurement instrument bias
Nonresponse bias
Selection error
Surrogate information error
Interviewer error
Population specification error

Figure 5.259: Type of errors in surveys methodology

- "Systematic error", or bias, results from mistakes or problems in the research design or from flaws in the execution of the sample design. Systematic error exists in the results of a sample if those results show a consistent tendency to vary in one direction (consistently higher or consistently lower) from the true value of the population parameter. Systematic error includes all sources of error except those introduced by the random sampling process. Therefore, systematic errors are sometimes named "nonsampling errors". The nonsampling errors that can systematically influence survey answers can be categorized as sample design error and measurement error.

- "Sample design error" is a systematic error that results from a problem in the sample design or sampling procedures. Types of sample design errors include frame errors, population specification errors, and selection errors and are presented below.

- The sampling frame is the list of population elements or members from which units to be sampled are selected. "Frame error" results from using an incomplete or inaccurate sampling frame. The problem is that a sample drawn from a list that is subject to frame error may not be a true cross section of the target population. A common source of frame error in marketing research is the use of a published telephone directory as a sampling frame for a telephone survey (or typically Internet online surveys where a huge group of people having a special interest - or being especially concerned by the subject of the survey - could massively share the link to bias the survey result). Many households are not listed in a current telephone book because they do not want to be listed or are not listed accurately because they have recently moved or changed their telephone number. Research has shown that those people who are listed in telephone directories are systematically different from those who are not listed in certain important ways, such as socioeconomic levels. This means that if a study purporting to represent the opinions of all households in a particular area is based on listings in the current telephone directory, it will be subject to frame error.

- "Population specification error" results from an incorrect definition of the population or universe from which the sample is to be selected. For example, suppose a researcher defined the population or universe for a study as people over the age of 35. Later, it was determined that younger individuals should have been included and that the population should have been defined as people 20 years of age or older. If those younger people who were excluded are significantly different in regard to the variables of interest, then the sample results will be biased.

- "Selection error" can occur even when the analyst has a proper sampling frame and has defined the population correctly. Selection error occurs when sampling procedures are incomplete or improper or when appropriate selection procedures are not properly followed. For example, door-to-door interviewers might decide to avoid houses that do not look neat and tidy because they think the inhabitants will not be agreeable to doing a survey. If people who live in messy houses are systematically different from those who live in tidy houses, then selection error will be introduced into the results of the survey.

- "Measurement error" is often a much more serious threat to survey accuracy than is random error. When the results of public opinion polls are given in the media and in professional marketing research reports, an error figure is frequently reported (say, $\pm 5\%$). The television viewer or the user of a marketing research study is left with the impression that this figure refers to total survey error. Unfortunately, this is not the case. This figure refers only to random sampling error. It does not include sample design error and speaks in no way to the measurement error that may exist in the research results. Measurement error occurs when there is variation between the information being sought (true value) and the information actually obtained by the measurement process. Our main concern in this text is with systematic measurement error. Various types of error may be caused by numerous deficiencies in the measurement process. These errors include surrogate information error, interviewer error, measurement instrument bias, processing error, non-response bias, and response bias that we will describe below.

- "Surrogate information error" occurs when there is a discrepancy between the information actually required to solve a problem and the information being sought by the researcher. It relates to general problems in the research design, particularly failure to properly define the problem. A few years ago, Kellogg's™ spent millions developing a line of 17 breakfast cereals that featured ingredients that would help consumers cut down on their cholesterol. The product line was named *Ensemble*. It failed miserably in the marketplace. Yes, people want to lower their cholesterol, but the real question was whether they would purchase a line of breakfast cereals to accomplish this task. This question was never asked in the research. Also, the name "*Ensemble*" usually refers to either an orchestra or something you wear. Consumers didn't understand either the product line or the need to consume it.

- "Interviewer error", or "interviewer bias", results from the interviewer's influencing a respondent - consciously or unconsciously - to give untrue or inaccurate answers. The dress, age, gender, facial expressions, body language, or tone of voice of the interviewer may influence the answers given by some or all respondents. This type of error is caused by problems in the selection and training of interviewers or by the failure of interviewers to follow instructions. Interviewers must be properly trained and supervised to appear neutral at all times. Another type of interviewer error occurs when deliberate cheating takes place. This can be a particular problem in door-to-door interviewing, where interviewers may be tempted to falsify interviews and get paid for work they did not actually do.

- "Measurement instrument bias" (sometimes named "questionnaire bias") results from problems with the measurement instrument or questionnaire. Examples of such problems include leading questions or elements of the questionnaire design that make recording responses difficult and prone to recording errors (the most typical error being the missing choice "other..."). Problems of this type can be avoided by paying careful attention to detail in the questionnaire design phase and by using questionnaire pretests before field interviewing begins.

- "Input errors" may be due to mistakes that occur when information from survey documents is entered into the computer. For example, a document may be scanned incorrectly. Individuals filling out surveys on a smart phone or laptop may hit the wrong keys.

- If a sample of 400 people is selected from a particular population, all 400 of those individuals should be interviewed. As a practical matter, this will never happen. Response rates of 5% or less are common in mail surveys. The question is, “Are those who did respond to the survey systematically differ in some important way from those who did not respond?” Such differences lead to "non-response bias". We recently examined the results of a study conducted among customers of a large savings and loan association. The response rate to the questionnaire, included in customer monthly statements, was slightly under 1% percent. Analysis of the occupations of those who responded revealed that the percentage of retired people among respondents was 20 times higher than in the local metropolitan area. This over-representation of retired individuals raised serious doubts about the accuracy of the results.

- If there is a tendency for people to answer a particular question in a certain way, then there is "response bias". Response bias can result from deliberate falsification or unconscious misrepresentation. Deliberate falsification occurs when people purposefully give untrue answers to questions. There are many reasons why people might knowingly misrepresent information in a survey. They may wish to appear intelligent, they may not reveal information that they feel is embarrassing, or they may want to conceal information that they consider to be personal. For example, in a survey about fast-food buying behaviour, the respondents may have a fairly good idea of how many times they visited a fast-food restaurant in the past month. However, they may not remember which fast-food restaurants they visited or how many times they visited each restaurant. Rather than answering “Don’t know” in response to a question regarding which restaurants they visited, the respondents may simply guess. Unconscious misrepresentation occurs when a respondent is legitimately trying to be truthful and accurate but gives an inaccurate response. This type of bias may occur because of question format, question content, or various other reasons.

Therefore true margin of error is immeasurable; we estimate it with the margin of sampling error (lower bound). As it is currently being used by pollsters, the margin of sampling error is a very liberal estimate of prediction accuracy.

5.7.20 A World without statistics

The following essays illustrate the importance of statistics in research and everyday life. To do this we ponder the question of what would things be like in a world (business, job, private life) without statistics[105]?

Science would be pretty much ok without statistics. Isaac Newton didn't need statistics for his theories of gravity, motion, and light, nor did Albert Einstein need statistics for the theory of relativity. Thermodynamics and quantum mechanics are fundamentally statistical, but lots of progress could have been made in these areas without statistics. The second law of thermodynamics is an observable fact (in isolated systems and at respectable scales!), ditto the two-slit experiment and various experimental results revealing the nature of the atom. The A-bomb and, almost certainly, the H-bomb, maybe these would never have been invented without statistics, but on balance we can think that most people would feel that the world would be a better place without these particular scientific developments. Without statistics, we could forget about discovering the Higgs boson etc, but that doesn't seem like such a loss for humanity.

However:

- Statistics helped to win World War II, most notably in cracking the Enigma code (see section Cryptography page 7219)
- Statistics helps to assess observational data facts (weather change, new medication approval, new management method, new agricultural method, etc.) be eliminating the human cognitive bias and therefore to get a general consensus more quick than people debating with subjective bias.
- Statistics with automated softwares gives the possibility to corporations to automate decisions and analysis and therefore to be more competitive and sell less expensive services than the competitors that do the jobs manually.
- Statistics help to search optimum in R&D by reducing the number of experiments that can be huge or very expensive in some industrial fields. Therefore those that use statistics will be more competitive.
- Statistics helps to build survey pool in an efficient way to minimize the costs and maximize the reliability of the result (this also include Quality Sampling for lot rejection in the industry!). They help also to calculate the tolerance interval (error) of the resulting survey.
- Statistics is used in insurance as they have been proven to be more efficient that human chosen criteria (see section Quantitative Management Techniques page 8170).
- Statistics are used in fraud detection (extreme value analysis tools) as manually the analysis would be impossible on populations of more than a hundred millions (see section Numerical Methods page 6768).

---

[105] The critics (bias) of the "*statistics always lie*" statement has already been treated in the Introduction (and the non-constructive arguments of statistics hater as "*your statistics are funny*" or "*I go prepare the meal to my* 1.2314 *children...*" belongs to the same bias!)

- Statistics are used in modern finance as they are automated with computer (therefore less expensive than a human broker) and more reliable and efficient on the long term (see section Economy page 7485).
- Statistics are used on critical large size project management to estimate margin errors on budgeting and time planning (see section Quantitative Management page 8074). In some projects the customer will not accept a proposal without modern estimations methods (otherwise the supplier will be suspected as being highly amateur).
- Statistics are used in Data Mining and Machine Learning to anticipate trends on financial markets or also on social networks behaviours or publicity targeting (see section Numerical Methods page 6768).
- Statistics make it possible to predict to a certain extent catastrophic events (earthquakes, tsunami, extreme weather conditions, machine breakdowns, reliability of means of transport) to evacuate the population / users and also to optimize agricultural and industrial methods.
- Statistics help computers to understand natural language input in search engine or also in typing error correction.
- Statistics would have helped to have better modern computer keyboards (as originally they were adapted for typewriters).
- Statistics are used to automate the analysis of the stability (capability) of production methods and therefore to be more competitive and sell less expensive products that competitors that do this manually (see section Industrial Engineering page 8674).
- Statistics are used in Quantum Mechanics and Statistical Mechanics (see section Statistical Mechanics page 3525) and helped to the possibility to imagine devices that would not have been discovered so quickly without (LASER, Transistor, etc.).
- Statistics are used in genetics in the context of micro-array analysis (see the `R` companion book) and help to do discover faster and develop vaccines sometimes very quickly.
- Statistics are used in Neural Networks, Deep learning and therefore Artificial Intelligence (see section Numerical Methods page 6951) that will change (it's already starting) radically the 121st century (holocene calendar) and further...
- Statistics are used in some court judgements when the evidence of an unprobable correlation seems to appear (see Lucie de Berk case on Internet for example).
- Statistics are used in astronomy to support statistically the observation of new planets or new kind of stars.
- Statistics are used for products guarantee demonstrations plans and the calculation of optimal lifetime guarantee of new products that are sell on the market in huge quantities (see section Industrial Engineering page 9049).
- Statistics are used in modern countries to make decisions based on evidence presented by Economists who cannot convince anyone with anecdotal evidence but with conclusions

derived from Econometric models or Mathematical Programming models or variants of both.

- Statistics are used nation-wide to get information about its people: unemployment, gender proportion, wage distribution, health trends, aging, and so one and it would be impossible to take political decisions and do accurate communication without such statistics in modern countries.

The reader must however keep in mind that affect, fear and emotion are our on-board tags; always with us, they are operational in a lot of situations. But for others situations it is the rational brain that should take over. Averages, frequencies, standard deviations, correlations, randomized experiments, etc. ... these are things that none of our biological sensors are designed to recognize. That's why a percentage of the population reject the scientific method and most of it reject statistics (they're a uncomfortable with the scientific evidence).

Also many charlatans and bigots reject Statistical Analysis/Studies for the simple reason that they know that if their practices (business) and beliefs (most religions are trillion dollars businesses) were to be put to the test of the Scientific Method then the latter would show that all of this is no better, and often worse, than the placebo effect (for example the reader can found on Internet plenty of scientific studies published in high impact factor journals that have shown that prayers have a small nocebo effect and that alternative medicines don't do better than a placebo...)!

> ❞ *It is easy to lie with statistics, but easier to lie without them.* ❞
>
> Fred Mosteller

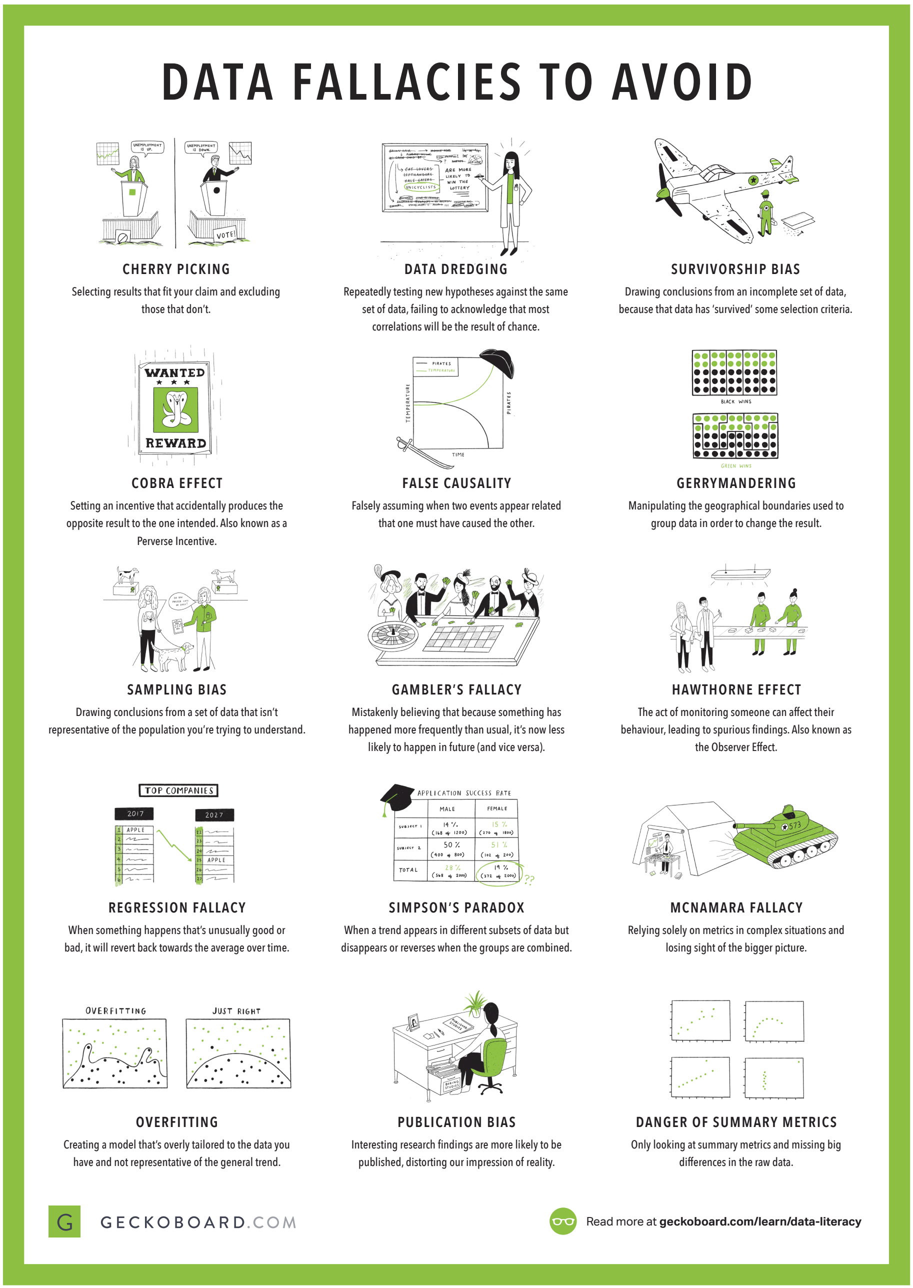
quote
5.7:1341.#51

The Charlatan	The Professional Researcher
Says he helps others as a hobby but still charges for his help...	Charges for his services because it is his job and his only source of income
Its effectiveness is based only on anecdotes because it does not invest time or money in a representative statistical database and is not interested in verifying the effectiveness of its method	Its effectiveness is based on the costly analysis of representative cohorts in order to control covariates and quantify the benefit-risk ratio validated by peers in peer-reviewed journals
Does not do any short, medium or long term monitoring of its patients	Performs short, medium and long term follow-up of his patients to analyze remission with Kaplan-Meier analysis
Has no quantifiable written intervention protocol and does his actions with "the rule of thumb"	Has a quantifiable, measurable, repeatable, controllable intervention protocol for its actions
Does not publish or share his/her results because he/she does not follow up and does not care about the potential negative impacts	Publishes and shares his/her results because it follows up and communicates potential side effects because his/her is interested in the well-being of its patients
Refuses to have his/her method tested and analyzed using the control group/test group (controlled experiment) in double blind with the standard of treatment	Wants and needs to test and analyze his/her method using the control group/test group (controlled experiment) in double blind with the standard of treatment
When falsified, rejects the facts, gets angry, takes legal action but continues with his method	When falsified accept the facts and stop the method

5.7.20.1 Data fallacies

So far we have presented in details some common human problems and interpretation issues in statistics as (in addition to the deplorable way that the mass media communicate scientific results as seen on page 79) the fact that correlation is not always causation, a zero correlation doesn't mean an absence of pattern, the Simpson's paradox, the Anscombe's quartet, the usage of the wrong statistics indicators or tests, p-hacking, etc.

Some of them can be summarized in the following poster (remember that poster for when we will study Data Mining on page 6768):



DATA FALLACIES TO AVOID

CHERRY PICKING
Selecting results that fit your claim and excluding those that don't.

DATA DREDGING
Repeatedly testing new hypotheses against the same set of data, failing to acknowledge that most correlations will be the result of chance.

SURVIVORSHIP BIAS
Drawing conclusions from an incomplete set of data, because that data has 'survived' some selection criteria.

COBRA EFFECT
Setting an incentive that accidentally produces the opposite result to the one intended. Also known as a Perverse Incentive.

FALSE CAUSALITY
Falsely assuming when two events appear related that one must have caused the other.

GERRYMANDERING
Manipulating the geographical boundaries used to group data in order to change the result.

SAMPLING BIAS
Drawing conclusions from a set of data that isn't representative of the population you're trying to understand.

GAMBLER'S FALLACY
Mistakenly believing that because something has happened more frequently than usual, it's now less likely to happen in future (and vice versa).

HAWTHORNE EFFECT
The act of monitoring someone can affect their behaviour, leading to spurious findings. Also known as the Observer Effect.

REGRESSION FALLACY
When something happens that's unusually good or bad, it will revert back towards the average over time.

SIMPSON'S PARADOX
When a trend appears in different subsets of data but disappears or reverses when the groups are combined.

MCNAMARA FALLACY
Relying solely on metrics in complex situations and losing sight of the bigger picture.

OVERFITTING
Creating a model that's overly tailored to the data you have and not representative of the general trend.

PUBLICATION BIAS
Interesting research findings are more likely to be published, distorting our impression of reality.

DANGER OF SUMMARY METRICS
Only looking at summary metrics and missing big differences in the raw data.

6.1. Calculus

In the Arithmetic chapter of this textbook we have written extensively on various theorems using abstract numbers in order to extend the scope of the validity of the latter. However we have only discussed a few on how we should handle these abstract numbers. This is what we will see now.

As you may know already know, a number may be considered by making an abstraction of the nature of the objects that constitutes the group that it characterizes and as well as how to codify it (Indo-Arabic numbers, Roman numbers or other system...). We then say that the number is an "abstract number" and when we handle these kinds of objects we say that we are doing "algebra calculus" or also "literal calculation".

Definition (#6.1.165): "Literal calculation" is the fact to calculate with variables (that is to say with letters) as you would with numbers.

For the mathematicians it is often not advantageous to work with numerical values $(1,2,3,\ldots)$ because they represent only specific cases. What look for physicists, engineers and mathematicians are universally applicable relations in a most general framework as possible.

These abstract numbers today commonly named "variable" are often represented by the Latin alphabet (for which the first letters of the Latin alphabet $a,b,c,\ldots$ often denote imposed values and the last $\ldots,x,y,z$ variables values), Greek alphabet is also mostly used to represent more or less complex mathematical operators. Latin and Greek letters are also used to represent "Universal constants" such as the speed of light c, the gravitational constant G, the value of π, the Euler number e, etc.

Remark

It seems that the letters to represent numbers were used for the first time by Viète in the middle of the 116th century (but the notation of exponents did not exist at this time).

A variable is therefore likely to take different numerical values. All these values can vary according to the character of the problem considered. Let us recall (we had already defined this in the section on Numbers of the Arithmetic chapter) that given two numbers a and b such that $a<b$, then:

R1. We name "domain of definition" of a variable, all numerical values it is likely to take between two specified limits (endpoints) or on a set (like $\mathbb{N},\mathbb{R},\mathbb{R}^+$, etc.).

R2. We name "closed interval with endpoints a and b", the set of all numbers x between these two values and we denote as example as follows:

$$[a,b]=\{x\in\mathbb{R}\,|\,a\leq x\leq b\} \tag{6.1.1}$$

R3. We name "open interval with endpoints a and b", the set of all numbers x between these two values not included and we denote it as example as follows:

$$]a,b[=\{x\in\mathbb{R}\,|\,a<x<b\} \tag{6.1.2}$$

R4. We name "interval closed, left open right" or "semi-closed left" the following relation as example:

$$[a,b[=\{x\in\mathbb{R}\,|\,a\leq x<b\} \tag{6.1.3}$$

R5. We name "interval open left, closed right" or "semi-closed right" the following relation as example:

$$]a,b]=\{x\in\mathbb{R}\,|\,a<x\leq b\} \tag{6.1.4}$$

Remark

If the variable x can take all possible negative and positive values we write therefore: $]-\infty,+\infty[$ where the symbol "∞" means "infinite". Obviously there can be combinations of open infinite right intervals with left endpoint and vice versa.

Definition (#6.1.166): We name "neighbourhood of a", any open interval containing a (it's a simple concept that we will use later to define a continuous function). So:

$$\forall\varepsilon>0,]a-\varepsilon,a+\varepsilon[\tag{6.1.5}$$

is a neighbourhood of a.

6.1.1 Equations and Inequations

Elementary algebra consists starting from the definitions of addition, subtraction, multiplication, and power and their properties (associativity, distributivity, commutativity, identity element, inverse, ...) - this is according to which set we are working with a field or a commutative abelian group or not (see section Set Theory page 416) - to handle within a fixed goal "algebraic equations" linking together variables and constants.

We will define afterwards what an equation and an inequality are but first we want to define some of their properties:

Let A and B be any two polynomials (or monomials) - see definitions a little further - the expressions:

$$A>B,A=B,A<B,A\leq B,A\geq B \tag{6.1.6}$$

satisfy the following properties:

P1. We can always add or subtract from the two members of an equation or inequality same polynomial by obtaining an equivalent equation or inequality (i.e. with the same solutions or reductions). We then say that the equality or inequality remain "true" by the operations of addition or subtraction member to member.

P2. If we multiply or if we divide both members of an equation or inequality by the same positive number we also get an equivalent equation or inequality (we have already seen this in the sections below). We then say that the equality or inequality remains "true" by the operation of multiplication or division member to member.

P3. If we multiply or if we divide both sides of an inequality by the same negative number and if we reverse the direction of inequality, then we get an inequality or equivalent equation.

6.1.1.1 Equations

Definition (#6.1.167): An "equation" is a relation of equality between all abstract values (i.e.: two algebraic expressions) or not all abstract (since we're talking about equations with one unknown, two unknowns, three unknowns and some constants...) interconnected by various operators.

The perfect mastery of elementary algebra is fundamental in physics and mathematics and in the industry!!! Since there are an infinite number of types of equations, we will not present them all here. It is the role of the teacher/trainer in classes to train the brain of his audience for several years (2-3 years on average) to solve a lot of different configurations of algebraic equations (exposed as every day, purely mathematical problems or geometric problems) and this so that students manipulate these equations without errors in a logical and rigorous reasoning (practice makes perfect...)!!!

In other words: A teacher/trainer and an ad hoc institution are irreplaceable to acquire knowledge and experience and to have a feedback on experience!!!

Remark

We have attempted below to make a simple generalization of the basic rules of elementary algebra. This generalization will be more easy to understand to the reader that already have the habit of manipulating abstract quantities.

Thus, either $a, b, c, d, e, \ldots, x, y$ abstract numbers can take any numerical value (we stay within the high-school classical numbers...).

Let Ξ (the Greek capital letter ruling "Xi") representing one or more abstract numbers (variables) operating between them in any way as we have or not different and distinguishable algebraic monomials (one abstract number) or polynomials (poly = many). Therefore we do here a kind of abstract of the abstraction or if you prefer a variable of several variables.

Properties (in fact these are more examples that properties...):

P1. We will always have $\Xi=\Xi$ if and only if the term left Ξ of equality is the same term as the one Ξ that is on the right of the equality. If this condition is satisfied then we have:

$$\Xi-\Xi=0 \tag{6.1.7}$$

Otherwise:

$$\Xi-\Xi=\Xi \tag{6.1.8}$$

where we therefore exclude the case where all the Ξ above are identical to each other (otherwise we get again the property P1).

P2. We have if $\Xi \neq 0$:

$$\frac{\Xi}{\Xi}=1 \Leftrightarrow 1=1 \Leftrightarrow \Xi=\Xi \qquad (6.1.9)$$

which verifies the symbolism of the equation $\Xi=\Xi$ in the case only where the elements are identical between them (we obviously exclude the case with zero denominator).

P3. If all the Ξ are identical, then:

$$\Xi\cdot\Xi\cdot\Xi\cdot\ldots\cdot\Xi=\prod\Xi=\Xi^n \qquad (6.1.10)$$

Otherwise we have:

$$\Xi\cdot\Xi\cdot\Xi\cdot\ldots\cdot\Xi \qquad (6.1.11)$$

which cannot be written in a simple condensed form. It may also happen that:

$$\Xi\cdot\Xi\cdot\Xi\cdot\ldots\cdot\Xi=\Xi \qquad (6.1.12)$$

with the Ξ on the right of equality identical to none, one or more Ξ of the left member of equality.

P4. We can have:

$$\frac{\Xi^{\Xi}}{\Xi^{\Xi}}=1 \qquad (6.1.13)$$

without necessarily having the numerator or denominator to be equals (we exclude for sure the case where the denominator is equal to zero).

Otherwise we can also have:

$$\frac{\Xi^{\Xi}}{\Xi^{\Xi}}=\Xi \quad \text{or} \quad \frac{\Xi^{\Xi}}{\Xi^{\Xi}}=\Xi^{\Xi-\Xi} \qquad (6.1.14)$$

But don't forget (see section Operators page 313) that in the general case where the numerator and denominator are not equal that:

$$\frac{\Xi^{\Xi}}{\Xi^{\Xi}}\neq\frac{\Xi^{\Xi}+c^{te}}{\Xi^{\Xi}+c^{te}} \qquad (6.1.15)$$

P5. We have if all denominators are strictly equals:

$$\cfrac{\Xi}{\cfrac{\Xi}{\cfrac{\Xi}{\cfrac{\Xi}{\ldots}}}}=\frac{\Xi}{\Xi^n}=\Xi^{1-n} \qquad (6.1.16)$$

but it is however not impossible to have:

$$\frac{\Xi}{\frac{\Xi}{\frac{\Xi}{\frac{\Xi}{\ldots}}}}=\Xi \tag{6.1.17}$$

with the Ξ at the right of equality identical to any one or more of the left member of the equality or even it is quite possible to have:

$$\frac{\Xi}{\frac{\Xi}{\frac{\Xi}{\frac{\Xi}{\ldots}}}}=\Xi^{\Xi} \tag{6.1.18}$$

P6. Let $\star$ represent exclusively the addition or the subtraction symbol we have (at a given sign variation):

$$\star\Xi\star\Xi\star\ldots\star\Xi=n\cdot\Xi \tag{6.1.19}$$

if all the Ξ are identical to each other or if the combination of an indeterminate number of Ξ are equal to the Ξ on the right of equality.

Otherwise we will have (meaning that the result will give any undetermined monomial or polynomial):

$$\star\Xi\star\Xi\star\ldots\star\Xi=\Xi \tag{6.1.20}$$

P7. We have if all Ξ (based) raised at the power are strictly identical:

$$\Xi^{\Xi}\cdot\Xi^{\Xi}\cdot\ldots\cdot\Xi^{\Xi}=\Xi^{\sum\Xi} \tag{6.1.21}$$

if and only if the bases Ξ are equal (or could be decomposable to be equal) and the powers Ξ are not necessarily equals.

From the knowledge of these 7 basic examples rules/properties, we can solve, simplify or show that a simple equation has solutions or not relatively to a given problem or statement.

Thus, given an operand or a sequence of any operations on one or more abstraction of abstracts and among all, one (or more) of which the numeric values is or are unknown (the others are known, so we could be able to prove that a relation (statement) like:

$$\Psi\Xi=\Psi\Xi \tag{6.1.22}$$

has existing solutions or not (that is to say: is True or False).

In the case of an equation with the absolute value (see section Operators page 324) of the type:

$$|\Psi\Xi|=\Psi\Xi \tag{6.1.23}$$

with the second member being strictly positive (otherwise the previous relations would be a nonsense) this is equivalent of course from the definition of absolute value to write:

$$\Psi\Xi=\Psi\Xi \quad \text{and} \quad \Psi\Xi=-\Psi\Xi \tag{6.1.24}$$

Remarks

R1. The presence of the absolute value in an algebraic equation in which we seek solutions often doubles the number of solutions.

R2. An equation is named "conditional equation" when there are numbers in the set of definitions that are not solutions (which is actually the most common case). Conversely, if any number of the definition set is solution of the equation then the equation is named an "identity equation".

We sometimes have to solve a "system of equations" (see for example the linear system of equations at page 6304).

- What is it?: It is a set of at least two equations to solve (solving is not always equivalent as to simplify an expression!).
- What is the specificity of such a system?: All solutions of the system are the intersection of all the solutions of the equations to be solved (for detailed examples see the sections of Linear Algebra and Numerical Methods).
- What is the usage?: It is endless (see the different chapters of the book), these systems solve problems involving applications of mathematics to other fields (finance, engineering, operational research, etc.).

Because of the unlimited variety of applications, it is difficult to establish precise general rules for solutions and the existing procedures to follow will for sure be useful only if the problem can be formulated into equations and the following procedures can help a little bit at least to avoid some errors:

1. If we have a problem statement already written, we read it several times carefully and we consider the given facts and the amount of unknowns to find and their domain of definition (summarizing statement on a sheet of paper or anywhere else is often useful for large problems!).
2. Select letters that represents the unknown quantities. This is one of the decisive steps in the search for solutions. Sentences containing words such as: find, what, how, where, when should help you to identify the unknown quantity.
3. Make a drawing (in your head or on paper) with captions. This is for sure possible most of the time only with problems having 1, 2 or 3 unknowns.
4. List the known facts and relations about the unknown quantities. A relation can be described by an equation in which appear in one or both sides of the equal sign statements written with normal sentences.
5. After the previous step, write one or more equations that accurately describe what was stated with sentences.
6. Solve the equation or the system of equations formulated in the previous steps using of the multiple heuristic existing techniques.

7. Check the solutions obtained in the previous step by referencing to the initial problem statement (check that the solution is consistent with the conditions of the statement).

Some methods of resolutions of systems of equations are treated in detail in the section of Numerical methods and also in the section Linear Algebra (you will thus therefore better understand the procedure above).

6.1.1.2 Inequations

Previously we have seen that an equation was composed from an equality of various calculations with different terms (with at least one "unknown" or an "abstract number") and that:

1. "Solve an equation" is to process consisting to calculate the value of the unknown to satisfy the equality (when a solution exists!)
2. "Simplify an equation" is the process consisting to mathematically minimize the number of terms (factoring or eliminate...)
3. "Develop an equation" is the process consisting to flatten all the terms.

Why do we need to recall the definition of an equation? Just because for the inequality, it is almost the same intellectual process! The difference ? If the equation is an equality, inequality is an inequality (...): As the equation, the inequality is composed of various calculations with different terms interconnected by any operators with at least one unknown.

Main differences between equality and inequality equations:

1. Equality: Symbolized by the symbol $=$
2. Inequality: Symbolized by the strict or large order relations $<, \leq, \geq, >$

When we solve an inequality, our unknown may have a range of values that satisfy the inequality. We say then that the inequality of the solution is a "set of values". This is the fundamental difference between equality (several solutions) and inequality (range of solutions)!

Let us make a refresh about the signs that we can meet in an inequality:

- $<$: Must be read "strictly inferior to" or "strictly less than". In this case the target numerical value is not included in the range and we can then represent the range (interval) with an open left square bracket $]\ldots$ or right square bracket $\ldots[$ next to the target value.

✍**Example:**

Writing $x < 5$ means $x \in]-\infty, 5[$ and $x < -5$ means $x \in]-\infty, -5[$.

- $>$: Must be "strictly superior to" or "strictly greater than". In this case the numerical target value is also not included in the range (interval) and we can then represent the range with an open left square bracket $]\ldots$ or right square bracket $\ldots[$ next to the target value.

✍**Example:**

Writing $x > 5$ means $x \in]5, +\infty[$ and $x > -5$ means $x \in]-5, +\infty[$.

- $\leq$: Must be read "inferior or equal to" or "less than or equal to". In this case, the numerical target value is in the range (interval) and we can then represent the range with a closed left square bracket $[\ldots$ or right square bracket $\ldots]$.

✍**Example:**

Writing $x \leq 5$ means $x \in]-\infty, 5]$ and $x < -5$ means $x \in]-\infty, -5]$.

- $\geq$: Must be read "superior or equal to" or "greater than or equal to". In this case, the numerical target value is in the range (interval) and we can then represent the range with a closed left square bracket $[\ldots$ or right square bracket $\ldots]$.

✍**Example:**

Writing $x \geq 5$ means $x \in [5, +\infty[$ and $x > -5$ means $x \in [-5, +\infty[$.

The objective of inequalities is most of the time (except aesthetics purpose) to have at least one numeric value that defines the domain of solution (of all the abstract terms - variables - of the inequality) that satisfies the inequality.

There are many ways to represent the domains of definition of variables which satisfy an inequality. We will see through small examples what are some of the most common possibilities:

✍Example:

Given a linear inequality (of first degree) on x with a single unknown on which we impose an arbitrary particular constraint for example (of course, the expression can contain more terms...):

$$x<2 \tag{6.1.25}$$

we have in the above inequation already simplified all the terms that were superfluous. Solve the inequality is like looking for the x values less than 2. Of course, there is not only one solution in $\mathbb{R}$ but a set (interval) of solutions and this is the principle of inequalities!

To solve the inequality, we first observe the type of inequality imposed ("strict" or "equal"). Then, in high-schools classes (and not only sometimes...) we represent the set $\mathbb{R}$ traditionally by a table such as:

$-\infty$	0	$+\infty$
....	.......|.......	....

Table 6.1: **Table for inequality resolution**

We intuitively know that the solution of our inequality includes all values below 2 (2 being itself excluded from the solutions) until $-\infty$. Then we write this interval or domain as follows:

$$S=]-\infty,2[\tag{6.1.26}$$

Then we can represent in a tabular way the set of solutions (it helps to understand and prepares the student for solving systems of equations and inequalities and to the study of functions variations). For this, we take back the template of the previous table and place in it our target value (we only have one in this special example but sometimes there can be several because there is a singularity or roots for certain values of the definition domain), that is to say the value 2:

$-\infty$	0	2	$+\infty$
....	.......|.......	.......[.......	....

Table 6.2: **Augmented table for inequality resolution**

and finally, we delimitate with color (...) the set of solutions to from $-\infty$ to $+2$ excluded:

$-\infty$	0	2	$+\infty$
....	.......|.......	.......[.......	....

Table 6.3: **Highlighted table for inequality resolution**

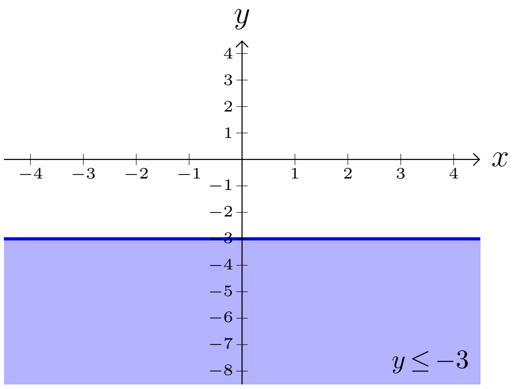
At the value 2, we do not forget to mark the sign $\ldots[$ to show that this value is excluded from the solutions. And that's it, and the concept can be extrapolated to much more complex inequalities.

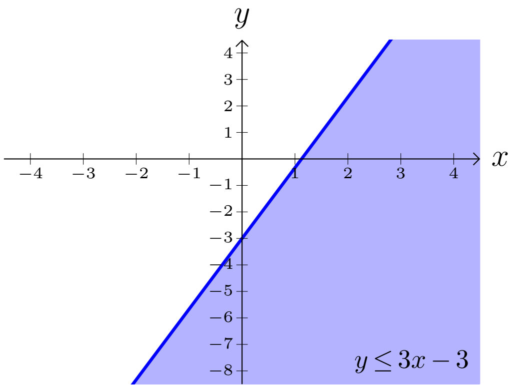
Remarks

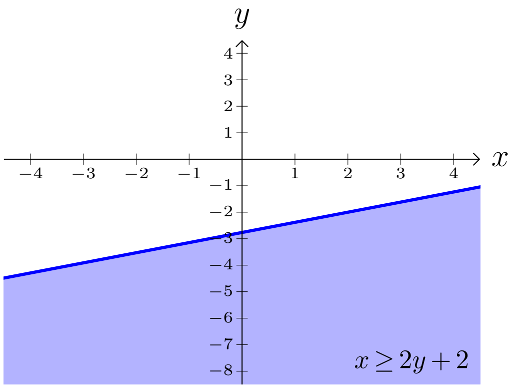
R1. Sometimes instead of representing tables as we have done above, some teachers (this is a completely artistic choice) ask their students to shade the boxes of the table and to draw small circles inside..., or they also use small arrows, or draw the graph of the inequality (the latter method is certainly aesthetic but takes time in complex case but an example is given below...).

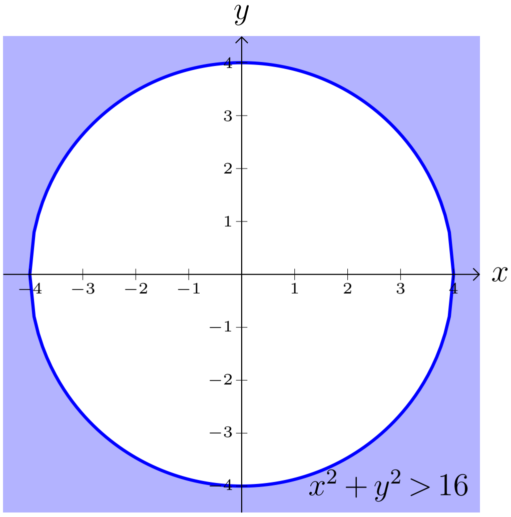
R2. As part of inequalities of degree greater than 1, it is necessary (see later what that means exactly) first too determine the roots of the inequality that determine the intervals and then by trial and error, determine which intervals are to reject or keep.

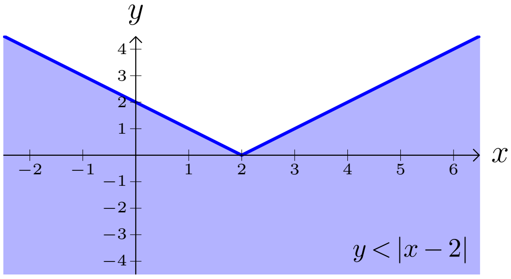
Here are some graphical examples of some very simple univariate inequalities:











We can also (just like equations) sometimes have to solve a "system of inequalities". What is it ?: It is a set of at least two inequalities to solve. The peculiarity of the system ?: The set of solutions of the system is the intersection of all the solutions of every inequality.

For example the system of three inequalities:

$$\begin{aligned} -x_1+2x_2 &\leq 3 \\ 2x_1-x_2 &\leq 5 \\ x_1+x_2 &\geq 3 \end{aligned} \tag{6.1.27}$$

In other words, the method is the same as the previous one, with the difference that our table (representing the areas of solutions) will include an additional line for each additional inequality in the system plus one line of synthesis which is the projection of the possible solutions areas of the system.

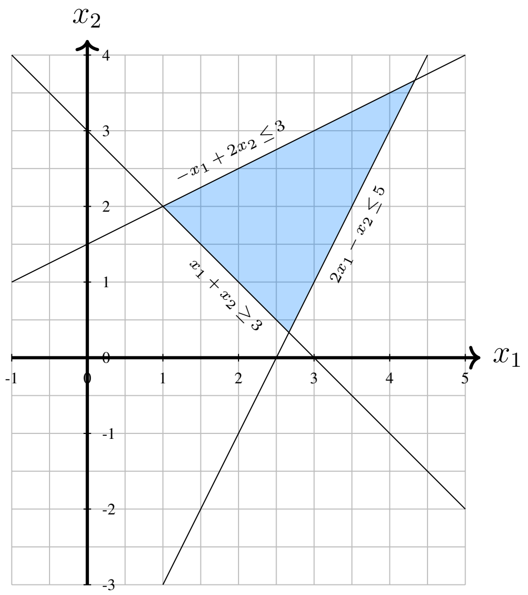
Thus, a system of n inequalities will have obviously a summary table with $n+1$ lines.

Mathematically, the areas (there may be several which are disjoint) can be written as a set of domains:

$$S=\{]\ldots,\ldots],[\ldots,\ldots],\ldots,[\ldots,\ldots[\} \tag{6.1.28}$$

Systems of inequalities are very common in many problems of mathematics, physics, econometrics, etc. It is important to practice solve them during your studies with the help of your teacher.

For example, here is a possible representation of the solution domain of the previous system of inequalities:



6.1.2 Remarkable Identities

The remarkable identities are some kind of magical relations that we use most often for factoring or solving algebraic equations in all fields relative to Applied Mathematics. They have an important place and must be absolutely be mastered by the reader.

Let us recall some notions that have already study in the section of Set Theory and of the chapter Arithmetic (we assume the concept of neutral element known as already defined):

- Commutativity:

$$a+b=b+a \qquad \text{and} \qquad ab=ba \tag{6.1.29}$$

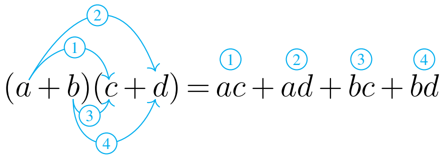
- Associativity:

$$a+(b+c)=(a+b)+c \qquad \text{and} \qquad a(bc)=(ab)c \tag{6.1.30}$$

- Distributivity (for reminder the inverse operation being named the factorization):

$$a(b+c)=ab+ac \tag{6.1.31}$$

Or illustrated:



$$(a+b)(c+d)=\overset{①}{ac}+\overset{②}{ad}+\overset{③}{bc}+\overset{④}{bd}$$

Similar properties are valid with the subtraction operation of course with the adequate domain of definition.

We can check with numerical values (by replacing each abstract number a randomly chosen number), or by development (it would be better, so you are sure you have understood what we were talking about until now), that the following algebraic identities are satisfied (they are the most known one):

1. Second degree identity:

$$(a+b)^2=(a+b)(a+b)=a^2+ab+ba+b^2=a^2+2ab+b^2 \tag{6.1.32}$$

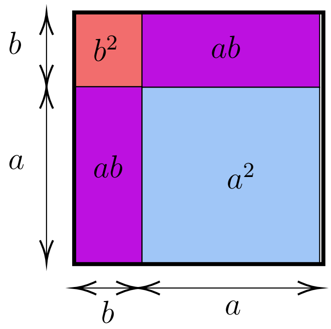


Figure 6.1: Visual of squared binomial identity

A funny mental application of this second degree identity (apart from the fact that the latter is encountered a lot in engineering and physics) is that you can easily found the square of any two-digit number (and maybe impress some of your friends) as any two-digit number xy can be rewritten as $10\cdot x+y$ and therefore the square can be found by easily applying:

$$(10x+y)^2=100x^2+20xy+y^2$$

2. Third degree identity:

$$(a+b)^3=(a+b)(a+b)^2=(a+b)(a^2+2ab+b^2)=a^3+3a^2b+3ab^2+b^3 \tag{6.1.33}$$

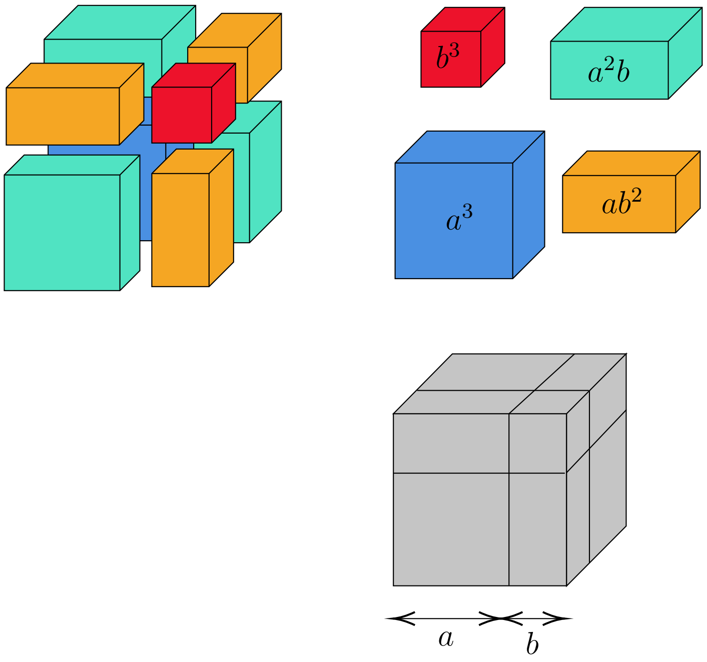

Figure 6.2: Visual of cubic binomial identity

Remark

We can very well put that in practice that $(a+(c+d))^2 := (a+b)^2$ where we obviously putted that $b := c+d$ (we do an "abstract of the abstraction" or more commonly: a "change of variable"). And therefore:

$$(a+b+c)^2 = a^2+2a(b+c)+(b+c)^2 = a^2+b^2+c^2+2ab+2bc+2ac \tag{6.1.34}$$

We can thus notice that in generality, to calculate the development $(a+b)^n$, we use the development of $(a+b)^{n-1}$, that is to say with the identity calculated with the previous value of n.

We can also see a pattern if we put all together:

$$\begin{aligned}(a+b)^0 &= 1\\ (a+b)^1 &= 1a+1b\\ (a+b)^2 &= 1a^2+2ab+1b^2\\ (a+b)^3 &= 1a^3+3a^2b+3ab^2+1b^3\\ &\ldots\end{aligned} \tag{6.1.35}$$

We thus notice the following properties for a and b:

1. The powers of a decreasing from n to 0 ($a^0 = 1$, so it is not noted in the last term).
2. The powers of b increase from 0 to n ($a^0 = 1$, so it is not noted in the first term).
3. In each term, the sum of the powers of a and b is equal to n.
4. The multiplier coefficients in front of each term are calculated by summing the multipliers of two terms of development achieved with the previous value of n (see figure below).

The so named "binomial coefficients" can then be obtained by the construction of the "Pascal's triangle" below:

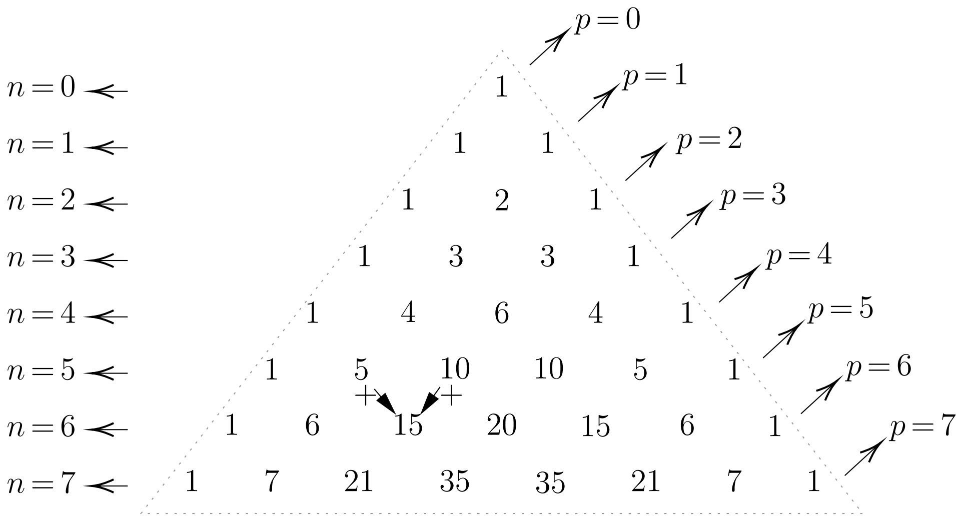

Figure 6.3: **Pascal triangle**

Where each element is given by (see section Probabilities page 522):

$$C_p^n=\frac{n!}{p!(n-p)!} \tag{6.1.36}$$

with $n,p\in\mathbb{N}^+$.

Theorem 6.1. We can then prove that:

$$\boxed{(a+b)^n=\sum_{p=0}^{n}C_p^n a^{n-p}b^p} \tag{6.1.37}$$

which is the famous "Newton's binomial" (that we will reuse many times in different chapters and thus sections of this textbook) or also named "Binomial theorem".

More explicitly:

$$(a+b)^n=\sum_{p=0}^{n}C_p^n a^{n-p}b^p=a^n+\frac{n}{1}a^{n-1}b+\frac{n(n-1)}{1\cdot 2}a^{n-2}b^2+\frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}a^{n-3}b^3+\ldots+b^n \tag{6.1.38}$$

also named "binomial series".

Proof 6.1.1. This relation can be proved quite simply by induction assuming true the previous relation and calculating it for the rank 1:

$$(a+b)^1=a+b=C_0^1a^1b^0+C_1^1a^0b^1=a+b \tag{6.1.39}$$

Then we get:

$$\begin{aligned}(a+b)^{n+1}&=(a+b)(a+b)^n=(a+b)\sum_{p=0}^{n}C_p^n a^{n-p}b^p\\&=\sum_{p=0}^{n}C_p^n a^{n+1-p}b^p+\sum_{p=0}^{n}C_p^n a^{n-p}b^{p+1}\\&=C_0^n a^{n+1}+\sum_{p=1}^{n}C_p^n a^{n+1-p}b^p+\sum_{p=0}^{n-1}C_p^n a^{n-p}b^{p+1}+C_n^n b^{p+1}\\&=C_0^n a^{n+1}+\sum_{p=1}^{n}C_p^n a^{n+1-p}b^p+\sum_{p=1}^{n}C_{p-1}^n a^{n+1-p}b^p+C_n^n b^{p+1}\\&=C_0^n a^{n+1}+\sum_{p=1}^{n}\left(C_p^n+C_{p-1}^n\right)a^{n+1-p}b^p+C_n^n b^{p+1}\\&=C_0^n a^{n+1}+\sum_{p=1}^{n}C_p^{n+1}a^{n+1-p}b^p+C_n^n b^{p+1}\\&=\sum_{p=0}^{n+1}C_p^{n+1}a^{n+1-p}b^p\end{aligned} \tag{6.1.40}$$

The relation is true for rank $n+1$, so it is true for any n.

■ Q.E.D.

By applying the binomial formula twice, we can get for the fun the following trinomial formula:

$$\begin{aligned}(a+b+c)^n&=((a+b)+c)^n\\&=\sum_{k=0}^{n}C_k^n(a+b)^kc^{n-k}=\sum_{k=0}^{n}C_k^n\left(\sum_{l=0}^{k}C_l^ka^lb^{k-l}\right)c^{n-k}\\&=\sum_{k=0}^{n}\sum_{l=0}^{k}C_k^nC_l^ka^lb^{k-l}c^{n-k}=\sum_{k=0}^{n}\sum_{l=0}^{k}\frac{n!}{k!(n-k)!}\cdot\frac{k!}{l!(k-l)!}a^lb^{k-l}c^{n-k}\\&=\sum_{k=0}^{n}\sum_{l=0}^{k}\frac{n!}{l!(k-l)!(n-k)!}a^lb^{k-l}c^{n-k}=\sum_{0\leq l,j,m\leq n,l+j+m=n}\frac{n!}{l!j!m!}a^lb^jc^m\end{aligned}\tag{6.1.41}$$

Regarding remarkable identities with negative values, there is no need to memorize the location of the sign "$-$". Just make a change of variable and once the development is made we replace the variable back (inverse change of variable).

✍**Example:**

$$\begin{aligned}(a-b)^2\underset{c:=-b}{=}(a+c)^2=a^2+2ac+c^2=a^2+2a(-b)+(-b)^2\\=a^2-2ab+(-b)(-b)=a^2-2ab+b^2\end{aligned}\tag{6.1.42}$$

and so on for all finite power n.

We can of course mix genders (...) such as (particularly famous example):

$$(a+b)(a-b)=a(a-b)+b(a-b)=a^2-b^2\tag{6.1.43}$$

and some remarkable additional practical relation that are often used in small classes for exercises:

$$\begin{aligned}a^3+b^3&=(a+b)(a^2-ab+b^2)\\a^3-b^3&=(a-b)(a^2+ab+b^2)\\(x+a)(x+b)&=x^2+(a+b)x+ab\\(x+a)(x-b)&=x^2+(a-b)x-ab\\(x-a)(x-b)&=x^2-(a+b)x+ab\\(ax+b)(cx+d)&=acx^2+(ad+bc)x+bd\end{aligned}\tag{6.1.44}$$

Remark

When, from the right-hand side (in a simplified numerical form) the teacher asks his students as an exercise to get the factoring of the left of the equality, there is no other way but to proceed by successive tests.

For information we also get following famous development that is immediately deducible from what we have seen before:

$$(1+b)^n=\sum_{p=0}^{n}C_p^n 1^{n-p}b^p=\sum_{p=0}^{n}C_p^n b^p=1+nb+\frac{n(n-1)}{2!}b^2+\ldots \tag{6.1.45}$$

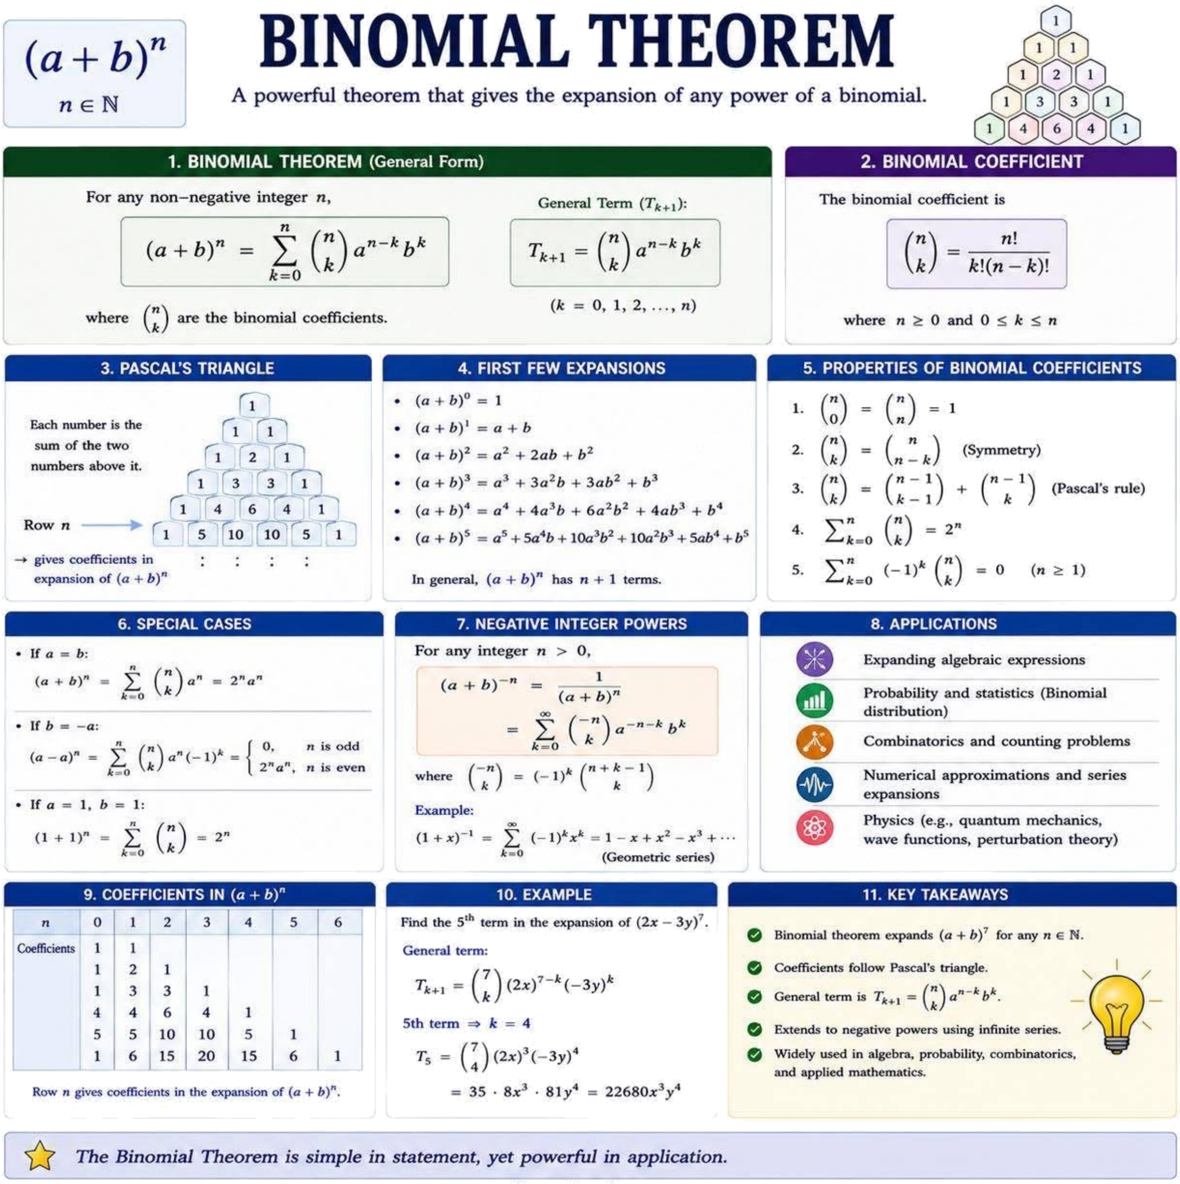
which is valid for any value of b and is named the "binomial expansion".

For small b we could neglect all terms involving b^2 or higher power of b, giving us the approximation relation:

$$(1+b)^n\cong 1+nb \tag{6.1.46}$$

with $b\ll 1$.

Of course there is still a lot of more useful relations with monomial (from which the biggest part is only a generalization of those presented above) that the reader will discover by his own reasoning and according to his practice and in this textbook through the different chapters.



$(a+b)^n$

$n\in\mathbb{N}$

BINOMIAL THEOREM

A powerful theorem that gives the expansion of any power of a binomial.

1
1 1
1 2 1
1 3 3 1
1 4 6 4 1

1. BINOMIAL THEOREM (General Form)

For any non–negative integer n,

$$(a+b)^n=\sum_{k=0}^{n}\binom{n}{k}a^{n-k}b^k$$

where $\binom{n}{k}$ are the binomial coefficients.

General Term (T_{k+1}):

$$T_{k+1}=\binom{n}{k}a^{n-k}b^k$$

$(k=0,1,2,\ldots,n)$

2. BINOMIAL COEFFICIENT

The binomial coefficient is

$$\binom{n}{k}=\frac{n!}{k!(n-k)!}$$

where $n\geq 0$ and $0\leq k\leq n$

3. PASCAL'S TRIANGLE

Each number is the sum of the two numbers above it.

1
1 1
1 2 1
1 3 3 1
1 4 6 4 1
1 5 10 10 5 1
: : : :

Row n →

→ gives coefficients in expansion of $(a+b)^n$

4. FIRST FEW EXPANSIONS

- $(a+b)^0=1$
- $(a+b)^1=a+b$
- $(a+b)^2=a^2+2ab+b^2$
- $(a+b)^3=a^3+3a^2b+3ab^2+b^3$
- $(a+b)^4=a^4+4a^3b+6a^2b^2+4ab^3+b^4$
- $(a+b)^5=a^5+5a^4b+10a^3b^2+10a^2b^3+5ab^4+b^5$

In general, $(a+b)^n$ has $n+1$ terms.

5. PROPERTIES OF BINOMIAL COEFFICIENTS

1. $\binom{n}{0}=\binom{n}{n}=1$
2. $\binom{n}{k}=\binom{n}{n-k}$ (Symmetry)
3. $\binom{n}{k}=\binom{n-1}{k-1}+\binom{n-1}{k}$ (Pascal's rule)
4. $\sum_{k=0}^{n}\binom{n}{k}=2^n$
5. $\sum_{k=0}^{n}(-1)^k\binom{n}{k}=0 \quad (n\geq 1)$

6. SPECIAL CASES

- If $a=b$:

$$(a+b)^n=\sum_{k=0}^{n}\binom{n}{k}a^n=2^na^n$$

- If $b=-a$:

$$(a-a)^n=\sum_{k=0}^{n}\binom{n}{k}a^n(-1)^k=\begin{cases}0, & n \text{ is odd}\\ 2^na^n, & n \text{ is even}\end{cases}$$

- If $a=1,\ b=1$:

$$(1+1)^n=\sum_{k=0}^{n}\binom{n}{k}=2^n$$

7. NEGATIVE INTEGER POWERS

For any integer $n>0$,

$$(a+b)^{-n}=\frac{1}{(a+b)^n}=\sum_{k=0}^{\infty}\binom{-n}{k}a^{-n-k}b^k$$

where $\binom{-n}{k}=(-1)^k\binom{n+k-1}{k}$

Example:

$$(1+x)^{-1}=\sum_{k=0}^{\infty}(-1)^kx^k=1-x+x^2-x^3+\cdots$$

(Geometric series)

8. APPLICATIONS

Expanding algebraic expressions

Probability and statistics (Binomial distribution)

Combinatorics and counting problems

Numerical approximations and series expansions

Physics (e.g., quantum mechanics, wave functions, perturbation theory)

9. COEFFICIENTS IN $(a+b)^n$

n	0	1	2	3	4	5	6
Coefficients	1	1					
	1	2	1				
	1	3	3	1			
	4	4	6	4	1		
	5	5	10	10	5	1	
	1	6	15	20	15	6	1

Row n gives coefficients in the expansion of $(a+b)^n$.

10. EXAMPLE

Find the 5th term in the expansion of $(2x-3y)^7$.

General term:

$$T_{k+1}=\binom{7}{k}(2x)^{7-k}(-3y)^k$$

5th term $\Rightarrow k=4$

$$T_5=\binom{7}{4}(2x)^3(-3y)^4$$

$$=35\cdot 8x^3\cdot 81y^4=22680x^3y^4$$

11. KEY TAKEAWAYS

- ✓ Binomial theorem expands $(a+b)^7$ for any $n\in\mathbb{N}$.
- ✓ Coefficients follow Pascal's triangle.
- ✓ General term is $T_{k+1}=\binom{n}{k}a^{n-k}b^k$.
- ✓ Extends to negative powers using infinite series.
- ✓ Widely used in algebra, probability, combinatorics, and applied mathematics.

The Binomial Theorem is simple in statement, yet powerful in application.

Remark

It is of course possible to multiply polynomials between them and distribute the multiplicative terms. Conversely, it is often asked to students in small classes to do the reverse procedure ("factoring" or "decompose" a polynomial) so they get used to the handling of remarkable identities. Decomposed into a product of factors is an important operation in mathematics, since it is thus possible to reduce the study of complicated expressions to the study of several simpler expressions having interesting properties depending on the context.

We can generalize the binomial theorem (that's useful when we need to prove the epsilon-delta continuity of some power functions) such that for $|x|<1$ and a real number α, we still can write $(1+x)^\alpha$ as the convergent series:

$$(1+x)^\alpha=\sum_{k=0}^{+\infty}\begin{pmatrix}\alpha\\k\end{pmatrix}x^k \tag{6.1.47}$$

Where for reminder:

$$\begin{pmatrix}\alpha\\k\end{pmatrix}=\frac{\alpha!}{k!(\alpha-k)!}=\frac{\alpha(\alpha-1)(\alpha-2)\cdots(\alpha-k+1)}{k!} \tag{6.1.48}$$

For example:

$$\begin{aligned}\begin{pmatrix}1/2\\4\end{pmatrix}&=\frac{\frac{1}{2}\cdot\left(-\frac{1}{2}\right)\cdot\left(-\frac{3}{2}\right)\cdot\left(-\frac{5}{2}\right)}{24}=-\frac{15}{16\cdot 24}\\ \begin{pmatrix}-n\\k\end{pmatrix}&=\frac{-n\cdot(-n-1)\cdots(-n-k+1)}{k!}=(-1)^k\frac{n(n+1)\cdots(n+k-1)}{k!}=\\&=(-1)^k\frac{(n+k-1)!}{(n-1)!k!}=(-1)^k\begin{pmatrix}n+k-1\\k\end{pmatrix}\end{aligned} \tag{6.1.49}$$

Now, to use this effectively when $(a+b)^{-n}$, you need at least one between a and b not to be zero and $|a|\neq|b|$. Then, pick the one with the highest absolute value and factor it out. If it is a, this means writing all as:

$$a^{-n}\left(1+\frac{b}{a}\right)^{-n}=a^{-n}\sum_{k=0}^{\infty}\begin{pmatrix}-n\\k\end{pmatrix}\frac{b^k}{a^k}=\sum_{k=0}^{\infty}\begin{pmatrix}n+k-1\\k\end{pmatrix}(-b)^k a^{-k-n} \tag{6.1.50}$$

This can be even extended further to complex numbers ($\mathbb{C}$) (again for the study of the continuity of complex defined functions) using the Euler Gamma function (see section Integral and Differential Calculus page 1574) by using the fact that (however it is not defined when $x+1$ is equal to zero or to a negative integer):

$$\Gamma(x+1)=x! \tag{6.1.51}$$

Therefore:

$$\begin{pmatrix}\alpha\\k\end{pmatrix}=\frac{\alpha!}{k!(\alpha-k)!}=\frac{\Gamma(\alpha+1)}{\Gamma(k+1)\Gamma(\alpha-k+1)} \tag{6.1.52}$$

6.1.3 Polynomials

Definition (naive version #168): We name "algebraic univariate polynomial $P(x)$" a function of degree $n\in\mathbb{N}$ which is written:

$$\boxed{P_n(x)=P(x)=a_nx^n+a_{n-1}x^{n-1}+\ldots+a_1x^1+a_0} \tag{6.1.53}$$

or in a more condensed manner by:

$$P_n(x)=\sum_{k=0}^{n}a_kx^k \tag{6.1.54}$$

where the "dominant factor" of a polynomial, also named "leading coefficient", is the coefficient of the monomial of highest degree a_n and the "leading term" is simply a_nx^n. If $a_n=1$ is equal to 1 then we speak of "normalized polynomial".

If we consider each coefficient of the polynomial as the component of a vector, then we can manipulate polynomials as vector spaces denoted $P_n(\mathbb{R})$ and of dimension $n+1$.

Remarks

R1. The subscript n of $P(x)$ is most of time omitted as explicitly defined in the expression of the polynomial itself.

R2. The reader who has read the section of Set Theory, probably remember that the set of all polynomial of degree n or lower form a vector space structure!

We will assume without proof and obvious (because we are engineers or physicists but not mathematicians) that if we denote $\text{deg}(P_n(x))=n$ the degree of a polynomial, and that $P_n(x)$ and $P_m(x)$ are both polynomials, that then:

$$\text{deg}(P_n(x)+Q_m(x))\leq\max(\text{deg}(P_n(x)),\text{deg}(Q_m(x))) \tag{6.1.55}$$

and:

$$\text{deg}(P_n(x)\cdot Q_m(x))=\text{deg}(P_n(x))+\text{deg}(Q_m(x)) \tag{6.1.56}$$

Definition (set theory version #169): Let k be a ring (see section Set Theory page 426) and $n\in\mathbb{N}^*$, the "polynomial ring" in n indeterminate (or variables) $k[X_1,\ldots,X_n]$ is constructed from an elementary polynomial, named "monomial" of the form:

$$\lambda X_1^{m_1}\ldots X_m^{m_n} \tag{6.1.57}$$

where $\lambda\in k$ is the "coefficient of the monomial", $m_1,m_2,\ldots,m_n$ are positive non-null integers and where $X_1^{m_1}\ldots X_m^{m_n}$ forms the "literal part of the monomial". Thus, by construction, a polynomial is a sum of a finite number of monomials named the "terms of the polynomial".

Therefore, the common special case used in small classes and presented at the beginning is $k[X]$, that is to say the ring of univariate polynomials with coefficients in k. Indeed most of time engineers and students deals with "ring of univariate polynomials with coefficient in $\mathbb{R}$" and denoted by $\mathbb{R}[X]$. Any element of $k[X]$ is therefore written as:

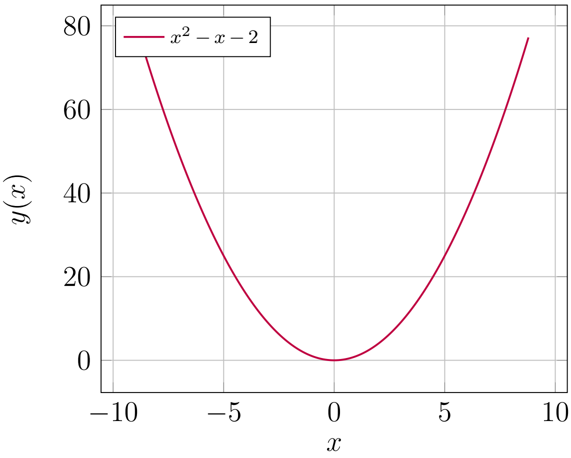
$$\sum_{i=0}^{n} a_i X^i \tag{6.1.58}$$

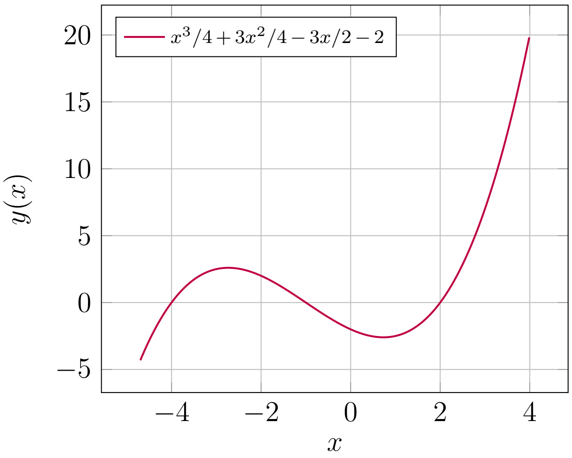
with $a_i \in k$ (most of time $a_i \in \mathbb{R}$), $i = 0 \ldots n$ and $n \in \mathbb{N}$.

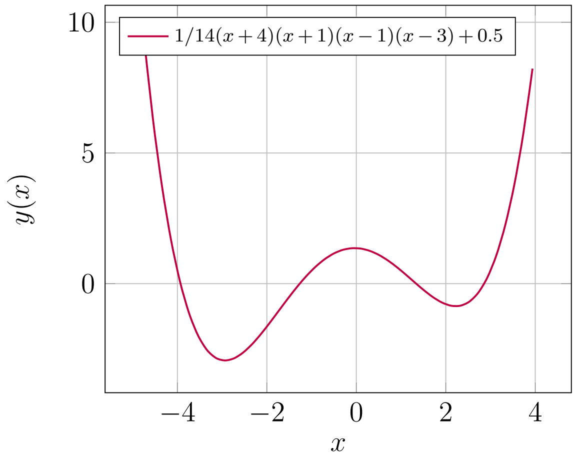
Remarks

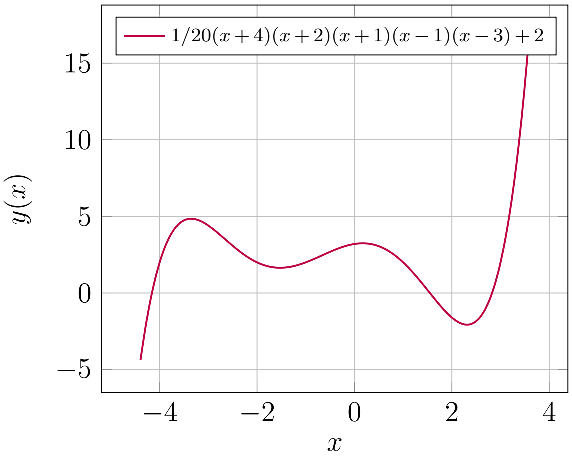
R1. Notice that the powers i are always positive or null in $k[X]$!!!

R2. We say that two polynomials are "similar" if they have the same literal part.









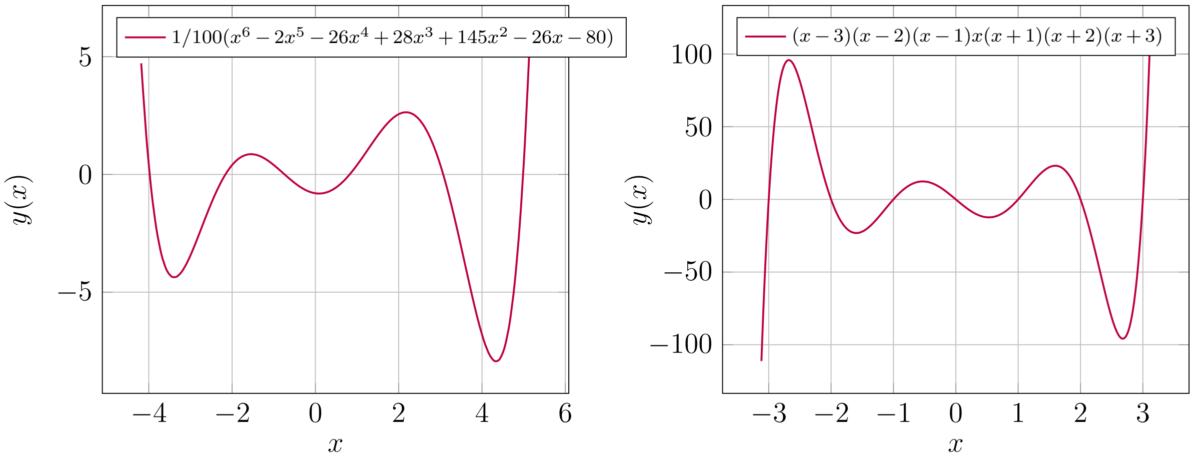


Figure 6.6: Some polynomials plotted with TikZ

The "limiting behaviour" of a function describes what happens to the function as $x \to \pm\infty$. The degree of a polynomial and the sign of its leading coefficient dictates its limiting behaviour. In particular:

- If the degree of a polynomial $f(x)$ is even and the leading coefficient is positive, then $f(x) \to +\infty$ as $x \to \pm\infty$.
- If $f(x)$ is an even degree polynomial with negative leading coefficient, then $f(x) \to -\infty$ as $x \to \pm\infty$.
- If $f(x)$ is an odd degree polynomial with positive leading coefficient, then $f(x) \to -\infty$ as $x \to +\infty$ and $f(x) \to +\infty$ as $x \to +\infty$.
- If $f(x)$ is an odd degree polynomial with negative leading coefficient, then $f(x) \to +\infty$ as $x \to -\infty$ and $f(x) \to -\infty$ as $x \to +\infty$.

These results are summarized in the table below:

Degree of the polynomial	**Leading coefficient**	
	$+$	$-$
Even	$f(x) \to +\infty$ as $x \to \pm\infty$	$f(x) \to -\infty$ as $x \to \pm\infty$
Odd	$f(x) \to -\infty$ as $x \to -\infty$ $f(x) \to -\infty$ as $x \to -\infty$	$f(x) \to +\infty$ as $x \to -\infty$ $f(x) \to -\infty$ as $x \to +\infty$

Table 6.4: Limiting behaviour of polynomials

Definition (#6.1.170): We name "turning point" a point at which the graph changes direction from increasing to decreasing or decreasing to increasing (or differently said: where the derivatives is equal to zero).

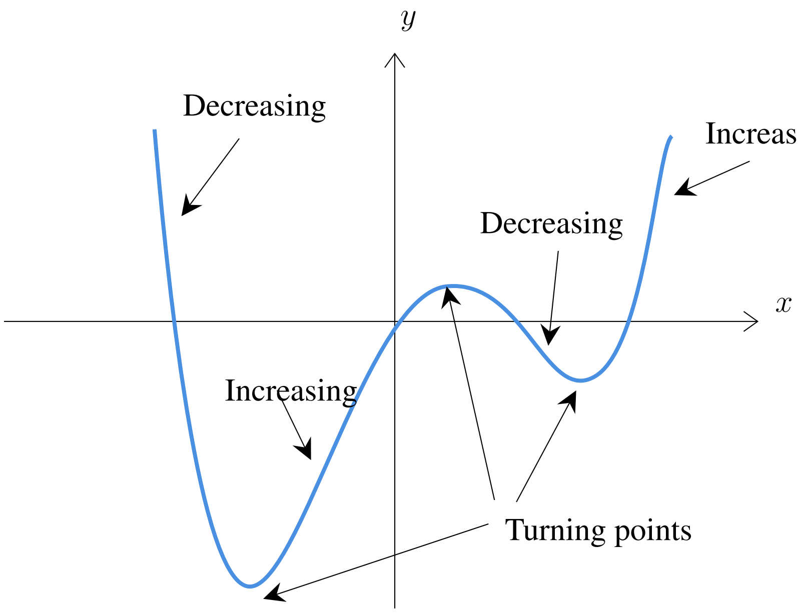

Figure 6.7: **Turning point explicitly highlighted**

The function f above is a 4^{th} degree polynomial and has 3 turning points. The maximum number of turning points of a polynomial function is always one less than the degree of the function.

Definition (#6.1.171): We name "root" or "zero of (univariate) polynomial", the x values such as the "polynomial equation" $P(x)=0$ is satisfied at the condition that at least one of the a_n with $n>0$ is not null.

If the polynomial is normalized[1] and admits one or more roots r_n we can then obviously factorize it as following (we will prove it more rigorously further below):

$$P(x)=(x-r_n)(x-r_{n-1})\ldots(x-r_2)(x-r_1) \qquad (6.1.59)$$

so that when x takes the value of one of the roots r_n, the expression above is zero. This is what we name by convention "factorize a polynomial".

If the polynomial is not normalized then the factorization will be obviously given by:

$$P(x)=a_n(x-r_n)(x-r_{n-1})\ldots(x-r_2)(x-r_1) \qquad (6.1.60)$$

Algebraic identities are particular forms of polynomial functions. Indeed, consider a constant c and a variable x and:

$$(c+x)^n=\sum_{k=0}^{n}C_k^n c^k x^{n-k}=C_0^n c^0 x^n+C_1^n c^1 x^{n-1}+\ldots+C_{n-1}^n c^{n-1}x^1+C_n^n c^n \qquad (6.1.61)$$

We see that if we put:

$$C_0^n c^0=a_n,\; C_1^n c^1=a_{n-1},\; \ldots,\; C_{n-1}^n c^{n-1}=a_1,\; C_n^n c^n=a_0 \qquad (6.1.62)$$

---

[1] Indeed, if you develop the given expression, you will see that the factor in front of the highest order term x^n is 1.

we fall back on:

$$(c+x)^n = a_n x^n + a_{n-1} x^{n-1} + \ldots + a_1 x^1 + a_0 \tag{6.1.63}$$

Definitions (#6.1.172):

D1. A polynomial in one indeterminate is named an "univariate polynomial", a polynomial in more than one indeterminate is named a "multivariate polynomial". A polynomial with two indeterminates is named a "bivariate polynomial".

A famous example in pure mathematics of a multivariate polynomial given many times in undergraduates course is:

$$x^n + y^n = z^n \tag{6.1.64}$$

D2. In the case of polynomials in more than one indeterminate, a polynomial is named "homogeneous of degree n if all its non-zero terms have degree n (the example just above is such a polynomial!).

6.1.3.1 General relations between roots and coefficients

Let us see now an interesting relation between the roots of a polynomial and its coefficients.

For this, let us consider the following polynomial:

$$P = a_n x^n + a_{n-1}x^{n-1} + a_{n-2}x^{n-2} + \ldots + a_2 x^2 + a_0 \tag{6.1.65}$$

And let us denote its roots by $r_1, r_2, \ldots, r_n$ (n root does not necessarily mean n distinct roots...). We then have:

$$\begin{aligned} P &= a_n x^n + a_{n-1}x^{n-1} + a_{n-2}x^{n-2} + \ldots + a_2 x^2 + a_0 \\ &= a_n(x-r_1)(x-r_2)\ldots(x-r_{n-1})(x-r_n) \end{aligned} \tag{6.1.66}$$

We then deduce by developing the last equality and by identifying with the coefficients that:

$$\begin{aligned} r_1 + r_2 + r_3 + \ldots + r_{n-1} + r_n &= -\frac{a_{n-1}}{a_n} \\ r_1 r_2 + r_1 r_3 + \ldots + \ldots + r_{n-1} r_n &= \frac{a_{n-2}}{a_n} \\ r_1 r_2 r_3 + r_1 r_2 r_4 + \ldots + r_{n-2} r_{n-1} r_n &= -\frac{a_{n-3}}{a_n} \\ &\ldots \\ r_1 r_2 r_3 r_4 r_5 r_6 r_7 r_8 \ldots r_{n-1} r_n &= (-1)^n \frac{a_0}{a_n} \end{aligned} \tag{6.1.67}$$

We can write it again differently by defining the numbers $\sigma_1, \sigma_2, \ldots, \sigma_n$ as following:

$$\boxed{\begin{aligned} &\sigma_1 = \sum_{i=1}^{n} r_i = r_1 + r_2 + r_3 + \ldots + r_{n-1} + r_n = -\frac{a_{n-1}}{a_n} \\ &\sigma_2 = \sum_{i<j} r_i r_j = r_1 r_2 + r_1 r_3 + \ldots + \ldots + r_{n-1} r_n = \frac{a_{n-2}}{a_n} \\ &\sigma_3 = \sum_{i<j<k} r_i r_j r_k = r_1 r_2 r_3 + r_1 r_2 r_4 + \ldots + r_{n-2} r_{n-1} r_n = -\frac{a_{n-3}}{a_n} \\ &\ldots \\ &\sigma_n = \prod_{i=1}^{n} r_i = (-1)^n \frac{a_0}{a_n} \end{aligned}} \tag{6.1.68}$$

Conversely if the $r_1, r_2, \ldots, r_n$ satisfies the preceding system, then they are the roots of a normalized polynomial of the form:

$$P = a_n\left(x^n - \sigma_1 x^{n-1} + \sigma_2 x^{n-2} + \ldots + (-1)^n \sigma_n\right) \tag{6.1.69}$$

Notice that for the famous case $n = 2$ that we found:

$$\begin{aligned} \sigma_1 &= \sum_{i=1}^{2} r_i = r_1 + r_2 = -\frac{a_1}{a_2} \\ \sigma_2 &= \sum_{i<j} r_i r_j = r_1 r_2 = \frac{a_0}{a_2} \end{aligned} \tag{6.1.70}$$

If we consider individuals that are identical apart from one covariate x, the hazard ratio becomes as we already know:

$$\frac{h_i}{h_j}=\frac{e^{\beta x_i}}{e^{\beta x_j}}=e^{\beta(x_i-x_j)} \tag{6.1.71}$$

The confidence interval of the hazard ratio is therefore:

$$\boxed{e^{\left(\hat{\beta}-Z_{\alpha/2}\text{SE}\left(\hat{\beta}\right)\right)(x_i-x_j)}\leq \text{H.R.}\leq e^{\left(\hat{\beta}+Z_{\alpha/2}\text{SE}\left(\hat{\beta}\right)\right)(x_i-x_j)}} \tag{6.1.72}$$

6.1.3.2 Multiplication of Polynomials

The product of the two polynomials P (of degree n) and Q (of degree m) is obviously given by:

$$(PQ)(x)\equiv P(x)Q(x)=\sum_{i=0}^{n}a_ix^i\sum_{j=0}^{m}b_jx^j=\sum_{i=0}^{n}\sum_{j=0}^{m}a_ib_jx^{i+j} \tag{6.1.73}$$

There is no much things more to say about the multiplication of polynomials for the needs of this textbook.

6.1.3.3 Euclidean Division of Polynomials

Let us put ourselves now in the ring $k[X]$. If $P(x)\in k[X]$, we denote by $\text{deg}(P)$ the degree of the polynomial $P(X)$ with coefficients in a ring k (real or complex ... whatever!)

Remark

By convention:

$$\text{deg}(0)=-\infty \tag{6.1.74}$$

Theorem 6.2. Given:

$$u(X)=\sum_{i=0}^{k}u_iX^i,v(X)=\sum_{i=0}^{m}v_iX^i\in k[X] \tag{6.1.75}$$

with $k,m>0$. Then there are two unique polynomial $q(X),r(X)\in k[X]$ such as:

$$\text{deg}(r)<\text{deg}(v)=m \tag{6.1.76}$$

and:

$$u(X)=q(X)v(X)+r(X) \tag{6.1.77}$$

where $q(X)$ is the "quotient polynomial" and $r(X)$ the "residual polynomial".

Proof 6.2.1. If $u(X)=0$ the result is obvious. Let us suppose that $u(X)\neq 0$ and let us prove the existence by induction on the degree k of $u(X)$.

If $k=0$ then $q(X)=0$ (since $m>0$) and therefore $r(X)=u(X)$ will do the job.

Now let us suppose the statement for any $k\leq n$... (this supposition is completely free of charge...):

Let $u(X)$ be of degree $k=n+1$. If $m>n+1$ then $q(X)=0$ and $r(X)=u(X)$ can also do the job.

Otherwise, if $m\leq n+1$ then by writing (u_{n+1} is the $n+1$-th coefficient of the polynomial $u(X)$ and v_m the m-th coefficient of $v(X)$:

$$u(X)-\frac{u_{n+1}}{v_m}X^{n+1-m}v(X) \tag{6.1.78}$$

we reduce then $u(X)$ to a polynomial of degree $\leq n$ since $v(X)$ is of degree m (and that it exists)!

Indeed, the term:

$$\frac{u_{n+1}}{v_m}X^{n+1-m}v(X) \tag{6.1.79}$$

removed (at least) the term of highest degree $u_{n+1}X^{n+1}$.

By the induction hypothesis, there are $f(X)$ and $g(X)$ such as:

$$u(X)-\frac{u_{n+1}}{v_m}X^{n+1-m}v(X)=f(X)v(X)+g(X) \tag{6.1.80}$$

with $\text{deg}(g)<m$. So after rearranging:

$$u(X)=\left(\frac{u_{n+1}}{v_m}X^{n+1-m}v(X)+f(X)\right)v(X)+g(X) \tag{6.1.81}$$

and therefore:

$$q(X)=\frac{u_{n+1}}{v_m}X^{n+1-m}v(X)+f(X) \qquad r(X)=g(X) \tag{6.1.82}$$

do the job!

So by induction we see that the Euclidean division exists in the polynomial ring $k[X]$.

■ Q.E.D.

Remark

This proof allowed us in the section of Set Theory to show that this ring is "principal".

✍**Example:**

We will see only one example as the idea is always same. We want to divide x^3+x^2 by $x-1$ we get:

$$
\begin{array}{rrrrr|l}
x^3 & +x^2 & & & \cdot(-1) & x \quad -1 \\ \cline{6-6}
-x^3 & +x^2 & & & & x^2 \ +2x \ +2 \\ \cline{1-2}
 & 2x^2 & & & & \\
 & -2x^2 & +2x & & & \\ \cline{2-3}
 & & 2x & & & \\
 & & -2x & +2 & & \\ \cline{3-4}
 & & & +1 & &
\end{array}
\tag{6.1.83}
$$

6.1.3.4 Factorization Theorem of Polynomials

We will now prove an important theorem that is in fact originally illustrated (among others) by the remarkable identities we saw above:

Theorem 6.3. If a polynomial $P(X)\in k[\mathbb{K}]$ with coefficients in k of degree $n\geq 1$ has a root $x=r$ in the ring k, then we can factorize $P(x)$ by $(x-r)$ such that:

$$P(x)=(x-r)Q(x) \tag{6.1.84}$$

where Q is a polynomial of degree $n-1$ (and therefore can be a simple monomial).

In other words, "factorize a polynomial", it is written it as a product of monomials (in the general case: of polynomial). When not only applied to polynomials or also simply to numbers, factorization is an operation that transforms a sum into a product!

Proof 6.3.1. The idea is to perform the Euclidean division of $P(x)$ by $(x-r)$. According to the previous theorem, there exists a pair (Q,R) of polynomials such as:

$$P(x)=(x-r)Q+R \tag{6.1.85}$$

and according to the result of the previous theorem on the Euclidean division:

$$\text{deg}(R)<\text{deg}(x-r) \tag{6.1.86}$$

But $\text{deg}(x-r)=1$, so $\text{deg}(R)=0$ (or $-\infty$ by convention). $R(x)$ is therefore a constant polynomial function. Moreover, by hypothesis, r is a root of $P(x)$. We have therefore:

$$0=P(r)=(r-r)Q(r)+R(r) \tag{6.1.87}$$

So $R(r)=0$. Therefore $R(x)$ is the zero polynomial and the theorem is practically proved. It remains to prove that $\text{deg}(Q)=n-1$, which is an immediate consequence of the relation:

$$\text{deg}(P(x))=\text{deg}(x-r)+\text{deg}(Q(x)) \tag{6.1.88}$$

Hence:

$$n=1+\text{deg}(Q) \tag{6.1.89}$$

■ Q.E.D.

From this property to factorize a polynomial, named sometimes "factorization theorem", we can give a foretaste of a much more important theorem:

Theorem 6.4. Let us show that if we have a polynomial function $P(X)\in k[X]$ of degree $n\in\mathbb{N}$ with coefficients in k, then it has at most a finite number n of roots (some being possibly confused) in k.

Proof 6.4.1. First, because $P(x)$ has a degree (order), $P(x)$ is not a zero polynomial function. Then, let us argue by the absurd:

If the function $P(x)$ has n roots with $p>n$ (more roots than degree....), by denoting these roots $r_1,\ldots,r_p$, we have, by the previous factorization theorem (applied p times):

$$P(x)=(x-r_1)(x-r_2)\ldots(x-r_p)Q(x) \tag{6.1.90}$$

where Q is a polynomial of degree:

$$n-p<0 \tag{6.1.91}$$

Now, since by definition a polynomial is a polynomial if and only if its degree (order) belongs to $\mathbb{N}$, the polynomial Q must be the zero polynomial such that:

$$Q(x)=0 \tag{6.1.92}$$

It follows that:

$$P(x)=0 \tag{6.1.93}$$

This contradicts the initial hypothesis that P is not the zero polynomial, hence:

$$p\leq n \tag{6.1.94}$$

■ Q.E.D.

6.1.3.5 Diophantine equation

If we generalize the concept of univariate polynomial with several variables such as:

$$P=P(x,y,z) \tag{6.1.95}$$

then we name "Diophantine equation" an equation of the form:

$$\boxed{P(x,y,z)=0} \tag{6.1.96}$$

where P is a polynomial with integer (or rational) coefficients for which seeks the radicals (roots) strictly in $\mathbb{N}$ or $\mathbb{Q}$. Conventional Diophantine equations are for examples:

- The linear Diophantine equations:

$$ax+by+c^{te}=0 \tag{6.1.97}$$

- The Pythagorean triples:

$$x^n+y^n=z^n \tag{6.1.98}$$

For the general proof of the latter, the reader will have to wait a little bit the time for the redactors of this textbook to have the time to understand the traditional proof to be able to simplified it (...).

6.1.3.6 First order univariate Polynomial and Equations

Given the linear function:

$$P_1(x) = ax + b = a\left(x + \frac{b}{a}\right) \tag{6.1.99}$$

If $a \neq 0$ then the first the equation:

$$a\left(x + \frac{b}{a}\right) = 0 \tag{6.1.100}$$

has a simple closed formed root given obviously by:

$$r = -\frac{b}{a} \tag{6.1.101}$$

such that $P_1(r) = 0$.

If $b = 0$ this polynomial is named an "affine function".

Remarks

R1. If the coefficients of the univariate polynomial of degree 1 are all such that $a, b \in \mathbb{R}$ then the root also belongs to $\mathbb{R}$.

R2. If one of coefficients of the univariate polynomial of degree 1 belongs to $\mathbb{C}$ then the root also belongs to $\mathbb{C}$.

R3. If the both coefficients of the univariate polynomial of degree 1 belongs to $\mathbb{C}$ then the root also belongs to $\mathbb{C}$ or $\mathbb{R}$.

R4. We say that two polynomial equations are "equivalent" if the admit the same solutions.

Here are also some properties for univariate first order polynomials that we give without proof as they seem very very intuitive to us (except on reader request):

P1. If we add (or respectively subtract) a same number to each member of the equation (left from the "$=$" sign, and also right), we get an equation that has the same solutions as the original equation (and this whatever is its degree).

P2. If we multiply (or respectively divide) each me member of an equation (left from the "$=$" sign, and also right) by a same non-null number, we get an equation that has the same solutions as the original equation (and this whatever is its degree).

The method should be general enough to by applied to all equations of the same kind, be build on the four arithmetic basis operations (addition, subtraction, multiplication and division) and the extraction of roots. We can find the solutions (roots), of an equation thanks to its coefficients, using only the previous operations (that is to say in a "closed form"), we then say that the equation can be solved by "radicals".

6.1.3.6.1 Solving by circular reference

Many executives in the small, medium and international companies no longer know how to solve linear equations of the first degree (and beyond also of course...). So I think i the be interesting to the student of see how the hug majority of the people that are not able to solve such high-school level problems proceed (it's especially interesting when you know that they are paid quite a lot to solve such "complicated" problem according to their board committee) The easiest way to see this is how I see they use the spreadsheet software Microsoft® Excel®. Indeed, consider the following example:

A company makes a turnover (income) of $1,500.-$ and has to pay $1,000.-$ of fixed costs (costs). It has 40% tax payable after deduction. The company would like to make a donation (tax deductible) such that the amount of this donation represents 10% of taxes after deduction.

This is written mathematically simply if we denote by R the turnover, C the fixed costs, D the donation, t the tax rate:

$$D = 10\% \cdot (R - C - D)(1 - t) \tag{6.1.102}$$

After some small trivial rearrangements we get:

$$D = \frac{10\%(R - C)(1 - t)}{1 + 10\%(1 - t)} = \frac{10\%(1500 - 1000)}{1 + 10\%(1 - 40\%)} \cong 28.301 \tag{6.1.103}$$

This corresponds well to the 10% tax after deduction since:

$$(R - C - D)(1 - t) \cong 283.01.- \tag{6.1.104}$$

And here's how (bad) executives using a spreadsheet like Microsoft® Excel® and "solve" this (you can trust me I really see people do this in corporation because they are not able to solve problem on the paper anymore). First they write in the spreadsheet software (which automatically detects the inconsistency of the user by indicating it with a blue arrow to highlight the "circular reference"):

	A	B
1	**Turnover:**	1500
2	**Tax:**	0.4
3	**Costs:**	1000
4	**Donation:**	=10%*B5
5	**Profit after taxation:**	=(B1-B3-B4)*(1-B2)

Figure 6.8: **Solving simple equation by circular reference in Microsoft® Excel®**

Validated this gives:

	A	B	C
1	**Turnover:**	1500	
2	**Tax:**	0.4	
3	**Costs:**	1000	
4	**Donation:**	0	
5	**Profit after taxation:**	0	
6			
7			
8			
9			

Circular Reference
$B$4

To solve this equation, it is necessary to activate in the software options the authorization to use the iteration (the position of this option depends on the version of the spreadsheet).

Figure 6.9: **Recurring equation solving option in Microsoft® Excel® 14.0.7183**

Which then gives:

	A	B
1	**Turnover:**	1500
2	**Tax:**	0.4
3	**Costs:**	1000
4	**Donation:**	28.301909
5	**Profit after taxation:**	283.01885

So as we can see, this is quite a non-efficient way to solve a simple high-school problem (a shame for managers or business analysts that have MBA...!).

6.1.3.7 Second order univariate Polynomial and Equations

Given the following univariate polynomial with coefficient in $\mathbb{R}$ (trinomial of second degree):

$$P_2(x)=ax^2+bx+c=a\left[\left(x+\frac{b}{2a}\right)^2-\frac{b^2-4ac}{4a^2}\right] \tag{6.1.105}$$

If we represent this univariate polynomial on the plane, this give us:

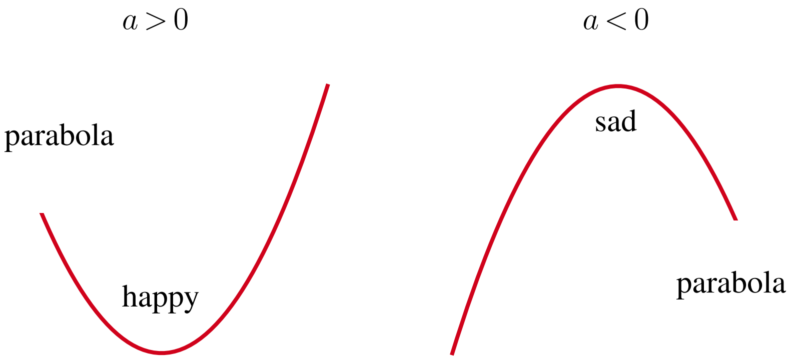

Figure 6.10: **Typical orientation for second degree polynomials**

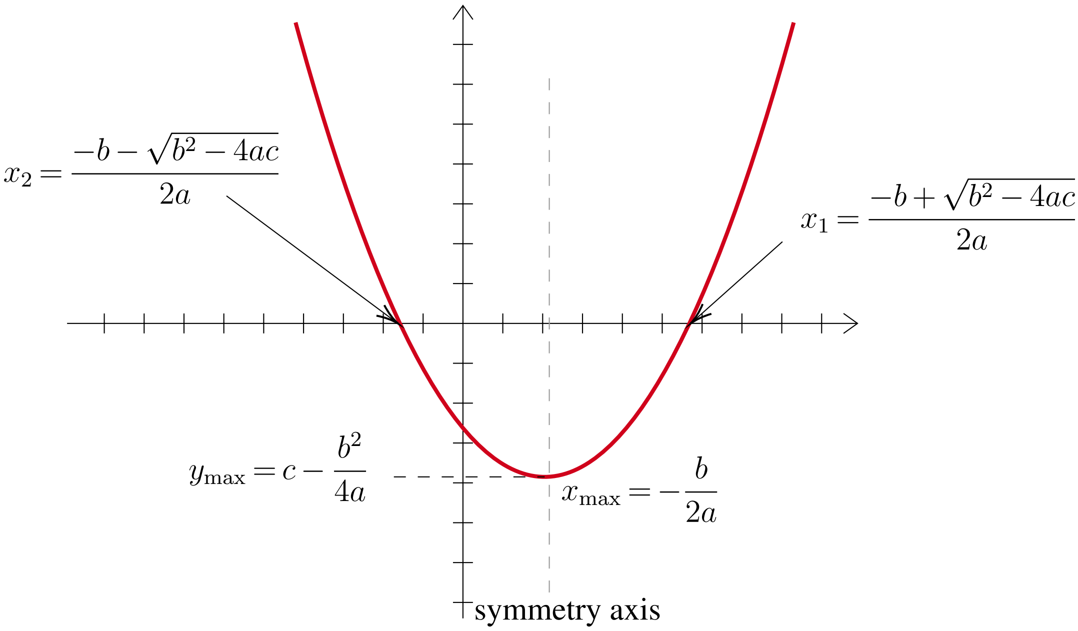
If we take the derivative of this function (see section Differential and Integral Calculus page 1450) and we search in what point the derivative is equal to zero, we will always found the optimum on the inflection point (see section Differential and Integral Calculus page 1454) of the parabola (which corresponds also to its symmetry axis):



$x_2 = \frac{-b-\sqrt{b^2-4ac}}{2a}$
$x_1 = \frac{-b+\sqrt{b^2-4ac}}{2a}$
$y_{\max} = c - \frac{b^2}{4a}$
$x_{\max} = -\frac{b}{2a}$
symmetry axis

Figure 6.11: **Inflection point of the tangent?**

If $a \neq 0$, then we have:

$$\left(x+\frac{b}{2a}\right)=\frac{b^2-4ac}{4a^2} \Rightarrow x+\frac{b}{2a}=\pm\frac{\sqrt{b^2-4ac}}{2a} \Rightarrow x=\frac{-b\pm\sqrt{b^2-4ac}}{2a} \qquad (6.1.106)$$

We then have a "double root" (or "root of multiplicity 2") that we denote by:

$$r_{1,2}=\frac{-b\pm\sqrt{b^2-4ac}}{2a} \qquad (6.1.107)$$

such that $P(r_{1,2})=0$ and we define a new term named sometimes the "determinant of the polynomial" and most commonly the "discriminant of the polynomial":

$$\Delta = b^2-4ac \qquad (6.1.108)$$

Finally:

$$\boxed{r_{1,2}=\frac{-b\pm\sqrt{b^2-4ac}}{2a}=\frac{-b\pm\sqrt{\Delta}}{2a}} \qquad (6.1.109)$$

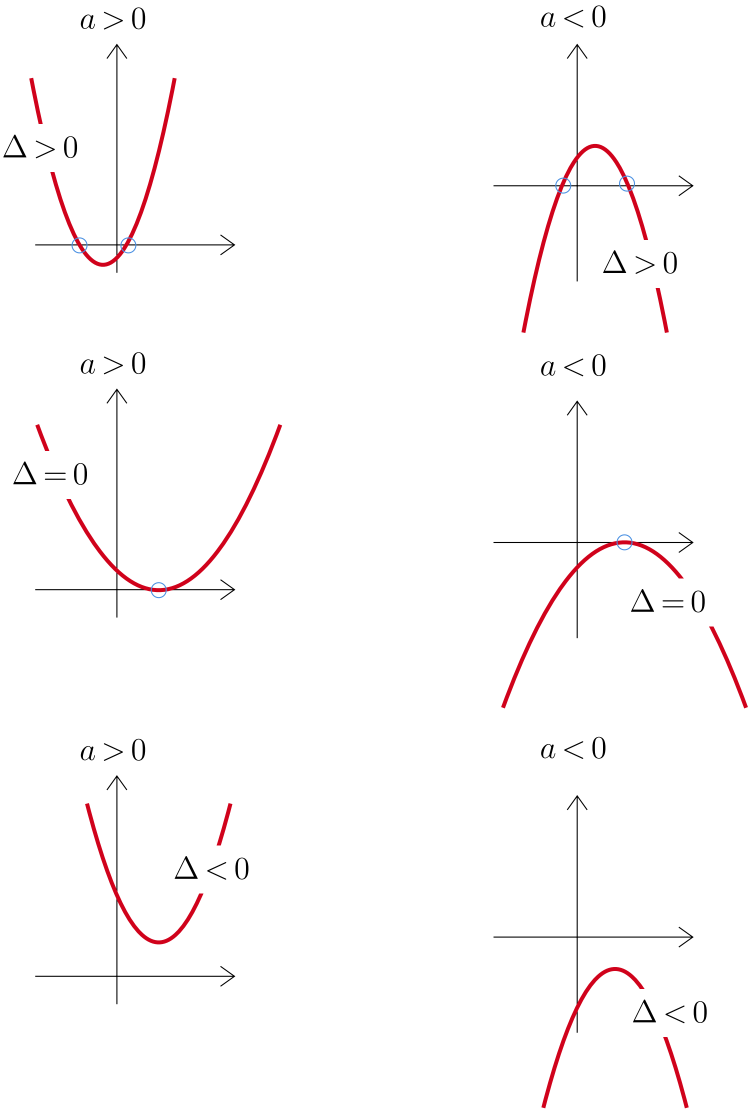
If the second order univariate polynomial on x has two root, we can then factorize it in an irreducible form (following the factorization theorem proved earlier) in the following form:

$$P(x)=a(x-r_1)(x-r_2) \qquad (6.1.110)$$

We also prove easily from the expression of the root by doing simple algebra the "Vieta relations" (on request of the readers we can detail the developments in necessary):

$$r_1+r_2=-\frac{b}{a} \qquad r_1r_2=\frac{c}{a} \qquad (6.1.111)$$

Depending on the sign of $2a$ and this of the discriminant Δ, we have:



$a > 0$
$\Delta > 0$
$a < 0$
$\Delta > 0$
$a > 0$
$\Delta = 0$
$a < 0$
$\Delta = 0$
$a > 0$
$\Delta < 0$
$a < 0$
$\Delta < 0$

Or with some real polynomials:

$y = x^2 - 2x + 3$	$y = x^2 - 2x + 1$	$y = x^2 - 2x - 3$
		$\Delta = b^2 - 4ac$ $= (-2)^2 - 4 \cdot 1 \cdot 3$ $= -8$	$\Delta = b^2 - 4ac$ $= (-2)^2 - 4 \cdot 1 \cdot 1$ $= 0$	$\Delta = b^2 - 4ac$ $= (-2)^2 - 4 \cdot 1 \cdot (-3)$ $= 16$
$\Delta < 0$	$\Delta = 0$	$\Delta > 0$

Figure 6.12: Some real example of second degree polynomials (author: Lê Huy Tien)

Therefore:

- If $\Delta < 0$ our polynomial has no real roots and cannot be factorized in a multiplication of monomial with real ($\mathbb{R}$) factor but with complex one ($\mathbb{C}$). Therefore (it is recommended to have read first the part about Complex Numbers page 243 in the section Numbers of this textbook):
$$r_{1,2} = \frac{-b \pm \sqrt{(-1)(b^2-4ac)}}{2a} = \frac{-b \pm \sqrt{\mathrm{i}^2(b^2-4ac)}}{2a} = \frac{-b \pm \mathrm{i}\sqrt{(b^2-4ac)}}{2a} = 0 \tag{6.1.112}$$
and we know that we can write any complex number in a condensed form (Euler formula) and as the complex roots of a polynomial of the second degree are conjugate (we already know this jargon) we have:
$$r_{1,2} = re^{\pm(\varphi+2k\pi)} \tag{6.1.113}$$
where (recall) r is the module of the complex roots (module that is equal for the both) and φ the argument of the complex roots (equal in absolute value).
- If $\Delta = 0$ the polynomial equation then has a single solution that is obviously:
$$r_{1,2} = \frac{-b \pm \sqrt{0}}{2a} = \frac{-b}{2a} \tag{6.1.114}$$
- If $\Delta > 0$ the polynomial equation then has two solutions defined by the general relations which we have already given above:
$$r_{1,2} = \frac{-b \pm \sqrt{b^2-4ac}}{2a} \tag{6.1.115}$$

About the complex case, let us take as an example the following quadratic polynomial:
$$x^2 + 1 = 0 \tag{6.1.116}$$
that admits only two complex roots that are i and $-$i. In the real plane this polynomial will be represented in Maple™ 4.00b by:

```
>plot(x^2+1,x=-5..5);
```

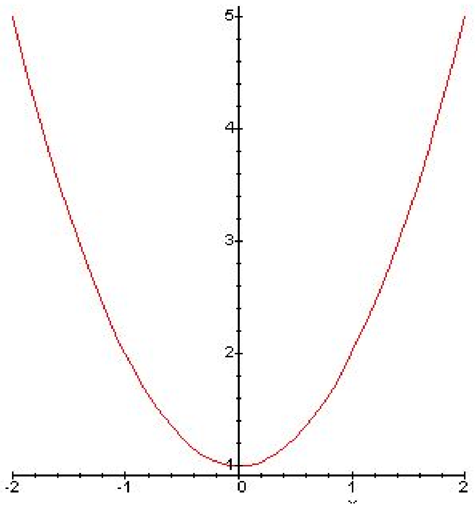


Figure 6.13: **Plot example of a polynomial of degree 2 which admits only complex solutions**

where we see well that there is no real solutions (zeros). While placing us in the complex $\mathbb{C}$, we have:

```
>plot3d(abs((re+I*im)^2+1),re=-2..2,im=0..2,view=[-2..2,-2..2,0..2],
orientation=[-130,70],contours=50,style=PATCHCONTOUR,axes=frame,
grid=[100,100],numpoints=10000);
```

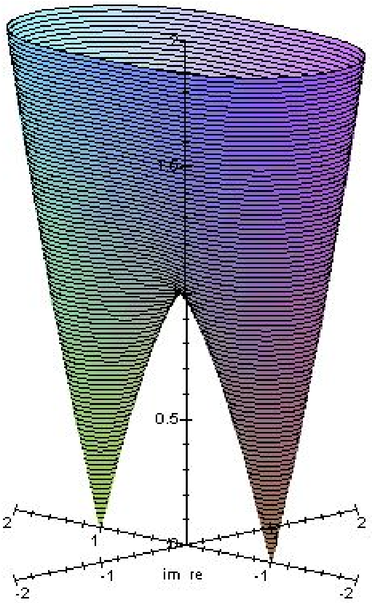

Figure 6.14: **The same polynomial but playing with the complex representation**

where the two zeros are visible on the imaginary axis at -1 and $+1$. Obviously when it's the first time we see a function shown in a figure taking into account the complex values we try to find where is the corresponding parabola of the purely real case. To do this, we simply cut the surface above on two on the imaginary axis and we get then:

```
>plot3d(abs((re+I*im)^2+1),re=-2..2,im=0..2,view=[-2..2,-2..2,0..2],
orientation=[-130,70],contours=50,style=PATCHCONTOUR,axes=frame,
grid=[100,100],numpoints=10000);
```

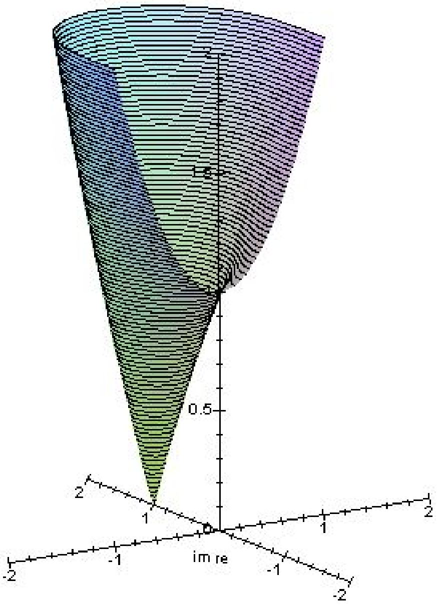

Figure 6.15: **A little zoom on the same polynomial**

where we find again clearly our parabola visible on the cutted surface. So we can ask ourselves whether the complex numbers are a natural extension of our conventional space beyond our physical senses and our common measuring devices...!

6.1.3.7.1 Irrational Equations

The practitioner must always take the habit to verify the solution in the original equation to be sure of the validation of the definition domain of the function. Indeed, there are solutions to the resolution of equations that do not satisfy the original equation and this is what we name "extraneous solutions" and this is typically the case of irrational equations.

Definition (#6.1.173): An "irrational equation" is an equation where the unknown is under a radical (that is to say in typical case: under a square root).

✍**Example:**

Consider the following equation:

$$\sqrt{2+x}+4-\sqrt{10-3x}=0 \tag{6.1.117}$$

To solve it first we can redistribute:

$$\sqrt{2+x}+4=\sqrt{10-3x} \tag{6.1.118}$$

We take the power of 2:

$$2+x+8\sqrt{2+x}+16=10-3x \tag{6.1.119}$$

We simplify little bit:

$$8\sqrt{2+x}=-8-4x \tag{6.1.120}$$

again:

$$2\sqrt{2+x}=-2-x \tag{6.1.121}$$

We take the power of 2 again:

$$4(2+x)=4+4x+x^2 \tag{6.1.122}$$

We simplify a last time:

$$x^2=4 \tag{6.1.123}$$

We get two trivial solutions that are $x_1=-2$ and $x_2=2$. But only the solution $x_1=-2$ satisfy the proposed equation. Indeed, if you put the first solution in the original equation we get:

$$\sqrt{2+(-2)}+4-\sqrt{10-3\cdot(-2)}=\sqrt{0}+4-\sqrt{16}=4-4=0 \tag{6.1.124}$$

But if we put the second one:

$$\sqrt{2+(2)}+4-\sqrt{10-3\cdot(2)}=\sqrt{4}+4-\sqrt{4}=2+4-2=4\neq 0 \tag{6.1.125}$$

6.1.3.7.2 Golden Ratio

There is a second order univariate polynomial whose solution is famous around the world. The solution is a value named the "Golden ratio" or "Divine proportion" (...) and is found in architectural, aesthetic or in phyllotaxis (that is to say, in the arrangement of the leaves around the stem of the plants).

This number is:

$$\boxed{\varphi=\frac{1+\sqrt{5}}{2}=1.6180339887\ldots} \tag{6.1.126}$$

The golden ratio is also an algebraic number (any complex number that is a root of a non-zero polynomial in one variable with rational coefficients) and even an algebraic integer (complex number that is a root of some monic polynomial with coefficients in $\mathbb{Z}$) as it is solution of:

$$x^2-x-1=0 \tag{6.1.127}$$

Historically, the reader should know that two quantities a and b are said to be "in the Golden ratio φ" if their ratio is the same as the ratio of their sum to the larger of the two quantities:

$$\frac{a+b}{a}=\frac{a}{b}=\varphi \tag{6.1.128}$$

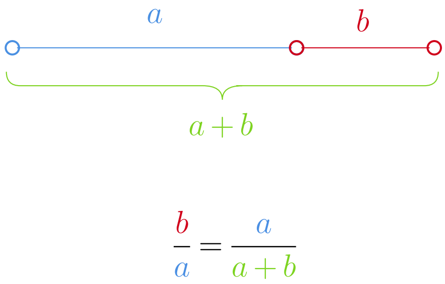

Figure 6.16: **Golden ratio illustration**

One method for finding the value of φ is to start with the left fraction. Through simplifying the fraction and substituting in $b/a=1/\varphi$:

$$\frac{a+b}{a}=1+\frac{b}{a}=1+\frac{1}{\varphi} \tag{6.1.129}$$

Therefore:

$$1+\frac{1}{\varphi}=\varphi \tag{6.1.130}$$

Multiplying by φ gives:

$$\varphi+1=\varphi^2 \tag{6.1.131}$$

which can be rearranged to:

$$\varphi^2-\varphi-1=0 \tag{6.1.132}$$

Using the quadratic formula, two solutions are obtained:

$$\varphi_1=\frac{1+\sqrt{5}}{2}=1.6180339887\ldots \qquad \varphi_2=\frac{1-\sqrt{5}}{2}=-0.6180339887\ldots \tag{6.1.133}$$

Because φ is the ratio between positive quantities φ is necessarily positive:

$$\varphi=\frac{1+\sqrt{5}}{2}=1.6180339887\ldots \tag{6.1.134}$$

Now let us introduce a useful relation for when we will study the ordinary generating function (see page 1783) relatively to the Fibonacci sequence. Let us recall that we started from:

$$1+\frac{1}{\varphi}=\varphi \tag{6.1.135}$$

we then have:

$$-\frac{1}{\varphi}=1-\varphi=1-\frac{1-\sqrt{5}}{2}=\varphi_2 \tag{6.1.136}$$

This is why $-1/\varphi$ is named the "Golden ratio conjugate"!

6.1.3.8 Third order univariate Polynomial and Equations

Even if it is rare to solve such a thing in theoretical physics or in engineering, solving an univariate polynomial of the 3rd degree is quite recreational and shows a good example of an already mature mathematical reasoning (we have these developments thanks Scipione del Ferro and Jerome Cardan mathematicians of the 116th century...).

Given the equation:

$$ax^3+bx^2+cx+d=0 \tag{6.1.137}$$

with the coefficients in $\mathbb{R}$ (to begin...). In a first time, the reader will be able to see that the reasoning that we have applied for the polynomial a smaller order than 3 stuck when the order is greater (excepted for special simple cases obviously...).

We will avoid the problem by using a change of variables subtle but quite justified.

Thus, nothing prevents us from putting that:

$$\exists X \Rightarrow x=X-\frac{b}{3a} \tag{6.1.138}$$

and that by dividing the polynomial of degree 3 by a to write:

$$\begin{aligned}
&x^3+\frac{b}{a}x^2+\frac{c}{a}x+\frac{d}{a}=0\\
&\left(X-\frac{b}{3a}\right)^3+\frac{b}{a}\left(X-\frac{b}{3a}\right)^2+\frac{c}{a}\left(X-\frac{b}{3a}\right)+\frac{d}{a}=0\\
&\left(X^3-\cancel{3}X^2\frac{b}{\cancel{3}a}+\cancel{3}X\frac{b^2}{3\cancel{3}a^2}-\frac{b^3}{27a^3}\right)+\frac{b}{a}\left(X^2-2X\frac{b}{3a}+\frac{b^2}{9a^2}\right)+\frac{c}{a}\left(X-\frac{b}{3a}\right)+\frac{d}{a}=0
\end{aligned} \tag{6.1.139}$$

By grouping the terms of the same order:

$$X^3+X^2\left(-\frac{b}{a}+\frac{b}{a}\right)+X\left(\frac{b^2}{3a^2}-2\frac{b^2}{3a^2}+\frac{c}{a}\right)+\left(-\frac{b^3}{27a^3}+\frac{b^3}{9a^3}-\frac{cb}{3a^2}+\frac{d}{a}\right)=0$$
$$X^3+X\left(\frac{c}{a}-\frac{b^2}{3a^2}\right)+\left(\frac{2b^3}{27a^3}-\frac{cb}{3a^2}+\frac{d}{a}\right)=0 \tag{6.1.140}$$

and let us write (nothing, but really nothing prevent us to do this):

$$\begin{cases}(1) \quad x=X-\dfrac{b}{3a}\\ (2) \quad p=\dfrac{c}{a}-\dfrac{b^2}{3a^2}\\ (3) \quad q=\dfrac{2b^3}{27a^3}-\dfrac{cb}{3a^2}+\dfrac{d}{a}\end{cases} \tag{6.1.141}$$

where (1) is known if and only if X is known and where p,q are anyway unknowns.

The polynomial[2]:

$$P=X^3+pX+q=0 \tag{6.1.142}$$

being of odd degree, it admits (as it can be seen from any visual plot of such a polynomial with real coefficients) at least one real root, named the "certain root" and at maximum three roots. The reader will easily check by himself that with a graphical representation of an odd degree polynomial this is trivial!

The left hand side of this equation is a "monic trinomial" called a "depressed cubic", because the quadratic term has coefficient 0.

Now let us make another subtle change of variable (we have the right to do this):

$$X=u+v \tag{6.1.143}$$

by imposing the condition that u,v must be such that $3uv=-p$ (nothing prevents us from imposing such a constraint), then we have:

$$P=X^3+pX+q=(u+v)^3-3uv(u+v)+q=0\Rightarrow u^3+v^3=-q \tag{6.1.144}$$

Therefore we have:

$$\begin{cases}(1') \quad u^3+v^3=-q\\ (2') \quad u^3v^3=\dfrac{-p^3}{27}\Leftrightarrow 3uv=-p\end{cases} \tag{6.1.145}$$

We can very well make an analogy between the two equations (1') and (2') and the Vieta relations we had obtained for the polynomial of degree 2 which we recall were:

$$r_1+r_2=-\frac{b}{a} \quad \text{and} \quad r_1r_2=\frac{c}{a} \tag{6.1.146}$$

---

[2] The first time I had to solve such a polynomial was to calculate the nutation of a gyroscope and the second time was for the calculation of the horizon of a Black Hole based on the Schwarzschild metric with cosmological constant that was in natural units: $\dfrac{\Lambda}{3}r^3-r-2M=0$

excepted that we have now (we adopt another notation for these intermediate roots):

$$z_1 = u^3 \qquad z_2 = v^3 \tag{6.1.147}$$

which gives us for the polynomial P by imposing (always by analogy) $a = 1$ a new equation:

$$Z^2 + qZ - \frac{p^3}{27} = 0 \tag{6.1.148}$$

for which z_1, z_2 are the roots. The latter equation has for discriminant:

$$\Delta = q^2 + 4\frac{p^3}{27} \tag{6.1.149}$$

Let us take now scenario by scenario:

1. If $\Delta > 0$, the equation on Z admits two solutions z_1, z_2 whose sum will give us indirectly the value of X since by definition $X = u + v$ and $z_1 = u^3$ and $z_2 = v^3$. We see that we have all the ingredients to find the first root of the original equation that will be the certain root (or "certain zero"). So:

   $$X_1 = u + v = \sqrt[3]{z_1} + \sqrt[3]{z_2} = \sqrt[3]{-\frac{q}{2} + \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}} + \sqrt[3]{-\frac{q}{2} - \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}} \tag{6.1.150}$$

   as $\Delta > 0$ and the superior roots are cubic we necessarily have $X_1 \in \mathbb{R}$ if all coefficient of the equation are well in $\mathbb{R}$.

2. If $\Delta = 0$, we know it, the equation on Z admit a double root and as the discriminant has a square power of q this means necessarily that p is negative.

   The polynomial P therefore also has a double root and the same for the original equation. We saw also that for a second degree polynomial if the discriminant is zero roots are:

   $$r_{1,2} = -\frac{b}{2a} \tag{6.1.151}$$

   Then by analogy:

   $$X_1 = X_2 = u + v = \sqrt[3]{z_1} + \sqrt[3]{z_2} = 2\sqrt[3]{z_{1,2}} = 2\sqrt[3]{\frac{-q}{2}} \tag{6.1.152}$$

3. If $\Delta < 0$ we must again use complex numbers as we did in our study of the polynomial of degree 2. Thus, we know that the equation Z admits two complex solutions such as:

   $$z_{1,2} = -\frac{q}{2} \pm \mathrm{i}\sqrt{-\frac{q^2}{4} - \frac{p^3}{27}} \tag{6.1.153}$$

   and once again as the roots are conjugated we can write in condensed form:

   $$z_{1,2} = re^{\pm\mathrm{i}(\varphi + 2k\pi)} \tag{6.1.154}$$

   and as:

   $$X = u + v = \sqrt[3]{z_1} + \sqrt[3]{z_2} \tag{6.1.155}$$

we therefore have:

$$\begin{aligned}X_k&=u_k+v_k=u_k+\bar{u}_k=\sqrt[3]{re^{\mathrm{i}(\varphi+2k\pi)}}+\sqrt[3]{re^{-\mathrm{i}(\varphi+2k\pi)}}\\&=\sqrt[3]{r}e^{\frac{\mathrm{i}(\varphi+2k\pi)}{3}}+\sqrt[3]{r}e^{-\frac{\mathrm{i}(\varphi+2k\pi)}{3}}\end{aligned}\tag{6.1.156}$$

As u_k,v_k are conjugated, we have necessarily $X_k\in\mathbb{R}$.

✍**Example:**

Consider the following equation:

$$x^3-15x-4=0\tag{6.1.157}$$

We therefore have:

$$\begin{aligned}x&=X-\frac{b}{3a}=X\\p&=\frac{c}{a}-\frac{b^2}{3a^2}=\frac{c}{a}=-15\\q&=\frac{2b^3}{27a^3}-\frac{cb}{3a^2}+\frac{d}{a}=-4\end{aligned}\tag{6.1.158}$$

and therefore:

$$\Delta=q^2+4\frac{p^3}{27}=16+4\frac{-3375}{27}=-484<0\tag{6.1.159}$$

We therefore have:

$$\begin{aligned}X&=\sqrt[3]{-\frac{q}{2}+\sqrt{\frac{q^2}{4}+\frac{p^3}{27}}}+\sqrt[3]{-\frac{q}{2}-\sqrt{\frac{q^2}{4}+\frac{p^3}{27}}}\\&=\sqrt[3]{2+\sqrt{\frac{15}{4}+\frac{-3375}{27}}}+\sqrt[3]{2-\sqrt{\frac{15}{4}+\frac{-3375}{27}}}\\&=\sqrt[3]{2+\sqrt{-121.25}}+\sqrt[3]{2-\sqrt{-121.25}}=\sqrt[3]{2+\mathrm{i}\sqrt{121.25}}+\sqrt[3]{2-\mathrm{i}\sqrt{121.25}}=4\end{aligned}\tag{6.1.160}$$

The polynomials of degree three are therefore well solvable by radicals.

Notice also another interesting approach due to Viète! We start again from:

$$X^3+pX+q=0\tag{6.1.161}$$

and let us set $X=u\cos(\theta)$. The idea is to choose u to make the previous equation coincide with the following trigonometric identity:

$$4\cos^3(\theta)-3\cos(\theta)-\cos(3\theta)=0\tag{6.1.162}$$

Before continuing let us prove this identity using the trigonometric identities proved in the section of Trigonometry:

$$\begin{aligned}\cos(3\theta) &= \cos(2\theta+\theta) = \cos(2\theta)\cos(\theta) - \sin(2\theta)\sin(\theta)\\ &= (\cos^2(\theta) - \sin^2(\theta))\cos(\theta) - 2\sin(\theta)\cos(\theta)\sin(\theta)\\ &= \cos^3(\theta) - \sin^2(\theta)\cos(\theta) - 2\sin^2(\theta)\cos(\theta)\\ &= \cos(\theta)(\cos^2(\theta) - \sin^2(\theta) - 2\sin^2(\theta)) = \cos(\theta)(\cos^2(\theta) - 3\sin^2(\theta))\\ &= \cos^3(\theta) - 3\sin^2(\theta)\cos(\theta) = \cos^3(\theta) - 3(1-\cos^2(\theta))\cos(\theta)\\ &= \cos^3(\theta) - 3\cos(\theta) + 3\cos^3(\theta) = 4\cos^3(\theta) - 3\cos(\theta)\end{aligned} \tag{6.1.163}$$

In fact, choosing $u = 2\sqrt{-\dfrac{p}{3}}$ and dividing the equation by $\dfrac{u^3}{4}$ we get:

$$4\cos^3(\theta) - 3\cos(\theta) - \frac{3q}{2p}\sqrt{\frac{-3}{p}} = 0 \tag{6.1.164}$$

Comparing with the above identity, we get:

$$\cos(3\theta) = \frac{3q}{2p}\sqrt{\frac{-3}{p}} \tag{6.1.165}$$

and thus the roots of the depressed cubic equation is:

$$X_k = 2\sqrt{-\frac{p}{3}}\cos\left(\frac{1}{3}\arccos\left(\frac{3q}{2p}\sqrt{\frac{-3}{p}}\right) - \frac{2\pi k}{3}\right) \quad \text{for} \quad k = 0,1,2 \tag{6.1.166}$$

6.1.3.9 Fourth order univariate Polynomial and Equations

The univariate polynomial equation to solve here is:

$$ax^4 + bx^3 + cx^2 + dx + e = 0 \tag{6.1.167}$$

with $a \neq 0$.

Remark

We own the method of resolution of 4th degree polynomial to the Italian mathematician Ludovico Ferrari (also) of the 116th century (holocene calendar).

If we divide by a we have:

$$x^4 + b'x^3 + c'x^2 + d'x + e' = 0 \tag{6.1.168}$$

And by putting:

$$x = y - \frac{b'}{4} \tag{6.1.169}$$

the equation will be reduce to:

$$\begin{aligned}
&\left(y'-\frac{b'}{4}\right)^4+b'\left(y'-\frac{b'}{4}\right)^3+c'\left(y'-\frac{b'}{4}\right)^2+d'\left(y'-\frac{b'}{4}\right)+e'\\
&=\left(y^4-4y^3\frac{b'}{4}+6y^2\frac{b'^2}{4^2}-4y\frac{b'^3}{4^3}+\frac{b'^4}{4^4}\right)+b'\left(y^3-3y^3\frac{b'}{4}+3y\frac{b'^2}{4^2}-\frac{b'^3}{4^3}\right)\\
&+c'\left(y^2-2y\frac{b'}{4}+\frac{b'^2}{4^2}\right)+d'\left(y-\frac{b'}{4}\right)+e'\\
&=y^4+(b'-b')y^3+\left(\frac{3}{4}b'^2+c'+\frac{3}{8}b'^2\right)y^2+\left(\frac{3}{16}b'^3-\frac{1}{2}c'b'-\frac{1}{16}b'^3+d'\right)y\\
&+\left(\frac{b'^4}{256}-\frac{1}{4}d'b'-\frac{1}{64}b'^4+\frac{1}{16}c'b'^2+e'\right)
\end{aligned} \tag{6.1.170}$$

where we see that the coefficient in front of the y^3 vanishes. Thus, any polynomial of the type:

$$P(x)=x^4+bx^3+cx^2+dx+1e \tag{6.1.171}$$

can be written in the following form:

$$y^4+c''y^2+d''y+e''=0 \tag{6.1.172}$$

By putting:

$$x=y-\frac{b'}{4} \tag{6.1.173}$$

$$c''=\frac{3}{4}b'^2+c'+\frac{3}{8}b'^2 \tag{6.1.174}$$

$$d''=\frac{3}{16}b'^3-\frac{1}{2}c'b'-\frac{1}{16}b'^3+d' \tag{6.1.175}$$

$$e''=\frac{b'^4}{256}-\frac{1}{4}d'b'-\frac{1}{64}b'^4+\frac{1}{16}c'b'^2+e' \tag{6.1.176}$$

Remark

If $d''=0$ the equation to solve is reality a "bisquare equation". The change of variable $X=y^2$ then allows to focus to a polynomial equation of the second degree (what we know is easily to solve).

We now introduce a parameter t (that we will choose wisely afterwards) and we rewrite the polynomial equation as follows:

$$(x^2+t)^2-\left[(2t-c'')x^2-d''x+(t^2-e'')\right]=0 \tag{6.1.177}$$

Remark

If the reader develop and distribute all the term of the previous relation he will fall back obviously on $x^4+c''x^2+d''x+e''=0$.

The underlying idea is to try to ensure that the bracketed part of the previous expression can be written as a square as:

$$(2t-c'')x^2-d''x+(t^2-e'')=(x-\lambda)^2 \tag{6.1.178}$$

Because in this case, using:

$$a^2-b^2=(a+b)(a-b) \tag{6.1.179}$$

Our polynomial equation can then be written:

$$(x^2+t)^2-(x-\lambda)^2=\big((x^2+t)+(x-\lambda)\big)\big((x^2+t)-(x-\lambda)\big)=0 \tag{6.1.180}$$

and we would have only to solve two polynomial equations of the second degree (what we know already how to do).

But for us to write:

$$(2t-c'')x^2-d''x+(t^2-e'')=(x-\lambda)^2 \tag{6.1.181}$$

the expression of second degree to the left of equality should have only one root. But we saw in our study of polynomial equations of the second degree that meant since the discriminant is zero:

$$\Delta=b^2-4ac=0 \tag{6.1.182}$$

and that the root was given by:

$$x=-\frac{b}{2a} \tag{6.1.183}$$

Which corresponds in our case to:

$$\Delta=d''^2-4(2t-c'')(t^2-e'')=0 \tag{6.1.184}$$

and therefore that:

$$4(2t-c'')(t^2-e'')=d''^2 \tag{6.1.185}$$

with:

$$\lambda=-\frac{-d''}{2(2t-c'')}=\frac{d''}{4t-2c''} \tag{6.1.186}$$

So finally, if t is such that $4(2t-c'')(t^2-e'')=d''^2$, then we have:

$$(2t-c'')x^2-d''x+(t^2-e'')=(2t-c'')(x-\lambda)(x-\lambda)=(2t-c'')\left(x-\frac{d''}{4t-2c''}\right)^2 \tag{6.1.187}$$

as the fundamental polynomial theorem give us for a polynomial of the second degree a unique root:

$$P(x)=ax^2+bx+c=a(x-r_1)(x-r_2)=a(x-r_1)^2 \tag{6.1.188}$$

To conclude, it is enough to find a number t satisfying the following relation:

$$4(2t-c'')(t^2-e'')=d''^2 \tag{6.1.189}$$

which is a degree 3 polynomial that we already know how to solve using the Cardan method.

Such general methods doesn't exist anymore for polynomial of degree higher or equal to 5 as we will prove it during our study of Galois Theory (see section Set Algebra page 1445).

6.1.3.10 Trigonometric Polynomials

Definition (#6.1.174): We name "trigonometric polynomial" of degree N any finite sum of the type:

$$S_N(\theta)=\sum_{n=-N}^{N} c_n e^{\mathrm{i}n\theta} \tag{6.1.190}$$

where $c_n \in \mathbb{C}$.

A trigonometric polynomial can also be written using the usual trigonometric functions with the following changes:

$$S_N(\theta)=c_0+\sum_{n=1}^{N} c_n e^{\mathrm{i}n\theta}+\sum_{n=1}^{N} c_{-n} e^{-\mathrm{i}n\theta} \tag{6.1.191}$$

Either using Euler's formula (see section Numbers page 251):

$$S_N(\theta)=c_0+\sum_{n=1}^{N} c_n(\cos(n\theta)+\mathrm{i}\sin(n\theta))+\sum_{n=1}^{N} c_{-n}(\cos(n\theta)-\mathrm{i}\sin(n\theta)) \tag{6.1.192}$$

What we can also rewrite as:

$$S_N(\theta)=c_0+\sum_{n=1}^{N}(c_n+c_{-n})\cos(n\theta)+\sum_{n+1}^{N}\mathrm{i}(c_n-c_{-n})\sin(n\theta) \tag{6.1.193}$$

By putting:

$$a_0=2c_0 \qquad a_n=c_n+c_{-n} \qquad b_n=\mathrm{i}(c_n-c_{-n}) \tag{6.1.194}$$

It comes:

$$S_N(\theta)=\frac{a_0}{2}+\sum_{i=1}^{N} a_n\cos(n\theta)+\sum_{n=1}^{N} b_n\sin(n\theta) \tag{6.1.195}$$

In engineering, the latter is often denoted:

$$S_N(t)=\frac{a_0}{2}+\sum_{i=1}^{N} a_n\cos(n2\pi f_0 t)+\sum_{n=1}^{N} b_n\sin(n2\pi f_0 t)=\frac{a_0}{2}+\sum_{i=1}^{N} a_n\cos\left(n\frac{2\pi}{T}t\right)+\sum_{n=1}^{N} b_n\sin\left(n\frac{2\pi}{T}t\right) \tag{6.1.196}$$

where f_0 is referred to as the "fundamental frequency".

We will extensively discussed in the section Sequences and Series how to use these polynomials in the context of the study of Fourier series (see page 1727).

6.1.3.11 Cyclotomic Polynomials

Definition (#6.1.175): If n is an integer (belongs to $\mathbb{N}$) and x a complex number (belongs to $\mathbb{C}$), we name "cyclotomic polynomial" that we denote traditionally by Φ_n and that we define as being the product of all monomials:

$$(x-\alpha) \tag{6.1.197}$$

where α is a nth primitive root of $\mathbb{C}$. In other words:

$$\Phi_n=(x-\alpha_0)(x-\alpha_2)(x-\alpha_2)\ldots(x-\alpha_{n-1}) \tag{6.1.198}$$

To recall an nth "unit root" (sometimes named "De Moivre number") is a complex number whose n-th power is equal to 1.

Thus, the set of all n-th unit roots is given by:

$$G_n=\{x\in\mathbb{C}\quad\text{such that}\quad x^n=1\} \tag{6.1.199}$$

which is a cyclic group (see the section Set Theory and also the section Set Algebra page 1417).

Then we name "n-th primitive root of unity" any element of this group generating it.

The elements of G_n are of the type:

$$e^{\frac{2\mathrm{i}k\pi}{n}} \tag{6.1.200}$$

with $k\in\mathbb{Z}$. We write then the set of the G_n in the form:

$$G_n=\left\{e^{\frac{2\mathrm{i}k\pi}{n}}\quad\text{with}\quad k\in\{0,\ldots,n-1\}\right\} \tag{6.1.201}$$

A small example of cyclotomic polynomial (more example will be given below):

$$\Phi_4(x)=(x-\mathrm{i})(x+\mathrm{i})(x-1)(x+1)=x^4-1 \tag{6.1.202}$$

with:

$$G_4=\left\{e^{\frac{2\mathrm{i}0\pi}{4}}=1,e^{\frac{2\mathrm{i}1\pi}{4}}=1,e^{\frac{2\mathrm{i}2\pi}{4}}=-1,e^{\frac{2\mathrm{i}3\pi}{4}}=-\mathrm{i}\right\} \tag{6.1.203}$$

which are therefore the 4th roots of unity (in other words: each of these number set to the power of 4 is equal to 1). They form the group G_4 and this can be generated only by i and $-\mathrm{i}$ (field generator according to what was seen in the section Set Theory).

So a cyclotomic polynomial is the product of factors that is written:

$$\Phi_n(x)=\prod_n\left(x-e^{\frac{2\mathrm{i}k\pi}{n}}\right) \tag{6.1.204}$$

with $k\in\{0,\ldots,n-1\}$.

We will see with the examples below that if n is even then:

$$\Phi_n(x)=x^n-1=\prod_n\left(x-e^{\frac{2\mathrm{i}k\pi}{n}}\right) \tag{6.1.205}$$

and if n is odd:

$$\Phi_n(x)=1+x+x^2+x^{n-1}=\sum_{k=0}^{n-1}x^k=\prod_n\left(x-e^{\frac{2\mathrm{i}k\pi}{n}}\right) \tag{6.1.206}$$

Example:

For n up to 30, the cyclotomic polynomials are:

$$\begin{aligned}
\Phi_1(x)&=x-1\\
\Phi_2(x)&=x+1\\
\Phi_3(x)&=x^2+x+1\\
\Phi_4(x)&=x^2+1\\
\Phi_5(x)&=x^4+x^3+x^2+x+1\\
\Phi_6(x)&=x^2-x+1\\
\Phi_7(x)&=x^6+x^5+x^4+x^3+x^2+x+1\\
\Phi_8(x)&=x^4+1\\
\Phi_9(x)&=x^6+x^3+1\\
\Phi_{10}(x)&=x^4-x^3+x^2-x+1\\
\Phi_{11}(x)&=x^{10}+x^9+x^8+x^7+x^6+x^5+x^4+x^3+x^2+x+1\\
\Phi_{12}(x)&=x^4-x^2+1\\
\Phi_{13}(x)&=x^{12}+x^{11}+x^{10}+x^9+x^8+x^7+x^6+x^5+x^4+x^3+x^2+x+1\\
\Phi_{14}(x)&=x^6-x^5+x^4-x^3+x^2-x+1\\
\Phi_{15}(x)&=x^8-x^7+x^5-x^4+x^3-x+1\\
\Phi_{16}(x)&=x^8+1\\
\Phi_{17}(x)&=x^{16}+x^{15}+x^{14}+x^{13}+x^{12}+x^{11}+x^{10}+x^9+x^8+x^7+x^6+x^5\\
&\quad+x^4+x^3+x^2+x+1\\
\Phi_{18}(x)&=x^6-x^3+1\\
\Phi_{19}(x)&=x^{18}+x^{17}+x^{16}+x^{15}+x^{14}+x^{13}+x^{12}+x^{11}+x^{10}+x^9+x^8+x^7\\
&\quad+x^6+x^5+x^4+x^3+x^2+x+1\\
\Phi_{20}(x)&=x^8-x^6+x^4-x^2+1\\
\Phi_{21}(x)&=x^{12}-x^{11}+x^9-x^8+x^6-x^4+x^3-x+1\\
\Phi_{22}(x)&=x^{10}-x^9+x^8-x^7+x^6-x^5+x^4-x^3+x^2-x+1\\
\Phi_{23}(x)&=x^{22}+x^{21}+x^{20}+x^{19}+x^{18}+x^{17}+x^{16}+x^{15}+x^{14}+x^{13}+x^{12}\\
&\quad+x^{11}+x^{10}+x^9+x^8+x^7+x^6+x^5+x^4+x^3+x^2+x+1\\
\Phi_{24}(x)&=x^8-x^4+1\\
\Phi_{25}(x)&=x^{20}+x^{15}+x^{10}+x^5+1\\
\Phi_{26}(x)&=x^{12}-x^{11}+x^{10}-x^9+x^8-x^7+x^6-x^5+x^4-x^3+x^2-x+1\\
\Phi_{27}(x)&=x^{18}+x^9+1\\
\Phi_{28}(x)&=x^{12}-x^{10}+x^8-x^6+x^4-x^2+1\\
\Phi_{29}(x)&=x^{28}+x^{27}+x^{26}+x^{25}+x^{24}+x^{23}+x^{22}+x^{21}+x^{20}+x^{19}+x^{18}+x^{17}+x^{16}+x^{15}\\
&\quad+x^{14}+x^{13}+x^{12}+x^{11}+x^{10}+x^9+x^8+x^7+x^6+x^5+x^4+x^3+x^2+x+1\\
\Phi_{30}(x)&=x^8+x^7-x^5-x^4-x^3+x+1
\end{aligned}\tag{6.1.207}$$

6.1.3.12 Legendre Polynomials

Definition (#6.1.176): Legendre polynomials are defined by (it is strongly recommended to read the sections of Differential and Integral Calculus page 1450 and also of Functional Analysis 2170 before continuing):

$$P_n(x)=\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^n}{\mathrm{d}x^n}(1-x^2)^n \tag{6.1.208}$$

where P_n is therefore a polynomial of degree n. We will see again these polynomials in the resolution of differential equations in physics (heat propagation, quantum physics, quantum chemistry, etc.). In most book the Legendre polynomial are written in the following equivalent form:

$$P_n(x)=\frac{1}{n!2^n}\frac{\mathrm{d}^n}{\mathrm{d}x^n}(x^2-1)^n \tag{6.1.209}$$

We will focus here only and uniquely on the properties that are used actually in the other Physics sections of this textbook!!!

Let us prove that following the definition of functional scalar product (see the sections Functional Analysis page 2379 and Vector Calculus 1821) Legendre polynomials are orthogonal. This is a very important property for our study of Quantum Chemistry (see page 6134) later!

Proof 6.4.2. Let P be a polynomial of degree $\leq n-1$. It suffices to prove that $\langle P_n|P\rangle=0$, that is to say that P_n is orthogonal to the space of polynomials of degree less than n. Indeed, we have:

$$\langle P_n|P\rangle=\int\limits_{-1}^{1}P_n(x)P(x)\mathrm{d}x=\frac{(-1)^n}{n!2^n}\int\limits_{-1}^{1}\frac{\mathrm{d}^n}{\mathrm{d}x^n}(1-x^2)^nP(x)\mathrm{d}x \tag{6.1.210}$$

integrating by parts we get:

$$\begin{aligned}\langle P_n|P\rangle&=\underbrace{\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^{n-1}}{\mathrm{d}x^{n-1}}(1-x^2)^nP(x)\Bigg|_{-1}^{1}}_{=0}-\frac{(-1)^n}{n!2^n}\int\limits_{-1}^{1}\frac{\mathrm{d}^{n-1}}{\mathrm{d}x^{n-1}}(1-x^2)^n\frac{\mathrm{d}}{\mathrm{d}x}P(x)\mathrm{d}x\\&=-\frac{(-1)^n}{n!2^n}\int\limits_{-1}^{1}\frac{\mathrm{d}^{n-1}}{\mathrm{d}x^{n-1}}(1-x^2)^n\frac{\mathrm{d}}{\mathrm{d}x}P(x)\mathrm{d}x\end{aligned} \tag{6.1.211}$$

> Caution!!! For the above zero term, only the term $(1-x^2)^n$ is derived there! So since x is squared, whatever the derivative the value will always be the same. This is what justifies that this term is equal to zero.

Continuing in this way we get after n integration by parts (see section Differential and Integral Calculus page 1532):

$$\langle P_n|P\rangle=-\frac{(-1)^n}{n!2^n}\int\limits_{-1}^{1}(1-x^2)^n\underbrace{\frac{\mathrm{d}^n}{\mathrm{d}x^n}P(x)}_{=0}\,\mathrm{d}x=0 \tag{6.1.212}$$

Remark

The derivative term is zero, since the derivative polynomial is of degree $n-1$.

■ Q.E.D.

Here are some useful properties for the section of Quantum Chemistry of the Legendre polynomials:

P1. We have $P_n(1)=1$:

Proof 6.4.3.

$$P_n(x)=\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^n}{\mathrm{d}x^n}(1-x^2)^n=\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^n}{\mathrm{d}x^n}((1+x)^n(1-x)^n) \tag{6.1.213}$$

and using the Leibniz differentiation rule for products (see section Differential and Integral Calculus page 1479) we have:

$$\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^n}{\mathrm{d}x^n}((1+x)^n(1-x)^n)=\frac{(-1)^n}{n!2^n}\sum_{j=0}^{n}\binom{n}{j}\frac{n!}{(n-j)!}(1+x)^{n-j}\frac{(-1)^{n-j}n!}{j!}(1-x)^j \tag{6.1.214}$$

Therefore:

$$P_n(1)=\frac{(-1)^n}{n!2^n}(-1)^n n!=1 \tag{6.1.215}$$

■ Q.E.D.

P2. We have $P_n(-x)=P_n(-x)$ if n is even:

Proof 6.4.4. If n is even:

$$\frac{\mathrm{d}^n}{\mathrm{d}x^n}(1-x^2)^n \tag{6.1.216}$$

is an even function and therefore:

$$P_n(x)=\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^n}{\mathrm{d}x^n}(1-x^2)^n \tag{6.1.217}$$

is even.

■ Q.E.D.

P3. We have $P_n(-x)=-P_n(x)$ if n is odd:

Proof 6.4.5. If n is odd:

$$\frac{\mathrm{d}^n}{\mathrm{d}x^n}(1-x^2)^n \tag{6.1.218}$$

is an odd function and therefore:

$$P_n(x)=\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^n}{\mathrm{d}x^n}(1-x^2)^n \tag{6.1.219}$$

is odd.

■ Q.E.D.

Theorem 6.5. We will now prove the validity of the following recurrence relation for the P_n (relations that we use in physics):

$$(n+1)P_{n+1}(x)=(2n+1)xP_n(x)-nP_{n-1}(x) \tag{6.1.220}$$

for $n\geq 1$.

Proof 6.5.1. $xP_n(x)$ is a polynomial of degree $n+1$, there exists therefore $a_j\in\mathbb{R}$ such that this polynomial can be expressed as a linear combination of the family of polynomials constituting the orthonormal basis (basis that enables us to generate/build the $xP_n(x)$):

$$xP_n(x)=\sum_{j=0}^{n+1}a_jP_j \tag{6.1.221}$$

Therefore we can write:

$$\langle xP_n|P_k\rangle=\left\langle\sum_{j=0}^{n+1}a_jP_j\middle|P_k\right\rangle=\sum_{j=0}^{n+1}a_j\langle P_j|P_k\rangle=a_k\|P_k\|^2 \tag{6.1.222}$$

but if we choose $k\leq n-2$ (because xP_k is therefore of degree $n-1$):

$$\langle xP_n|P_k\rangle=\int\limits_{-1}^{1}xP_n(x)P_k(x)\mathrm{d}x=\langle P_n|xP_k\rangle=0 \tag{6.1.223}$$

Therefore:

$$a_k\|P_k\|^2=0 \tag{6.1.224}$$

that is to say that $a_k=0$. Then it follows:

$$xP_n=a_{n+1}P_{n+1}+a_nP_n+a_{n-1}P_{n-1} \tag{6.1.225}$$

By the properties of the Legendre polynomials proved previously, we can write the equalities:

$$xP_n(x),x=1:\qquad 1=a_{n+1}+a_n+a_{n-1} \tag{6.1.226}$$

and:

$$xP_n(x),x=-1:\qquad 1=a_{n+1}-a_n+a_{n-1} \tag{6.1.227}$$

hence:

$$a_n=0\qquad\text{and}\qquad 1=a_{n+1}+a_{n-1} \tag{6.1.228}$$

The dominant coefficient of P_n denoted by $\text{dom}(P_n(x))$ is defined (for recall) as the coefficient of the monomial of the highest degree. Thus, it is given by:

$$\begin{aligned}P_n(x)&=\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^n}{\mathrm{d}x^n}(1-x^2)^n\Rightarrow P_n(x)=\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^n}{\mathrm{d}x^n}x^{2n}\\&\Rightarrow P_n(x)=\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^{n-1}}{\mathrm{d}x^{n-1}}(2nx^{2n-1})=\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^{n-n}}{\mathrm{d}x^{n-n}}(2n(2n-1)\ldots x^{2n-n})\\&=\frac{(-1)^n}{n!2^n}(2n(2n-1)\ldots(2n-(n-1))x^n)=\frac{(-1)^n}{n!2^n}(2n(2n-1)\ldots(n+1)x^n)=\frac{(2n)!}{(n!)^22^n}x^n\end{aligned} \tag{6.1.229}$$

Therefore:

$$\text{dom}(P_n(x))=\frac{(2n)!}{(n!)^22^n} \tag{6.1.230}$$

Remark

The reader will verify if needed for a given n that:

$$2n(2n-1)\ldots(n+1)=\frac{(2n)!}{n!} \tag{6.1.231}$$

The relation:

$$xP_n=a_{n+1}P_{n+1}+a_nP_n+a_{n-1}P_{n-1} \tag{6.1.232}$$

we got earlier impose us that the dominant coefficient of the polynomial of the linear combination to be equal to the dominant coefficient of the polynomial xP_n (we have eliminated the $(-1)^n$ which simplifies):

$$\cancel{(-1)^n}\frac{(2n)!}{(n!)^2 2^n}=a_{n+1}\cancel{(-1)^{n+2}}\frac{(2n+2)!}{(n+1)!^2 2^{n+1}} \tag{6.1.233}$$

After simplification we get:

$$a_{n+1}=\frac{(2n)!(n+1)!^2 2^{n+1}}{(n!)^2 2^n(2n+2)!}=\frac{(n+1)\cancel{(n+1)2}}{(2n+1)\cancel{(2n+2)}}=\frac{n+1}{2n+1} \tag{6.1.234}$$

and which finally gives easily:

$$a_{n-1}=\frac{n}{2n+1} \tag{6.1.235}$$

The relation:

$$xP_n=a_{n+1}P_{n+1}+a_nP_n+a_{n-1}P_{n-1} \tag{6.1.236}$$

becomes therefore:

$$(2n+1)xP_n=(n+1)P_{n+1}+nP_{n-1} \tag{6.1.237}$$

■ Q.E.D.

The first Legendre polynomials are:

$$\begin{aligned}
&P_0(x)=1\\
&P_1(x)=x\\
&P_2(x)=\frac{3}{2}x^2-\frac{1}{2}\\
&P_3(x)=\frac{5}{2}x^3-\frac{3}{2}x\\
&P_4(x)=\frac{35}{8}x^4-\frac{15}{4}x^2+\frac{3}{8}\\
&\qquad\ldots
\end{aligned} \tag{6.1.238}$$

The graphs of these polynomials (up to $n=5$) are shown below:

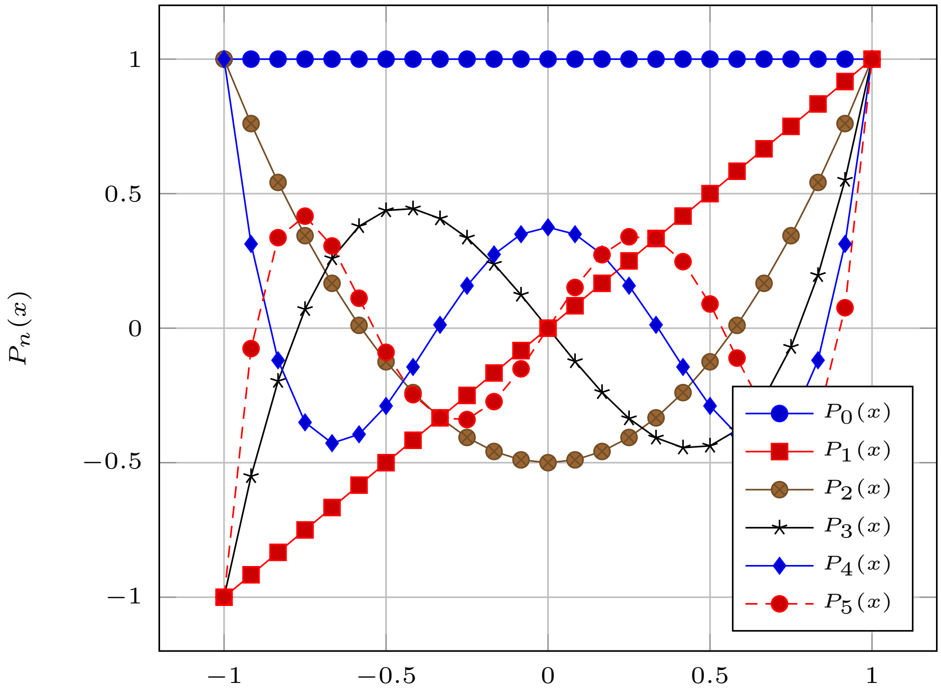

Figure 6.17: Five first Legendre polynomials

6.1.3.13 Laguerre Polynomials

Definition (#6.1.177): Before we deal with the maths of Laguerre polynomials the reader has to known the huge majority of the text below is a simple copy/paste of the content of the excellent textbook [24]. It is by the way strongly recommended to read the sections of Differential and Integral Calculus page 1450 and also of Functional Analysis 2170 before continuing!

"Laguerre's ordinary differential equation" (which derives from the radial partial differential equation of Schrödinger's for the hydrogen atom[3] as we will prove it in the section of Quantum Chemistry at page 6173) is:

$$\boxed{xy''(x)+(1-x)y'(x)+\lambda y(x)=0} \tag{6.1.239}$$

This equation has non-singular solutions only if n is a non-negative integer.

Let us derive a solution using the Frobenius method (see section Sequences and Series page 1773)! For that purpose we first assume that the solution y is given in the form:

$$y=\sum_{n=0}^{+\infty}a_nx^{r+n} \tag{6.1.240}$$

with its first two derivatives:

$$y'=\sum_{n=0}^{+\infty}(r+n)a_nx^{r+n-1} \tag{6.1.241}$$

---

[3] The Laguerre polynomials arise in quantum mechanics, in the radial part of the solution of the Schrödinger equation for a one-electron atom. They also describe the static Wigner functions of oscillator systems in quantum mechanics in phase space. They further enter in the quantum mechanics of the Morse potential and of the 3D isotropic harmonic oscillator.

and:

$$y'' = \sum_{n=0}^{+\infty} (r+n)(r+n-1)a_n x^{r+n-2} \tag{6.1.242}$$

By substituting these expressions in the given differential equation, we get:

$$x\sum_{n=0}^{+\infty}(r+n)(r+n-1)a_n x^{r+n-2} + (1-x)\sum_{n=0}^{+\infty}(r+n)a_n x^{r+n-1} + \lambda\sum_{n=0}^{+\infty} a_n x^{r+n} = 0 \tag{6.1.243}$$

By multiplying the factors with the corresponding summations, we get:

$$\sum_{n=0}^{+\infty}(r+n)(r+n-1)a_n x^{r+n-1} + \sum_{n=0}^{+\infty}(r+n)a_n x^{r+n-1} - \sum_{n=0}^{+\infty}(r+n)a_n x^{r+n} + \lambda\sum_{n=0}^{+\infty} a_n x^{r+n} = 0 \tag{6.1.244}$$

Now we adjust the index of the first two summations so that x in them has exponent $r+n$:

$$\sum_{n=-1}^{+\infty}(r+n+1)(r+n)a_{n+1} x^{r+n} + \sum_{n=-1}^{+\infty}(r+n+1)a_{n+1} x^{r+n} - \sum_{n=0}^{+\infty}(r+n)a_n x^{r+n} + \lambda\sum_{n=0}^{+\infty} a_n x^{r+n} = 0 \tag{6.1.245}$$

We evaluate a few terms so that all summations start at index $n=0$ and get:

$$\begin{gathered} r(r-1)a_0 x^{r-1} + \sum_{n=0}^{+\infty}(r+n+1)(r+n)a_{n+1}x^{r+n} + ra_0 x^{r-1} \\ + \sum_{n=0}^{+\infty}(r+n+1)a_{n+1}x^{r+n} - \sum_{n=0}^{+\infty}(r+n)a_n x^{r+n} + \lambda\sum_{n=0}^{+\infty} a_n x^{r+n} = 0 \end{gathered} \tag{6.1.246}$$

Combining the terms, we have:

$$[r(r-1)+r]a_0 x^r + \sum_{n=0}^{+\infty}\{[(r+n+1)(r+n)+(r+n+1)]a_{n+1} - (r+n-\lambda)a_n\}\, x^{r+n} = 0 \tag{6.1.247}$$

which is, after simplifying:

$$r^2 a_0 x^r + \sum_{n=0}^{+\infty}\left[(r+n+1)^2 a_{n+1} - (r+n-\lambda)a_n\right] x^{r+n} = 0 \tag{6.1.248}$$

Equating the coefficients on both sides, we get:

$$\begin{cases} r^2 a_0 = 0 \\ (r+n+1)^2 a_{n+1} - (r+n-\lambda)a_n = 0, \forall n \in \mathbb{N}_0 \end{cases} \tag{6.1.249}$$

Dividing the last equation by $r+n+1 \neq 0$ and shifting the indices, we get the "recurrence equation":

$$(r+n)^2 a_n - (r+n-1-\lambda)a_{n-1} = 0, \forall n \in \mathbb{N} \tag{6.1.250}$$

Since $a_0 \neq 0$, we get the "indical equation" of the initial equation:

$$r^2 = 0 \tag{6.1.251}$$

with roots $r_{1,2} = 0$.

The recurrence relation can be written as:

$$a_n = \frac{(r+n-1-\lambda)a_{n-1}}{(r+n)^2} = \frac{(n-1-\lambda)a_{n-1}}{n^2} \tag{6.1.252}$$

Therefore:

$$\begin{aligned}
a_0 &:= 1\\
a_1 &= \frac{-\lambda \cdot a_0}{1^2} = \frac{-\lambda \cdot 1}{1} = -\lambda\\
a_2 &= \frac{(1-\lambda)\cdot(-\lambda)}{4} = \frac{-\lambda+\lambda^2}{4} = \frac{\lambda(\lambda-1)}{2^2}\\
a_3 &= \frac{(2-\lambda)\cdot(-\lambda+\lambda^2)}{9\cdot 4} = \frac{(2-\lambda)\cdot\lambda(\lambda-1)}{2^2\cdot 3^2} = \frac{-\lambda(\lambda-1)(\lambda-2)}{2^2\cdot 3^2}\\
a_4 &= \frac{-\lambda(3-\lambda)(\lambda-1)(\lambda-2)}{4^2\cdot 3^2\cdot 2^2} = \frac{\lambda(\lambda-3)(\lambda-2)(\lambda-1)}{4^2\cdot 3^2\cdot 2^2}
\end{aligned} \tag{6.1.253}$$

Therefore, choosing $a_0 = 1$, the solution $y = y_1$ is equal to:

$$\begin{aligned}
y_1 &= x^r \sum_{n=0}^{+\infty} a_n x^n = 1 + \frac{-\lambda}{1^2}x + \frac{(-\lambda)(1-\lambda)}{1^2\cdot 2^2}x^2 + \frac{(-\lambda)(1-\lambda)(2-\lambda)}{1^2\ldots 2^2\ldots 3^2}x^3\\
&+\cdots + \frac{(-\lambda)(1-\lambda)\cdots(n-1-\lambda)}{(n!)^2} + \cdots\\
&= 1 - \lambda x + \frac{\lambda(\lambda-1)}{2^2}x^2 - \frac{\lambda(\lambda-1)(\lambda-2)}{2^2\cdot 3^2}x^3 + \frac{\lambda(\lambda-1)(\lambda-2)(\lambda-3)}{2^2\cdot 3^2\cdot 4^2}x^4 + \ldots
\end{aligned} \tag{6.1.254}$$

We see that this sum is finite as whatever the value of λ at a given moment all factor will have $(\lambda - \ldots)$ that is equal to zero. So all the terms will cancel. Thus the solution y_1 has finitely many terms and is a polynomial.

For $\lambda = n$, this solution becomes:

$$\begin{aligned}
y(t) &= 1 - x + \frac{1}{2}x^2 - \frac{1\cdot 2\cdot 3}{2^2\cdot 3^2}x^3 + \frac{1\cdot 2\cdot 3\cdot 4}{2^2\cdot 3^2\cdot 4^2}x^4 - \ldots\\
&= 1 - x + \frac{1}{2}x^2 - \frac{1}{2\cdot 3}x^3 + \frac{1}{2\cdot 3\cdot 4}x^4 - \ldots\\
&= 10x + \frac{1}{2!}x^2 - \frac{1}{3!}x^3 + \frac{1}{4!}x^4 - \ldots
\end{aligned} \tag{6.1.255}$$

We can see that this solution is polynomial if $\lambda = n$. Now let us come back to:

$$\begin{aligned}
y_1 &= 1 - \lambda x + \frac{\lambda(\lambda-1)}{2^2}x^2 - \frac{\lambda(\lambda-1)(\lambda-2)}{2^2\cdot 3^2}x^3 + \frac{\lambda(\lambda-1)(\lambda-2)(\lambda-3)}{2^2\cdot 3^2\cdot 4^2}x^4 + \ldots\\
&= 1 - \frac{\lambda(\lambda-1)!}{1^2(\lambda-1)!}x^1 + \frac{\lambda(\lambda-1)(\lambda-2)!}{1^2 2^2(\lambda-2)!}x^2 - \frac{\lambda(\lambda-1)(\lambda-2)(\lambda-3)!}{1^2 2^2 3^2(\lambda-3)!}x^3 + \frac{\lambda(\lambda-1)(\lambda-2)(\lambda-3)(\lambda-4)!}{1^2 2^2 3^2 4^2(\lambda-4)!}x^4 + \ldots\\
&= 1 - \frac{\lambda!}{(1!)^2(\lambda-1)!}x^1 + \frac{\lambda!}{(2!)^2(\lambda-2)!}x^2 - \frac{\lambda!}{(3!)^2(\lambda-3)!}x^3 + \frac{\lambda!}{(4!)^2(\lambda-4)!}x^4 + \ldots
\end{aligned} \tag{6.1.256}$$

That last relation bring us to define the Laguerre polynomial as:

$$\boxed{L_n(x)=\sum_{\lambda=0}^{n}\frac{(-1)^{\lambda}n!}{(\lambda!)^2(n-\lambda)!}x^{\lambda}=\sum_{\lambda=0}^{n}\binom{n}{\lambda}\frac{(-x)^{\lambda}}{\lambda!}} \tag{6.1.257}$$

That relation can often be found in textbooks under the following form:

$$\begin{aligned}L_n(x)&=\frac{(-1)^n}{n!}\left[x^n-\frac{n^2}{1!}x^{n-1}+\frac{n^2(n-1)^2}{2!}x^{n-2}-\cdots+(-1)^n n!\right]\\&=\sum_{m=0}^{n}\frac{(-1)^m n!x^m}{(n-m)(m!)^2}=\sum_{s=0}^{n}\frac{(-1)^{n-s}n!x^{n-s}}{((n-s)!)^2 s!}\end{aligned} \tag{6.1.258}$$

We can then build the following table:

n	$L_n(x)$
0	1
1	$-x+1$
2	$\frac{1}{2}(x^2-4x+2)$
3	$\frac{1}{6}(-x^3+9x^2-18x+6)$
4	$\frac{1}{24}(x^4-16x^3+72x^2-96x+24)$
5	$\frac{1}{120}(-x^5+25x^4-200x^3+600x^2-600x+120)$
6	$\frac{1}{720}(x^6-36x^5+450x^4-2400x^3+5400x^2-4320x+720)$
...	...
n	$\frac{1}{n!}((-x)^n+n^2(-x)^{n-1}+\ldots+n(n!)(-x)+n!)$

Table 6.5: **List of some Laguerre polynomials**

And let us give some plots of these Laguerre polynomials:

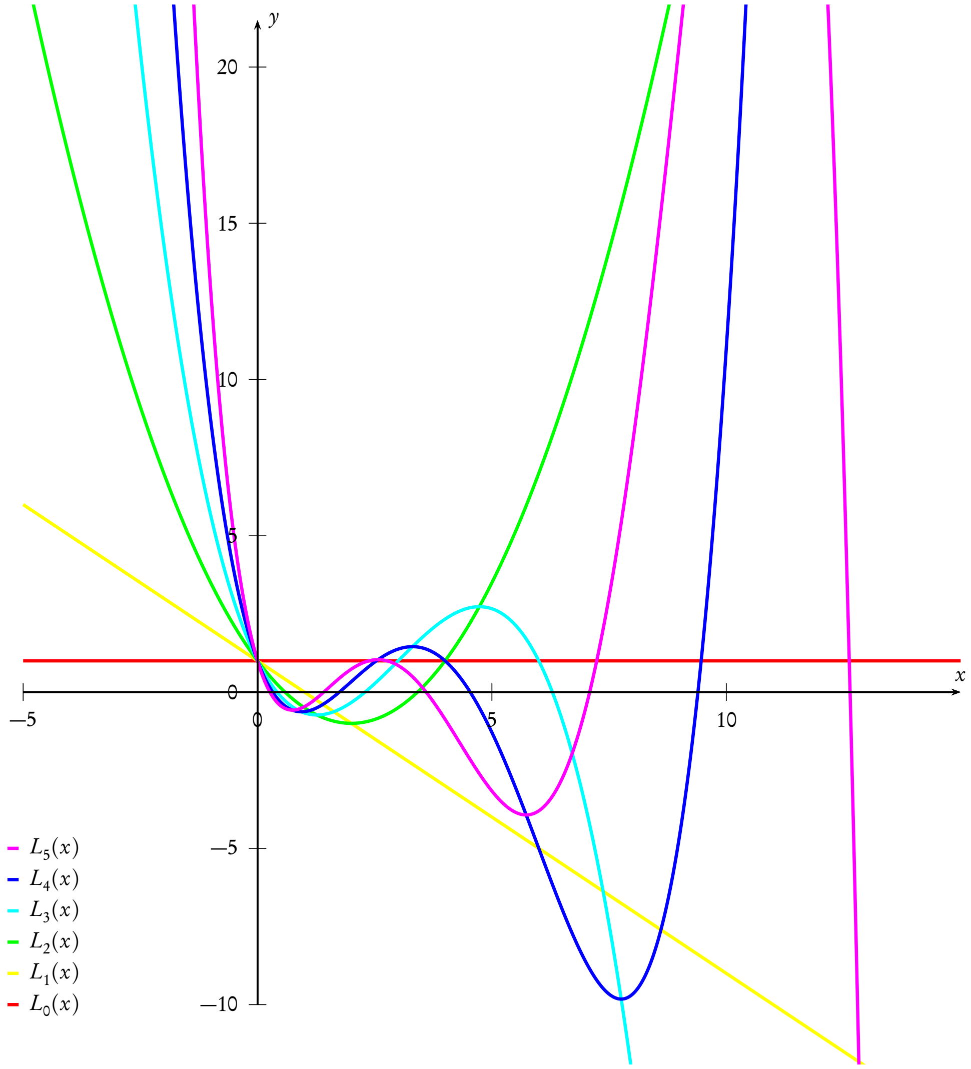

Figure 6.18: **Plot of six first Laguerre polynomials**

Now we can easily prove that:

$$\boxed{L_n(x)=\frac{e^x}{n!}\frac{\mathrm{d}^n}{\mathrm{d}x^n}\left(x^n e^{-x}\right)\qquad \text{(integral } n\text{)}} \tag{6.1.259}$$

named "Rodrigues' formula" for Laguerre polynomials (they are different way to express it and different versions also of it depending on what type of Laguerre polynomial we are dealing with!).

If we use the explicit representation for Laguerre polynomials:

$$L_n(x)=\sum_{k=0}^{n}\left(\begin{array}{c} n \\ k \end{array}\right)\frac{(-x)^k}{k!} \tag{6.1.260}$$

then the result follows easily from the Leibniz differentiation rule for products:

$$(f(x)g(x))^{(n)}=\sum_{k=0}^{n}\left(\begin{array}{c} n \\ k \end{array}\right) f^{(k)}(x)g^{(n-k)}(x) \tag{6.1.261}$$

Just let $f(x)=x^n$ and $g(x)=e^{-x}$. Then $f^{(k)}(x)=x^{n-k}n!/(n-k)!$ and $g^{(n-k)}(x)=(-1)^{n-k}e^{-x}$. Now if we clean it up and redo the sum in reverse order, i.e., $k\rightarrow n-k$ then we fall back on the Rodrigues' formula above.

Now let us prove that the functional generating function (see section Sequences and Series page 1789) of Laguerre polynomials is given by:

$$\boxed{G(x,t)=\sum_{n=0}^{+\infty}L_n(x)t^n,\quad |t|<1} \tag{6.1.262}$$

The short proof is given by (we simply use the Maclaurin series of e^z where $z=-xt/(1-t)$):

$$\begin{aligned}\sum_{n=0}^{+\infty}L_n(x)t^n&=\sum_{n=0}^{+\infty}\sum_{k=0}^{n}(-1)^k\begin{pmatrix}n\\k\end{pmatrix}\frac{x^kt^n}{k!}=\sum_{k=0}^{+\infty}\frac{(-1)^kx^k}{k!}\sum_{n=k}^{+\infty}\begin{pmatrix}n\\k\end{pmatrix}t^n\\&=\sum_{k=0}^{+\infty}\frac{(-1)^kx^k}{k!}\frac{t^k}{(1-t)^{k+1}}=\frac{1}{1-t}\sum_{k=0}^{+\infty}\frac{(-1)^k(xt)^k}{k!(1-t)^k}=\frac{1}{1-t}\sum_{k=0}^{+\infty}\frac{1}{k!}\left(\frac{(-xt)}{1-t}\right)^k\\&=\frac{e^{-xt/(1-t)}}{1-t}\end{aligned} \tag{6.1.263}$$

By differentiating the generating function above with respect to x and t, we get the two recurrence relations for the Laguerre polynomials as follows:

To derive the first recurrence relation we start from:

$$G(x,t)=\sum_{n=0}^{+\infty}L_n(x)t^n=\frac{\exp\{-xt/(1-t)\}}{1-t} \tag{6.1.264}$$

We differentiate both sides with respect to t to get:

$$\sum_{n=0}^{+\infty}L_n(x)nt^{n-1}=\frac{1}{(1-t)^2}e^{\frac{-xt}{1-t}}-\frac{1}{1-t}e^{-\frac{xt}{1-t}}\frac{x}{(1-t)^2} \tag{6.1.265}$$

$$=\frac{1}{1-t}\sum_{n=0}^{+\infty}L_n(x)t^n-\frac{x}{(1-t)^2}L_n(x)t^n \tag{6.1.266}$$

Multiplying both sides by $(1-t)^2$ and simplifying, we get:

$$\begin{aligned}\sum_{n=0}^{+\infty}nL_n(x)t^{n-1}-2\sum_{n=0}^{+\infty}nL_n(x)t^n+\sum_{n=0}^{+\infty}nL_n(x)t^{n+1}&=\sum_{n=0}^{+\infty}L_n(x)t^n\\&-\sum_{n=0}^{+\infty}L_n(x)t^{n+1}-x\sum_{n=0}^{+\infty}L_n(x)t^n\end{aligned} \tag{6.1.267}$$

We now equate the coefficients of t^n from both sides in the above relation to get:

$$\begin{aligned}(n+1)L_{n+1}(x)-2nL_n(x)+(n-1)L_{n-1}(x)=L_n(x)-L_{n-1}(x)-xL_n(x)\\\Rightarrow\quad(n+1)L_{n+1}(x)=(2n+1-x)L_n(x)-nL_{n-1}(x)\end{aligned} \tag{6.1.268}$$

To get the second recursion relation we start again form the generating function:

$$G(x,t)=\sum_{n=0}^{+\infty}L_n(x)t^n=\frac{e^{-xt/(1-t)}}{1-t} \tag{6.1.269}$$

We now differentiate both sides of the above equality with respect to x to get:

$$\sum_{n=0}^{+\infty}L'_n(x)t^n=\frac{1}{1-t}\cdot e^{-\frac{xt}{1-t}}\left[\frac{-t}{1-t}\right] \tag{6.1.270}$$

using the generating function that latter can be rewritten:

$$\sum_{n=0}^{+\infty}L'_n(x)t^n=\frac{-t}{1-t}\sum_{n=0}^{+\infty}L_n(x)t^n \tag{6.1.271}$$

Therefore:

$$\begin{gathered}(1-t)\sum_{n=0}^{+\infty}L'_n(x)t^n=-t\sum_{n=0}^{+\infty}L_n(x)t^n\\ \sum_{n=0}^{+\infty}L'_n(x)t^n-\sum_{n=0}^{+\infty}L'_n(x)t^{n+1}=\sum_{n=0}^{+\infty}L_n(x)t^{n+1}\end{gathered} \tag{6.1.272}$$

Equating the coefficients of t^n from both sides of the above gives:

$$\begin{gathered}L'_n(x)-L'_{n-1}(x)=-L_{n-1}(x)\\ \Rightarrow L'_{n-1}(x)=L'_n(x)+L_{n-1}(x)\end{gathered} \tag{6.1.273}$$

Therefore:

$$L'_n(x)=L'_{n+1}(x)+L_n(x) \tag{6.1.274}$$

and rearranging:

$$L'_{n+1}(x)=L'_n(x)-L_n(x) \tag{6.1.275}$$

From the first recurrence relation:

$$(n+1)L_{n+1}(x)=(2n+1-x)L_n(x)-nL_{n-1}(x) \tag{6.1.276}$$

We differentiate the above with respect to x to get:

$$(n+1)L'_{n+1}(x)=(2n+1-x)L'_n(x)-L_n(x)-nL'_{n-1}(x) \tag{6.1.277}$$

Substituting the values of $L'_{n-1}(x)$ and $L'_{n+1}(x)$ derived earlier in the previous relation, we get:

$$(n+1)\left[L'_n(x)-L_n(x)\right]=(2n+1-x)L'_n(x)-L_n(x)-n\left[L'_n(x)+L_{n-1}(x)\right] \tag{6.1.278}$$

and after simplification we get the second recurrence relation:

$$xL'_n(x)=nL_n(x)-nL_{n-1}(x) \tag{6.1.279}$$

For the proof of the orthogonality of Laguerre polynomials, the reader can refer to the section Analysis page 2386.

6.1.3.13.1 Associated Laguerre Polynomials

Definition (#6.1.178): In many applications, particularly in quantum mechanics (again!), we need the "associated Laguerre polynomials" also named "generalized Laguerre polynomials" defined by:

$$L_n^k(x) = (-1)^k \frac{\mathrm{d}^k}{\mathrm{d}x^k} L_{n+k}(x) \tag{6.1.280}$$

From the series form of $L_n(x)$ we verify that the lowest associated Laguerre polynomials are given by:

$$\begin{aligned} L_0^k(x) &= 1 \\ L_1^k(x) &= -x + k + 1 \\ L_2^k(x) &= \frac{x^2}{2} - (k+2)x + \frac{(k+2)(k+1)}{2} \end{aligned} \tag{6.1.281}$$

Therefore in general:

$$\boxed{L_n^k(x) = (-1)^k \frac{\mathrm{d}^k}{\mathrm{d}x^k} L_{n+k}(x) = \sum_{m=0}^{n} (-1)^m \frac{(n+k)!}{(n-m)!(k+m)!m!} x^m, \quad k > -1} \tag{6.1.282}$$

The first few associated Laguerre polynomials are:

n	$L_n^k(x)$
L_0^k	1
L_1^k	$-x + (k+1)$
L_2^k	$\frac{x^2}{2} - (k+2)x + \frac{(k+1)(k+2)}{2}$
L_3^k	$-\frac{x^3}{6} + \frac{(k+3)x^2}{2} - \frac{(k+2)(k+3)x}{2} + \frac{(k+1)(k+2)(+3)}{6}$
$\ldots$	$\ldots$

Table 6.6: **List of some associated Laguerre polynomials**

And a plot of some of them:

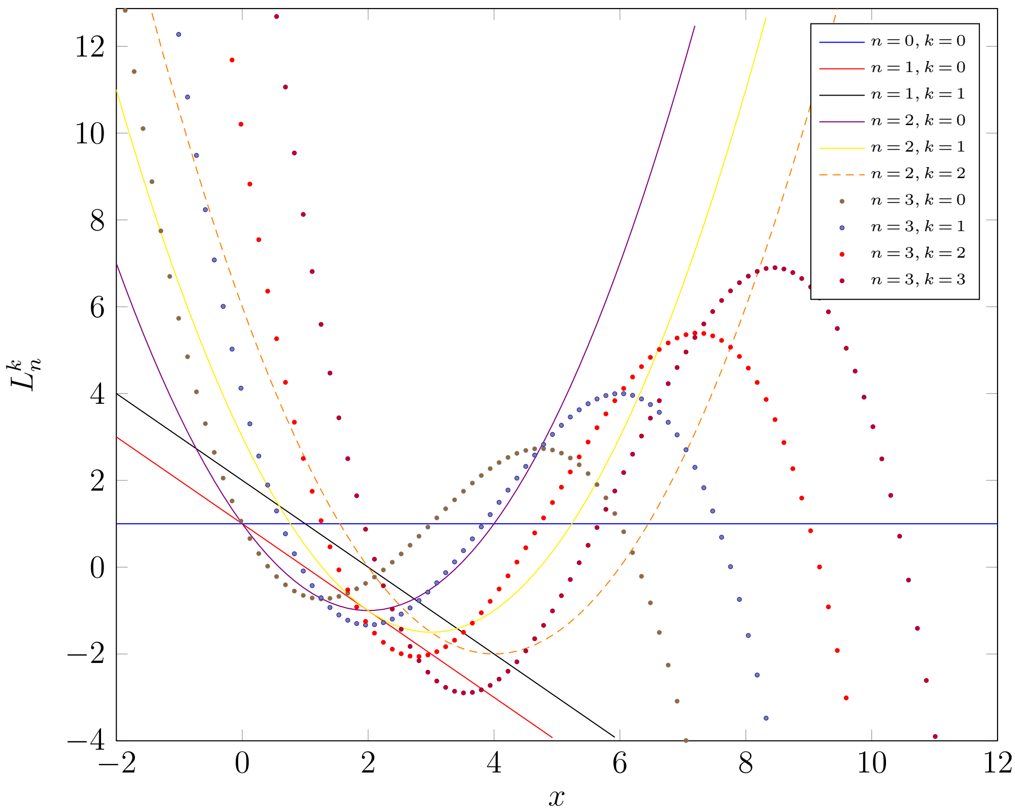

Figure 6.19: **Plot of some associated Laguerre polynomials (source: Wikipedia)**

Or using a recurrence relation for any $k \geq 1$:

$$L_{k+1}^{(\alpha)}(x)=\frac{(2k+1+\alpha-x)L_k^{(\alpha)}(x)-(k+\alpha)L_{k-1}^{(\alpha)}(x)}{k+1} \tag{6.1.283}$$

A generating function may be developed by differentiating the Laguerre generating function k times to yield:

$$\begin{aligned}(-1)^k\frac{\mathrm{d}^k}{\mathrm{d}x^k}\frac{e^{-xz/(1-z)}}{1-z}&=(-1)^k\sum_{n=0}^{+\infty}\frac{\mathrm{d}^k}{\mathrm{d}x^k}L_{n+k}(x)z^{n+k}=\sum_{n=0}^{+\infty}L_n^k(x)z^{n+k}\\&=\left(\frac{z}{1-z}\right)^k\frac{e^{xz/(1-z)}}{1-z}\end{aligned} \tag{6.1.284}$$

From the last two members of this equation, cancelling the common factor z^n, we get:

$$\frac{e^{-xz/(1-z)}}{(1-z)^{k+1}}=\sum_{n=0}^{+\infty}L_n^k(x)z^n,\quad |z|<1 \tag{6.1.285}$$

From this, for $x=0$, the binomial expansion:

$$\frac{1}{(1-z)^{k+1}}=\sum_{n=0}^{+\infty}\left(\begin{array}{c}-k-1\\n\end{array}\right)(-z)^n=\sum_{n=0}^{+\infty}L_n^k(0)z^n \tag{6.1.286}$$

yields:

$$L_n^k(0)=\frac{(n+k)!}{n!k!} \tag{6.1.287}$$

Recurrence relations can be derived from the generating function or by differentiating the Laguerre polynomial recurrence relations. Among the numerous possibilities are:

$$\begin{gathered}(n+1)L_{n+1}^k(x)=(2n+k+1-x)L_n^k(x)-(n+k)L_{n-1}^k(x)\\ x\frac{\mathrm{d}L_n^k(x)}{\mathrm{d}x}=nL_n^k(x)-(n+k)L_{n-1}^k(x)\end{gathered}\tag{6.1.288}$$

Thus, we obtain from differentiating Laguerre's ordinary differential equation once:

$$x\frac{\mathrm{d}L_n''}{\mathrm{d}x}+L_n''-L_n'+(1-x)\frac{\mathrm{d}L_n'}{\mathrm{d}x}+n\frac{\mathrm{d}L_n}{\mathrm{d}x}=0\tag{6.1.289}$$

and eventually from differentiating Laguerre's ordinary differential equation k times:

$$x\frac{\mathrm{d}^k}{\mathrm{d}x^k}L_n''+k\frac{\mathrm{d}^{k-1}}{\mathrm{d}x^{k-1}}L_n''-k\frac{\mathrm{d}^{k-1}}{\mathrm{d}x^{k-1}}L_n'+(1-x)\frac{\mathrm{d}^k}{\mathrm{d}x^k}L_n'+n\frac{\mathrm{d}^k}{\mathrm{d}x^k}L_n=0\tag{6.1.290}$$

Adjusting the index $n\rightarrow n+k$, we have the "associated Laguerre ordinary differential equation":

$$x\frac{\mathrm{d}^2L_n^k(x)}{\mathrm{d}x^2}+(k+1-x)\frac{\mathrm{d}L_n^k(x)}{\mathrm{d}x}+nL_n^k(x)=0\tag{6.1.291}$$

Most known under the following form:

$$\boxed{xy''+(\alpha+1-x)y'+ny=0}\tag{6.1.292}$$

When associated Laguerre polynomials appear in a physical problem it is usually because that physical problem involves the above differential equation. The most important application is the bound states of the hydrogen atom, which are derived from it! A "Rodrigues representation of the associated Laguerre polynomial":

$$\boxed{L_n^k(x)=\frac{e^x x^{-k}}{n!}\frac{\mathrm{d}^n}{\mathrm{d}x^n}\left(e^{-x}x^{n+k}\right)}\tag{6.1.293}$$

may be obtained by:

$$\begin{aligned}L_n^k(x)=&\frac{e^x x^{-k}}{n!}\frac{\mathrm{d}^n}{\mathrm{d}x^n}\left(e^{-x}x^{n+k}\right)=&(-1)^n\frac{\mathrm{d}^n}{\mathrm{d}x^n}\left[L_{n+k}(x)\right]\\ =&\sum_{m=0}^{+\infty}(-1)^m\frac{(n+k)!}{(n-m)!(k+m)!m!}x^m\end{aligned}\tag{6.1.294}$$

The associated Laguerre polynomials shows the same orthogonality properties as for the Laguerre polynomials!

Let us now derive a useful result again for our study of Quantum Chemistry: the normalization constant of the associated Laguerre polynomial!

Using Rodrigue's formula for the associated Laguerre polynomial we get:

$$L_n^k(x)=\frac{x^{-k}e^x}{n!}\frac{\mathrm{d}^n}{\mathrm{d}x^n}\left(x^{n+k}e^{-x}\right)\tag{6.1.295}$$

Therefore:

$$\begin{aligned}\int\limits_0^{+\infty} x^k e^{-x}\left(L_n^k(x)\right)^2\mathrm{d}x&=\frac{1}{n!}\int\limits_0^{+\infty} L_n^k(x)\frac{\mathrm{d}^n}{\mathrm{d}x^n}(x^{n+k}e^{-x})\mathrm{d}x\\&=\frac{(-1)^m}{n!}\int\limits_0^{+\infty}\left(\frac{\mathrm{d}^m}{\mathrm{d}x^m}L_n^k(x)\right)\left(\frac{\mathrm{d}^{n-m}}{\mathrm{d}x^{n-m}}(x^{n+k}e^{-x})\right)\mathrm{d}x\end{aligned}\tag{6.1.296}$$

for $m\leqslant n$ (using induction on m and integration by parts). Taking $m=n$ (recall that $L_n^k(x)$ is a polynomial of degree n with the leading coefficient equal to $(-1)^n/n!$), we get the needed:

$$\int\limits_0^{+\infty} x^k e^{-x}\left(L_n^k(x)\right)^2\mathrm{d}x=\frac{1}{n!}\int\limits_0^{+\infty} x^{n+k}e^{-x}\mathrm{d}x=\frac{(n+k)!}{n!}\tag{6.1.297}$$

6.1.3.13.2 Laguerre functions

By letting:

$$\psi_n^k(x)=e^{-x/2}x^{k/2}L_n^k(x)\tag{6.1.298}$$

$\psi_n^k(x)$ satisfies the self-adjoint ordinary differential equation:

$$x\frac{\mathrm{d}^2\psi_n^k(x)}{\mathrm{d}x^2}+\frac{\mathrm{d}\psi_n^k(x)}{\mathrm{d}x}+\left(-\frac{x}{4}+\frac{2n+k+1}{2}-\frac{k^2}{4x}\right)\psi_n^k(x)=0\tag{6.1.299}$$

The $\psi_n^k(x)$ are sometimes named "Laguerre functions".

A further useful form is given by defining (this corresponds to modifying the function $\psi_n^k(x)$ to eliminate the first derivative in the previous ordinary differential equation):

$$\Phi_n^k(x)=e^{-x/2}x^{(k+1)/2}L_n^k(x)\tag{6.1.300}$$

Substitution into the associated Laguerre equation yields (corresponding to the dimensionless ordinary differential equation of the radial term of the non-rigid rotator that we meet during our study of the hydrogenoid atom in the section of Quantum Chemistry):

$$\boxed{\frac{\mathrm{d}^2\Phi_n^k(x)}{\mathrm{d}x^2}+\left(-\frac{1}{4}+\frac{2n+k+1}{2x}-\frac{k^2-1}{4x^2}\right)\Phi_n^k(x)=0}\tag{6.1.301}$$

Let us prove that claim! To attain the second derivative, we need the first derivative, and use the notation:

$$y=e^{-x/2}x^{(k+1)/2}v\tag{6.1.302}$$

where $v=L_j^k(x)$, because the indices do not change and only serve to add clutter, and we can remember the independent variable is x. The first derivative is then:

$$\begin{aligned}y'&=-\frac{1}{2}e^{-x/2}x^{(k+1)/2}v+e^{-x/2}\left(\frac{k+1}{2}\right)x^{(k-1)/2}v+e^{-x/2}x^{(k+1)/2}v'\\&=\left[-\frac{1}{2}v+\left(\frac{k+1}{2x}\right)v+v'\right]e^{-x/2}x^{(k+1)/2}\\&\Rightarrow\quad\left(e^{x/2}x^{-(k+1)/2}\right)y'=-\frac{1}{2}v+\frac{k+1}{2x}v+v'\end{aligned}\tag{6.1.303}$$

In a similar way we get:

$$\left(e^{x/2}x^{-(k+1)/2}\right)y''=\frac{1}{4}v-\frac{1}{2}\frac{k+1}{2x}v-\frac{1}{2}v'-\frac{1}{2}\frac{k+1}{2x}v+\frac{k+1}{2x}\frac{k-1}{2x}v+\frac{k+1}{2x}v'-\frac{1}{2}v'+\frac{k+1}{2x}v'+v'' \tag{6.1.304}$$

By substituting the second derivative and the function in the associated Laguerre ordinary differential equation:

$$y''+\left(-\frac{1}{4}+\frac{2j+k+1}{2x}-\frac{k^2-1}{4x^2}\right)y=0 \tag{6.1.305}$$

and dividing by the common factor of $e^{-x/2}x^{(k+1)/2}$, the remaining terms are:

$$\begin{aligned}
&\left(\frac{1}{4}v-\frac{1}{2}\frac{k+1}{2x}v-\frac{1}{2}v'-\frac{1}{2}\frac{k+1}{2x}v+\frac{k+1}{2x}\frac{k-1}{2x}v+\frac{k+1}{2x}v'-\frac{1}{2}v'+\frac{k+1}{2x}v'+v''\right)\\
&\qquad\qquad+\left(-\frac{1}{4}+\frac{2j+k+1}{2x}-\frac{k^2-1}{4x^2}\right)v=0\\
&\Rightarrow v''+\cancel{\frac{1}{4}}v-\frac{1}{2}\frac{k+1}{2x}v-\frac{1}{2}v'-\frac{1}{2}\frac{k+1}{2x}v+\cancel{\frac{k^2+1}{4x^2}}v+\frac{k+1}{2x}v'-\frac{1}{2}v'+\frac{k+1}{2x}v'\\
&\qquad\qquad-\cancel{\frac{1}{4}}v+\frac{2j+k+1}{2x}v-\cancel{\frac{k^2+1}{4x^2}}v=0\\
&\Rightarrow v''-\cancel{\frac{k+1}{4x}}v-\frac{1}{2}v'-\cancel{\frac{k+1}{4x}}v+\frac{k+1}{x}v'-\frac{1}{2}v'+\frac{j}{x}v+\cancel{\frac{k+1}{2x}}v=0\\
&\Rightarrow v''-v'+\frac{k+1}{x}v'+\frac{j}{x}=0\\
&\Rightarrow xv''-xv'+(k+1)v'+jv=0\\
&\Rightarrow xv''+(1-x+k)v'+jv=0
\end{aligned} \tag{6.1.306}$$

which is the associated Laguerre equation. Since $v=L_j^k(x)$, and the $L_j^k(x)$ are solutions to the associated Laguerre equation. The above last line is equivalent to:

$$xL_j^{k''}(x)+(1-x+k)L_j^{k'}(x)+jL_j^k(x)=0 \tag{6.1.307}$$

which is the associated Laguerre equation, which we know to be a true statement, so:

$$y=e^{-x/2}x^{(k+1)/2}v=e^{-x/2}x^{(k+1)/2}L_j^k(x) \tag{6.1.308}$$

are solution to it! The proof is finished.

The corresponding normalization integral:

$$\int\limits_0^{+\infty}\left|\Phi_n^k(x)\right|^2\mathrm{d}x \tag{6.1.309}$$

is (without proof):

$$\int\limits_0^{+\infty}e^{-x}x^{k+1}\left[L_n^k(x)\right]^2\mathrm{d}x=\frac{(n+k)!}{n!}(2n+k+1) \tag{6.1.310}$$

Notice that the $\Phi_n^k(x)$ do not form an orthogonal set (except with x^{-1} as a weighting function) because of the x^{-1} in the term $(2n+k+1)/2x$.

To close this section, here is a summary of all polynomials we have seen so far and also of other polynomials we will prove later through this entire book:

Name	**Formulation**
Vanilla polynomials	$f(x)=\sum_n a_x x^n$
Trigonometric polynomials	$S_N(\theta)=\sum_{n=-N}^{N} c_n e^{in\theta}$
Cyclotomic polynomials	$\Phi_n(x)=\prod_n \left(x-e^{\frac{2ik\pi}{n}}\right)$
Legendre polynomials	$P_n(x)=\frac{(-1)^n}{n!2^n}\frac{\mathrm{d}^n}{\mathrm{d}x^n}(1-x^2)^n$
Laguerre polynomials	$L_n(x)=\sum_{\lambda=0}^{n}\frac{(-1)^\lambda n!}{(\lambda!)^2(n-\lambda)!}x^\lambda=\sum_{\lambda=0}^{n}\left(\begin{array}{c} n \\ \lambda \end{array}\right)\frac{(-x)^\lambda}{\lambda!}$
Associated Laguerre polynomials	$L_n^k(x)=\sum_{m=0}^{n}(-1)^m\frac{(n+k)!}{(n-m)!(k+m)!m!}x^m,\quad k>-1$
Bessel polynomials	$y_n(x)=\sum_{k=0}^{n}\frac{(n+k)!}{(n-k)!k!}\left(\frac{x}{2}\right)^k$
Hermite polynomials	$H_n(Q)=(-1)^n e^{Q^2}\frac{\mathrm{d}^n}{\mathrm{d}Q^n}e^{-Q^2}$
Bernstein polynomials	$B_{i,n}(t)=\frac{(n-1)!}{(1-i)!(n-i)!}t^{i-1}(1-t)^{n-i}=C_{i-1}^{n-1}t^{i-1}(1-t)^{n-i}$
Lagrange polynomials	$P(x)=\sum_{j=0}^{n}\left(\prod_{i=0,i\neq j}^{n}\frac{x-x_i}{x_j-x_i}\right)f(x_j)$
Newton polynomial	$N_n(x)=f[x_0]+\sum_{i=1}^{n}f[x_0,\ldots,x_i]\left(\prod_{j=0}^{i-1}(x-x_j)\right)$

6.2. Set Algebra

We will approach in this textbook the study of set structures very pragmatically (since you must remember that this textbook is dedicated to engineers). Thus, it will be made use of the minimum of formalism and only the proofs of the elements that we consider as absolutely essential to the engineer will be presented in this. Moreover, numerous proofs will be made by example and we will focus largely on the algebraic theory of groups as it has a prominent place in physics almost more than for other set-structures.

6.2.1 Groups Algebra and Geometry

The symmetries of geometric figures, of crystals and all the other items of macroscopic physics, are subject for centuries of observations and studies. In modern terms, the symmetries of a given object form a "group".

Since the mid-119th century (holocene calendar), the group theory took a huge extension, and its applications to quantum mechanics and the theory of elementary particles have developed throughout the 120th century (holocene calendar).

In a letter of 11877 (holocene calendar) to the mathematician Adolf Meyer, Sophus Lie wrote that he created the Theory of Groups in January 11873 (holocene calendar). It is of the groups he named "continuous groups" and that are named today "Lie groups". Lie sought to expand the use of groups from the domain of algebraic equations, where Galois had introduced them, to the differential equations.

Since 11871 (holocene calendar), the notion of infinitesimal generator of a one-parameter group of transformations appeared in his work. This is the set of infinitesimal generators of the subgroups with one parameter of a continuous group that forms what we name today a "Lie algebra".

It was Weyl and Wigner that show the pre-eminent role of the theory of groups and their representations in particular in the new quantum mechanics that Heisenberg and Dirac were developing. The general idea of representation theory is try to study a group by doing it acting on a vector space in a linear way: we try to see the group as a group of matrices (hence the term "representation "). We can, from relatively well-known properties of the automorphism group of the vector space (see section Set Theory page 443), get to deduce some group properties of main interest.

We can consider the theory of group representations as a vast generalization of the Fourier analysis. Its development is continuous and has, since the mid-120th century (holocene calendar), countless applications in differential geometry, ergodic theory, probability theory, number theory, the theory of automorphic forms, in that of dynamic systems as well as in physics, chemistry, molecular biology and signal processing. Currently, entire branches of mathematics and physics depend on it.

Before we begin, we refer the reader to the section on Set Theory to get a refresh of the structure and fundamental properties that make up a Group and also to the section of Linear Algebra (because we use some results proved in it).

6.2.1.1 Cyclic Groups

The cyclic group (whose definition of has already been given in the section of Set Theory) will serve us a basis for the study of finite groups. Moreover, rather than making generalized expansions we preferred to take specific examples to present the idea of cyclic group (more suitable for an engineering approach).

We will take then the very nice example of the hours of a clock... with three different approaches that will successively (!) and simple address the concept of a cyclic group.

1. First approach:

   Let us imagine a clock with a needle which can take 12 possible positions (but no intermediate positions). We will denote in a special way the 12 possible positions: $\overline{0},\overline{1},\overline{2},\ldots,\overline{11}$ (the line above the numbers is not innocent!).

   Nothing prevents us on all of these positions to define an addition, for example:

   $$\overline{2}+\overline{3}=\overline{5},\;\overline{3}+\overline{2}=\overline{5},\;\overline{5}+\overline{7}=\overline{0},\;\overline{9}+\overline{5}=\overline{2},\;\overline{1}-\overline{8}=\overline{5},\tag{6.2.1}$$

   which is similar to the results we get when we in our daily life we do calculations manipulating time.

2. Second approach (first extension):

   If we observe well a Watch or a Clock, we notice that every time we add 12 (or withdraw 12...) to a value of hours of our Watch/Clock then we fall back on the set of numbers that are well defined that are also in $\mathbb{Z}$. Therefore (obviously as part of a Watch/Clock only the first positive values are of interest to us most of the time but here we do math so we generalize a bit...):

   $$\begin{aligned}\overline{0}&:=0+12\mathbb{Z}=\{\ldots,-24,-12,0,12,24,\ldots\}\\\overline{1}&:=1+12\mathbb{Z}=\{\ldots,-11,1,13,25,\ldots\}\\\overline{2}&:=2+12\mathbb{Z}=\{\ldots,-10,2,14,26,\ldots\}\end{aligned}\tag{6.2.2}$$

   Here we fall back on a concept we had already seen in the section of Numbers Theory. This are congruence classes and all of these classes form the quotient set $\mathbb{Z}/12\mathbb{Z}$. If we endow this quotient set of an addition law, it is normally easy to observe that it is an internal law to the quotient set, that it is associative, that there exist a neutral element and that every element has an inverse (opposite).

   Thus, this quotient set equipped only with the addition law (if adding the multiplication we can form a ring) is a commutative group.

3. Third approach (second and last extension):

   Let us see a third and final approach which is why the quotient group is cyclic.

   If we project the rotation of the hands of our Watch/Clock (all rotations in the set-algebra are traditionally clockwise!) in $\mathbb{C}$ and that we define:

$$x := e^{\frac{2\pi \mathrm{i}}{12}} \tag{6.2.3}$$

   We then have $x^{12} = x^0 = 1$ and:

$$\forall a,k \in \mathbb{Z}: \qquad x = x^{a+12k} \tag{6.2.4}$$

   which is why the quotient group $(\mathbb{Z}/12\mathbb{Z},+)$ is named "cyclic group" (by group isomorphism according to what has been seen in the section Set Theory). Its isomorphic is noted by C_{12} and all elements are of modulus 1. It is common to denote all complex number of modulus 1 as following:

$$\mathbb{U} = \{z \in \mathbb{C} \| z| = 1\} \tag{6.2.5}$$

   If we represent in $\mathbb{C}$ the isomorphic set C_{12} we get then on the unit circle a polygon with n vertices as shown in the figure below:

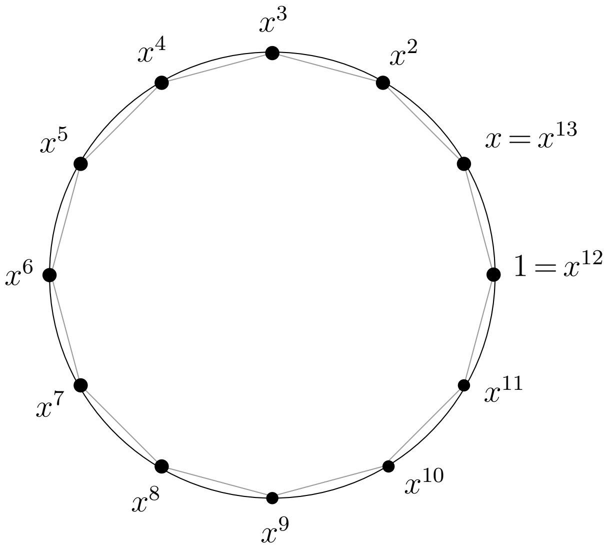

Figure 6.20: C_{12} **cyclic group**

   Furthermore, the number of component elements of $\mathbb{Z}/12\mathbb{Z}$ being finite, $(\mathbb{Z}/12\mathbb{Z},+)$ is finite. Unlike the group $(\mathbb{Z},+)$ which is itself a discrete infinite group.

   This concept of finitude is perhaps most obvious with the example that we will do afterwards with $\mathbb{Z}/4\mathbb{Z}$ where the reader will observe that this set has the same number of elements than C_4.

Remark

Mathematicians name C_n the "group of n-th roots of unity". An n-th root of the unit (sometimes named "De Moivre's number") is a complex number whose n-th power is equal to 1. Moreover, for a given integer n, all n-th roots of unit are located on the unit circle and are the vertices of a regular n-sided polygon having an apex of affix 1.

Definition (#6.2.179): A "finite group" is a mathematical group with a finite number of elements like "permutations groups", "symmetric groups", "cyclic groups", etc.

What interests particularly physicists at first are the representations of finite groups (also the continuous groups that we will see later). Thus, the representative of $\mathbb{Z}/n\mathbb{Z}$ is known to us as the rotation in the complex plane is given as we have shown during our study of complex numbers in the section Numbers:

$$\begin{bmatrix} \cos\left(\dfrac{2k\pi}{n}\right) & -\sin\left(\dfrac{2k\pi}{n}\right) \\ \sin\left(\dfrac{2k\pi}{n}\right) & \cos\left(\dfrac{2k\pi}{n}\right) \end{bmatrix} \tag{6.2.6}$$

with $k\in[0,n-1]$. This representative is a subgroup of the group of rotations $\text{O}(2)$ which will be discussed further. The group of rotations of the plane itself being a subgroup of the linear group $\text{GL}(2)$ (we will give a precise definition and an example further below).

In fact, mathematicians are able to prove that all quotients groups $\mathbb{Z}/n\mathbb{Z}$ are cyclic to an isomorphism with C_n and then they say that $\mathbb{Z}/n\mathbb{Z}$ is a finite quotient of the monogenic group $\mathbb{Z}$...

This approach is perhaps a bit abstract for the Padawan... So if the reader remembers the section Set Theory we saw a very precise definition of what is the cyclicity of a group: A group G is said to be cyclic if G is generated by the power of at least one of its elements $a\in G$ named the "generator" such that:

$$G=\{a^n,n\in\mathbb{Z}\} \tag{6.2.7}$$

Let us check whether this is the case for the group:

$$G=\{\mathbb{Z}/4\mathbb{Z},+\} \tag{6.2.8}$$

which is a school case.

We will denote the elements that make up this finite group:

$$\{0,1,2,3\} \tag{6.2.9}$$

This being done, we should be careful that in the set definition of a cyclic group we speak of "power" if the internal law of the group is multiplication but if the internal law is the addition, then we have:

$$G=\{n\cdot a,n\in\mathbb{Z}\} \tag{6.2.10}$$

The first generator of the group $G=\{\mathbb{Z}/4\mathbb{Z},+\}$ is 1. Indeed:

$$\begin{aligned} &1=1\cdot 1=1\\ &1+1=2\cdot 1=2\\ &1+1+1=3\cdot 1=3\\ &1+1+1+1=4\cdot 1=1 \end{aligned} \tag{6.2.11}$$

The second generating element of the same group is 3:

$$\begin{aligned}3&=1\cdot 3=3\\3+3&=2\cdot 3=2\\3+3+3&=3\cdot 3=1\\3+3+3+3&=4\cdot 3=0\end{aligned}\qquad(6.2.12)$$

For cons, the reader can check that 2 is not a generator of this group!

In fact, regarding the groups $G=\{\mathbb{Z}/n\mathbb{Z},+\}$ mathematicians are able to prove that only the elements of the group items that are prime with n are generators (that is to say elements whose greatest common divisor is 1).

Remark

Somewhat similar to the way prime numbers are the basic building blocks of the integers, there exist some special kind of finite groups that are the basic building groups of all finite common groups. These special kind of groups are named "finite simple groups". The classification of the finite, simple groups is unprecedented in the history of mathematics, for its proof is $15,000$ pages long, needed almost 50 years to be completed and involved a few hundred mathematicians. That's why it's named the "Enormous Theorem".

That's all for our introduction to cyclic groups for engineers. Let us turn now to another group category.

6.2.1.2 Transformations Groups

The transformations groups, that include the rotations groups, are the one that most interests physicists especially in the areas of continuum mechanics, chemistry, quantum physics and art ... Mathematicians appreciate obviously the study of rotations groups in the context of geometry (but not only!) and computer scientists equally linear groups. We have also seen an example of a rotations group just before.

Definition (#6.2.180): We name "linear group of order n" and we note $\text{GL}(n)$ the invertible matrices $n\times n$ or also named "regular matrices" (i.e. their determinant is not zero according to what we saw in the section Linear Algebra) which component are in any field or ring $\mathbb{K}$ (the ring $\mathbb{R}$ or the group $\mathbb{C}$ most of time):

$$\boxed{\text{GL}(n)=\text{GL}(n,\mathbb{K})=\text{GL}_n(\mathbb{K})=\{A\in M_n|\det(A)\neq 0\}}\qquad(6.2.13)$$

The group is so named because the columns of an invertible matrix are linearly independent.

We will consider here as obvious that $\text{GL}(n)$ is a group: the matrix multiplication is associative array and each matrix of $\text{GL}(n)$ has an inverse by definition (as the determinant is not null). On the other hand, the product of two regular matrices gives a regular matrix that is again invertible.

A simple and important example of linear group is that of the sub-"group of affine transformations" of the plane that is traditionally noted (that is intuitive):

$$F:M(x,y)\rightarrow M'(x',y'):\begin{cases}x'=ax+by+\alpha\\y'=cx+dy+\beta\end{cases}\qquad(6.2.14)$$

with $a,b,c,d,\alpha,\beta \in \mathbb{R}$, $ad-bc \neq 0$ (we will see why and how this latter inequality a little further below).

Definition (#6.2.181): The "affine group" or "general affine group" of any affine space A over a field $\mathbb{K}$ is the group denoted $\text{Aff}(A)$ or $\text{Aff}(n,\mathbb{K})$ of all invertible affine transformations from the space into itself. It is a "Lie group" if $\mathbb{K}$ is the real or complex field or quaternions.

Let us take a small practical example:

$$F:M(x,y)\rightarrow M'(x',y'):\begin{cases} x'=0.5x-0.4y+0.5 \\ y'=0.8x+0.2y-1.5 \end{cases} \tag{6.2.15}$$

whic applied to a circle gives:

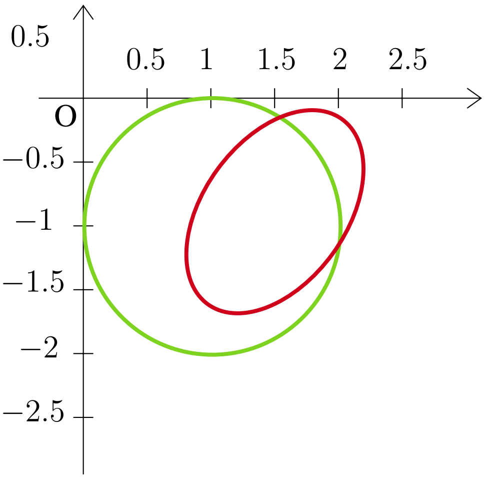

Figure 6.21: **Simple affine transformation on a circle**

This transformation is a way to define the ellipses as images of a circle by an affine transformation.

The coefficients α,β are irrelevant for the shape of the image figure. In fact, they obviously induce only translations to the figures. So we can do without them if we only seek to distort the original figure.

Therefore it remains:

$$F:M(x,y)\rightarrow M'(x',y'):\begin{cases} x'=ax+by \\ y'=cx+dy \end{cases} \tag{6.2.16}$$

which can be written in matrix form:

$$\begin{pmatrix} x' \\ y' \end{pmatrix}=\begin{bmatrix} a & b \\ c & d \end{bmatrix}\begin{pmatrix} x' \\ y' \end{pmatrix} \tag{6.2.17}$$

The affine transformation is therefore reduced to the matrix:

$$F=\begin{bmatrix} a & b \\ c & d \end{bmatrix} \tag{6.2.18}$$

and as we have seen in the section of Linear Algebra, matrix multiplication is associative but is not commutative, so the linear transformation is not either.

The neutral element is the matrix:

$$I=\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix} \tag{6.2.19}$$

and the inverse of F is:

$$F^{-1}=\begin{bmatrix}\dfrac{d}{ad-bc} & \dfrac{-b}{ad-bc}\\ \dfrac{-c}{ad-bc} & \dfrac{a}{ad-bc}\end{bmatrix}=\dfrac{1}{ad-bc}\begin{bmatrix}d & -b\\ -c & a\end{bmatrix} \tag{6.2.20}$$

and as we have imposed $ad-bc\neq 0$ any element has therefore an inverse. Thus, the linear affine group is not commutative and... is therefore a group...

As we will see it, all the "classics" Lie groups are subgroups of GL(n).

Definition (#6.2.182): We name "special linear group of order n" and denote by SL(n) the invertible (square $n\times n$) matrices with coefficients in an arbitrary field and with determinant equal to unity:

$$\boxed{\text{SL}(n)=\{A\in M_n|\det(A)=1\}} \tag{6.2.21}$$

This is obviously a subgroup of GL(n).

Returning to the previous example and remembering that the determinant of a square two-dimensional matrix is (see section Linear Algebra 1961):

$$\det(F)=ad-bc=1=\det(F^{-1}) \tag{6.2.22}$$

we notice geometrically well what it means to have a unit determinant in this case! Indeed we will see in the section of Linear Algebra during our geometric interpretation of the determinant that having a determinant is equivalent to have a surface. Thus, having $ad-bc$ equal to the unit allows us regardless of the processing order, to have the area equal to 1. Thus, the special linear is a group of transformation that keeps surfaces value.

Definition (#6.2.183): We name "orthogonal real group of order n" and denote by O(n) the invertible orthogonal (square $n\times n$) matrices (see the section Linear Algebra for a refresh of what are orthogonal matrices):

$$\boxed{\text{O}(n)=\{A\in M_n(\mathbb{R})|A^TA=I_n\}} \tag{6.2.23}$$

Furthermore, we proved in the section Linear Algebra in our study rotation matrices that $A^TA=I_n$ implies that $\det(A)=\pm 1$.

This is the case for example of the O(2) matrix seen previously (it belongs to the orthogonal group but also to the group of rotations that we will see further below):

$$\begin{bmatrix}\cos\left(\dfrac{2k\pi}{n}\right) & -\sin\left(\dfrac{2k\pi}{n}\right)\\ \sin\left(\dfrac{2k\pi}{n}\right) & \cos\left(\dfrac{2k\pi}{n}\right)\end{bmatrix} \tag{6.2.24}$$

which is orthogonal as it is easy to check (just multiple by the transposed to see if you get and identity matrix).

Remark

O(1) is made up of all trivial matrices... $[1][-1]$ that are simply one component vectors or just... simple scalars.

Definition (#6.2.184): If $A\in \text{O}(n)$ and that we have $\det(A)=1$ then we get a subgroup of O(n) named "special real group orthogonal of order n" and therefore defined by:

$$\boxed{\text{SO}(n)=\{A\in M_n(\mathbb{R})|A^TA=I_n,\det(A)=1\}\subset \text{O}(n)} \tag{6.2.25}$$

The rotation matrix given previously is part of this group since its determinant is equal to unity! Furthermore, this group occupies a very special place in physics and we will meet it again during our study of quantum physics.

The subgroup SO(2), also sometimes named "circle group" and denoted S^1 that we had also studied in the section of Euclidean Geometry has a representative given by the matrix:

$$R(\theta)=\begin{bmatrix}\cos(\theta) & -\sin(\theta)\\ \sin(\theta) & \cos(\theta)\end{bmatrix} \tag{6.2.26}$$

and occupies a special place in the family of the SO(n) groups with n greater than unity. Indeed it is the only one that is commutative. Moreover, it is isomorphic to $e^{\mathrm{i}\theta}$ either U(1) the multiplicative group of complex numbers of modulus 1. This is also the proper symmetry group of a circle and the equivalent continuous of C_n.

The subgroup SO(3) is given by the matrix (see section Euclidean Geometry page 2650):

$$R_X(\theta)=\begin{bmatrix}1 & 0 & 0\\ 0 & \cos(\theta) & \sin(\theta)\\ 0 & -\sin(\theta) & \cos(\theta)\end{bmatrix} \tag{6.2.27}$$

for the rotation around the x-axis in the three-dimensional space is not commutative (the rotation matrices in the plane being commutative for recall!). Moreover the quaternions that we have seen in the section Numbers, whose representative is therefore SO(3), form also a non-commutative group (relatively to the multiplication law) as we have seen in the section Numbers.

Compared to a unit vector makes we can relatively easily visually speaking see that SO(3) is a closed subgroup of GL(3), that is to say, the set of linear groups of dimension 3.

Remark

SO(1) consists in the matrix $[1]$.

Definition (#6.2.185): We name "unitary linear group of order n" and we denote it U(n) the matrices whose components are complex (as part of this textbook the most often) or real and which are orthogonal:

$$\boxed{\text{U}(n)=\{A\in M_n(\mathbb{C})|A^\dagger A=I_n\}} \tag{6.2.28}$$

Notice also that any unitary matrix with complex components and of one dimension (thus that belongs to $\text{U}(n)$...) is a complex number of unit module, which can always be written in the form $e^{\text{i}\mathbb{R}}$.

We have already seen an example in this textbook during our study of spinors (see section of the same name page 2145). These are the Pauli matrices (used in the section of Relativistic Quantum Physics) given by:

$$\sigma_x=\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix},\sigma_y=\begin{bmatrix}0 & -\text{i}\\ \text{i} & 0\end{bmatrix},\sigma_z=\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix} \tag{6.2.29}$$

Definition (#6.2.186): We name "special unitary group of order n" and we denote by $\text{SU}(n)$ the matrices whose entries are complex and are orthogonal and whose determinant is unity:

$$\boxed{\text{SU}(n)=\{A\in M_n(\mathbb{C})|A_\dagger A=I_n,\det(A)=1\}\subset\text{U}(n)} \tag{6.2.30}$$

Remark

$\text{U}(1)$ is equal to $\text{SU}(1)$ and it is therefore the complex unit circle equals to $e^{\text{i}\mathbb{R}}$. Moreover, $\text{SO}(2)$ is commutative and isomorphic to $\text{U}(1)$ because it is the set of the rotations of the plane.

A well known example is still the one of the Pauli matrices but simply written in the form used in Relativistic Quantum Physics (see section of the same name page 4937):

$$\text{i}\sigma_x=\begin{bmatrix}0 & \text{i}\\ \text{i} & 0\end{bmatrix},\text{i}\sigma_y=\begin{bmatrix}0 & 1\\ -1 & 0\end{bmatrix},\text{i}\sigma_z=\begin{bmatrix}\text{i} & 0\\ 0 & -\text{i}\end{bmatrix} \tag{6.2.31}$$

which are part of $\text{SU}(2)$ and as we have shown (implicitly) at the beginning of the section of Spinor Calculus isomorphic to the quaternion group $\text{SO}(3)$ of module 1. Relations that mathematicians name in the present situation a "homomorphism's overlay"...

Remark

The special unitary group has a particular importance in particle physics. If the unitary group $\text{U}(1)$ is the electromagnetic gauge group (think to the complex number appearing in the solutions of the wave equation!), $\text{SU}(2)$ is the group associated with the weak interaction, and $\text{SU}(3)$ the one of the strong interaction. This is for example due to the structure of representations of $\text{SU}(3)$ that Gell-Mann conjectured the existence of quarks!

Let us see with a different approach to that used in the section of Spinor Calculus how to show that the Pauli matrices are the bases of $\text{SU}(2)$?

First, the reader has to know that we proved in the section of Spinor Calculus that any rotation in space of three dimensions could be expressed using the relation (for small angles!):

$$R\left(\vec{L},\frac{\theta}{2}\right)=\cos\left(\frac{\theta}{2}\right)\sigma_0-\mathrm{i}\sin\left(\frac{\theta}{2}\right)\vec{L}\circ\vec{\sigma} \tag{6.2.32}$$

And we saw in the section of Quantum Computing that an explicit decomposed formulation of the previous relation was:

$$\begin{aligned}R_x(\theta)&=\begin{bmatrix}\cos\left(\dfrac{\theta}{2}\right) & -\mathrm{i}\sin\left(\dfrac{\theta}{2}\right)\\ -\mathrm{i}\sin\left(\dfrac{\theta}{2}\right) & \cos\left(\dfrac{\theta}{2}\right)\end{bmatrix}\\ R_y(\theta)&=\begin{bmatrix}\cos\left(\dfrac{\theta}{2}\right) & -\sin\left(\dfrac{\theta}{2}\right)\\ \sin\left(\dfrac{\theta}{2}\right) & \cos\left(\dfrac{\theta}{2}\right)\end{bmatrix}\\ R_z(\theta)&=\begin{bmatrix}e^{-\mathrm{i}\theta/2} & 0\\ 0 & e^{\mathrm{i}\theta/2}\end{bmatrix}\end{aligned} \tag{6.2.33}$$

and therefore that all $\text{SU}(2)$ element is produced from these three matrices which each make describe to the end of a vector a curve on the surface of a sphere!

Now, we notice that these three matrices are equal to when $\theta=0$:

$$R_x(\theta)=R_y(\theta)=R_z(\theta)=\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix} \tag{6.2.34}$$

We then obtain the identity matrix. So if we search the tangent at this point we can therefore build a base on it (three orthogonal vectors).

Let's look at this:

$$\begin{aligned}
\left.\frac{\mathrm{d}R_x(\theta)}{\mathrm{d}\theta}\right|_{\theta=0} &= \begin{bmatrix} -\dfrac{1}{2}\sin\left(\dfrac{\theta}{2}\right) & -\mathrm{i}\dfrac{1}{2}\cos\left(\dfrac{\theta}{2}\right) \\ -\mathrm{i}\dfrac{1}{2}\cos\left(\dfrac{\theta}{2}\right) & -\dfrac{1}{2}\sin\left(\dfrac{\theta}{2}\right) \end{bmatrix}\Bigg|_{\theta=0} = \begin{bmatrix} 0 & -\dfrac{1}{2}\mathrm{i} \\ -\dfrac{1}{2}\mathrm{i} & 0 \end{bmatrix} = -\frac{\mathrm{i}}{2}\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} = -\frac{\mathrm{i}}{2}\sigma_x \\
\left.\frac{\mathrm{d}R_y(\theta)}{\mathrm{d}\theta}\right|_{\theta=0} &= \begin{bmatrix} -\dfrac{1}{2}\sin\left(\dfrac{\theta}{2}\right) & -\dfrac{1}{2}\cos\left(\dfrac{\theta}{2}\right) \\ \dfrac{1}{2}\cos\left(\dfrac{\theta}{2}\right) & -\dfrac{1}{2}\sin\left(\dfrac{\theta}{2}\right) \end{bmatrix}_{\theta=0} = \begin{bmatrix} 0 & -\dfrac{1}{2} \\ \dfrac{1}{2} & 0 \end{bmatrix} = -\frac{1}{\mathrm{i}2}\begin{bmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{bmatrix} = -\frac{\mathrm{i}}{2}\sigma_y \\
\left.\frac{\mathrm{d}R_z(\theta)}{\mathrm{d}\theta}\right|_{\theta=0} &= \begin{bmatrix} -\dfrac{1}{2}\mathrm{i}e^{-\mathrm{i}\theta/2} & 0 \\ 0 & \dfrac{1}{2}\mathrm{i}e^{\mathrm{i}\theta/2} \end{bmatrix}_{\theta=0} = \begin{bmatrix} -\dfrac{1}{2}\mathrm{i} & 0 \\ 0 & \dfrac{1}{2}\mathrm{i} \end{bmatrix} = -\frac{\mathrm{i}}{2}\begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} = -\frac{\mathrm{i}}{2}\sigma_z
\end{aligned} \tag{6.2.35}$$

Thus, $\mathrm{SU}(2)$ has for basis:

$$\left\{-\frac{\mathrm{i}}{2}\sigma_x, -\frac{\mathrm{i}}{2}\sigma_y, -\frac{\mathrm{i}}{2}\sigma_z\right\} \tag{6.2.36}$$

and are in other words the infinitesimal generators of the group $\mathrm{SU}(2)$. $\mathrm{SU}(2)$ has therefore a basis that is a Lie algebra according to the vocabulary of mathematicians.

This result is quite remarkable ... Since $\mathrm{SU}(2)$ and $\mathrm{SO}(3)$ are isomorphic, then we can get the basis of the Lie algebra $\mathrm{SO}(3)$ while using the same method !!!

Let us see this! We proved in the section of Euclidean Geometry that the rotations matrices were given by (we change the R by a U so to not confuse with the previous matrices):

$$U_x = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos(\theta) & \sin(\theta) \\ 0 & -\sin(\theta) & \cos(\theta) \end{bmatrix}, U_y = \begin{bmatrix} \cos(\gamma) & 0 & -\sin(\gamma) \\ 0 & 1 & 0 \\ \sin(\gamma) & 0 & \cos(\gamma) \end{bmatrix}, U_z = \begin{bmatrix} \cos(\phi) & \sin(\phi) & 0 \\ -\sin(\phi) & \cos(\phi) & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{6.2.37}$$

We notice again that on $\theta = \gamma = \phi = 0$ the curve that is generated by the extremity of a vector from the three rotation matrices pass through:

$$U_x = U_y = U_z = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{6.2.38}$$

Then in the same manner as for $\mathrm{SU}(2)$, we calculate the derivatives in these angles to determine the generating base matrices of $\text{SO}(3)$:

$$\begin{aligned}
\left.\frac{\mathrm{d}U_x(\theta)}{\mathrm{d}\theta}\right|_{\theta=0} &= \begin{bmatrix} 1 & 0 & 0 \\ 0 & -\sin(\theta) & \cos(\theta) \\ 0 & -\cos(\theta) & -\sin(\theta) \end{bmatrix} \Big|_{\theta=0} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & -1 & 0 \end{bmatrix} = X_x \\
\left.\frac{\mathrm{d}U_y(\gamma)}{\mathrm{d}\gamma}\right|_{\gamma=0} &= \begin{bmatrix} -\sin(\gamma) & 0 & -\cos(\gamma) \\ 0 & 0 & 0 \\ \cos(\gamma) & 0 & -\sin(\gamma) \end{bmatrix} \Big|_{\gamma=0} = \begin{bmatrix} 0 & 0 & -1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix} = X_y \\
\left.\frac{\mathrm{d}U_z(\phi)}{\mathrm{d}\phi}\right|_{\phi=0} &= \begin{bmatrix} -\sin(\phi) & \cos(\phi) & 0 \\ -\cos(\phi) & -\sin(\phi) & 0 \\ 0 & 0 & 0 \end{bmatrix} \Big|_{\phi=0} = \begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} = X_z
\end{aligned} \tag{6.2.39}$$

The Lie algebra of $\text{SO}(3)$ has therefore for basis:

$$\{X_x, X_y, X_z\} \tag{6.2.40}$$

In physics, we prefer to work with complex matrices. We then introduce the matrices:

$$\{J_x = \mathrm{i}X_x, J_y = \mathrm{i}X_y, J_z = \mathrm{i}X_z\} \tag{6.2.41}$$

It must then been notice that if we define:

$$J_{\pm} = J_x \pm \mathrm{i}J_y = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & \mathrm{i} \\ 0 & -\mathrm{i} & 0 \end{bmatrix} \pm \mathrm{i} \begin{bmatrix} 0 & 0 & -\mathrm{i} \\ 0 & 0 & 0 \\ \mathrm{i} & -0 & 0 \end{bmatrix} \pm \mathrm{i} \begin{bmatrix} 0 & 0 & -\mathrm{i} \\ 0 & 0 & 0 \\ \mathrm{i} & -0 & 0 \end{bmatrix} = \begin{bmatrix} 0 & 0 & \pm 1 \\ 0 & 0 & \mathrm{i} \\ \pm 1 & -\mathrm{i} & 0 \end{bmatrix} \tag{6.2.42}$$

We trivially have to the complex conjugate of the transposed matrix:

$$(J_{\pm})^{\dagger} = J_{\mp} \tag{6.2.43}$$

and by the way ... we also have the following non-commutative relations (which we can develop on request):

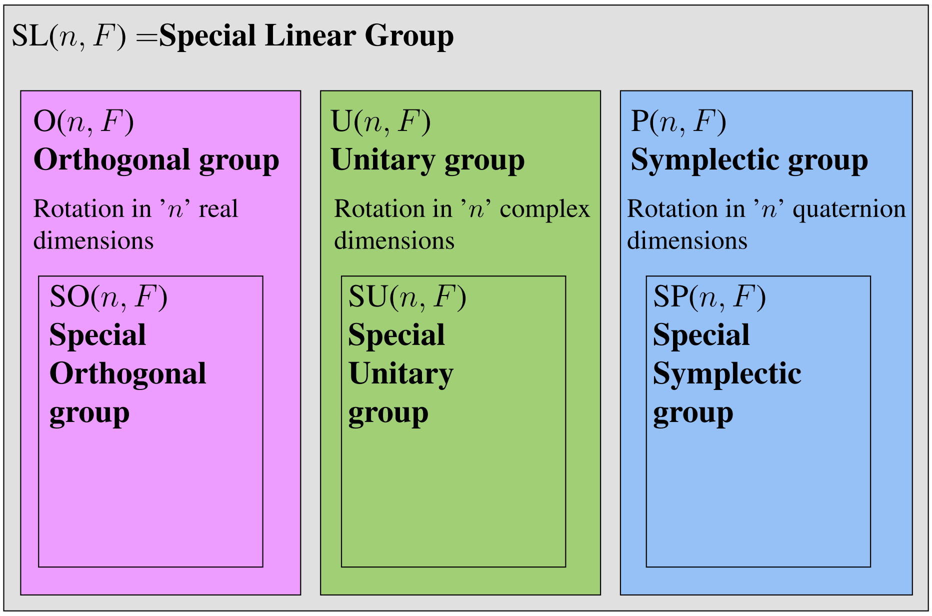
$$[J_x, J_y] = \mathrm{i}J_z \quad \text{(cycl.)} \tag{6.2.44}$$

and also the relation of commutation:

$$\left[J_z, \|\vec{J}\|^2\right] = 0 \quad \text{(cycl.)} \tag{6.2.45}$$

that the Pauli matrices also satisfy and ... for recall (or for information for those who have not yet read the section of Wave Quantum Physics) the J_i are the operators of the total angular momentum of the spin-orbit coupling system!!!

Most of the groups we have seen until so far can be summarised with the following figure:



SL(n, F) =**Special Linear Group**
O(n, F)
Orthogonal group
Rotation in 'n' real dimensions
SO(n, F)
Special Orthogonal group
U(n, F)
Unitary group
Rotation in 'n' complex dimensions
SU(n, F)
Special Unitary group
P(n, F)
Symplectic group
Rotation in 'n' quaternion dimensions
SP(n, F)
Special Symplectic group

The rotations with the quaternions indicated in the figure above are studied in the section Numbers of the chapter Arithmetic (see page 261).

Or also we can summarize what we have seen so far as a unique set or relationships (to accustom the reader to the absence of international standards for notation in mathematics...):

$$\boxed{\begin{aligned}
\mathrm{SL}_n(\mathbb{R}) &= \{X \in \mathrm{GL}_n(\mathbb{R}) : \det(X) = 1\}\\
\mathrm{SL}_n(\mathbb{C}) &= \{X \in \mathrm{GL}_n(\mathbb{C}) : \det(X) = 1\}\\
\mathrm{O}(n) &= \left\{X \in \mathrm{GL}_n(\mathbb{R}) : X^T X = \mathbb{1}_n\right\}\\
\mathrm{SO}(n) &= \mathrm{O}(n) \cap \mathrm{SL}_n(\mathbb{R})\\
\mathrm{O}(p,q) &= \left\{X \in \mathrm{GL}_{p+q}(\mathbb{R}) : X^T \mathbb{1}_{p,q} X = \mathbb{1}_{p,q}\right\}\\
\mathrm{SO}(p,q) &= \mathrm{O}(p,q) \cap \mathrm{SL}_{p+q}(\mathbb{R})\\
\mathrm{U}(n) &= \left\{X \in \mathrm{GL}_n(\mathbb{C}) : \bar{X} X = \mathbb{1}_n\right\}\\
\mathrm{SU}(n) &= \mathrm{U}(n) \cap \mathrm{SL}_n(\mathbb{C})
\end{aligned}} \tag{6.2.46}$$

Now let us talk about the "dimensions" (i.e. free parameters) of these groups. For $\mathrm{GL}_n(\mathbb{R})$ its dimensions are n^2 that's quite obvious and as $\mathrm{GL}_n(\mathbb{C})$ is made of complex numbers each having two real parameters, this doubles the number of dimensions is such that we have $2n^2$. $\mathrm{SL}_n(\mathbb{R})$ has a constraint that is its matrices must have a determinant equal to 1, this constraint reduces the free parameters by one unit, hence it has n^2-1 dimensions. For $\mathrm{SL}_n(\mathbb{C})$ we just multyply it by two again that gives $2n^2-2$. All others follow the same pattern.

6.2.1.3 Group of Symmetries

The symmetry group of an object denoted X (image, signal, etc. in 1D, 2D, 3D or other) is the group of all isometries (an isometry is a transformation that preserves length) under which it is invariant with composition as an operation.

Any group of symmetries which elements have a common fixed point, which is true for all symmetry groups of limited figures, can be represented as a subgroup of the orthogonal group $\text{O}(n)$ by choosing the origin as a fixed point. The proper symmetry group is a subgroup of the special orthogonal group $\text{SO}(n)$, and hence it is also named the "rotations group" of the figure.

In what follows, we will interpret the composition of two operation of symmetries or rotations as the multiplication as well as for permutations.

Let us see first two fundamental definitions!

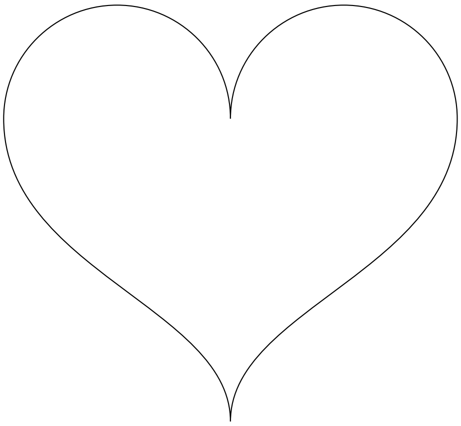
Definitions (#6.2.187):

D1. The "group of symmetries", also named "group of invariants" of X is the set of symmetries of X, generated by the multiplication structure given by the composition that leaves X invariant.

D2. The "order" of a group is the total number of all its symmetries only (including the identity!).

✍**Examples:**

E1. The heart (...):



has a group of symmetries of 2 elements, namely the identity application id and the application r_v that is the reflection in respect to the vertical axis (sub-group of symmetries with 1 item). We observe also that the symmetrical is also provided via the relation:

$$r_v \circ r_v = \text{id} \tag{6.2.47}$$

E2. The letter phi (...):

$$\Phi$$

has a total symmetry group of 4 elements, namely the identity application id, the both reflections r_h and r_v and the rotation of angle π which we denote by t_π (subgroup of rotations of 1 item). This form thus has a group of symmetries of order 3.

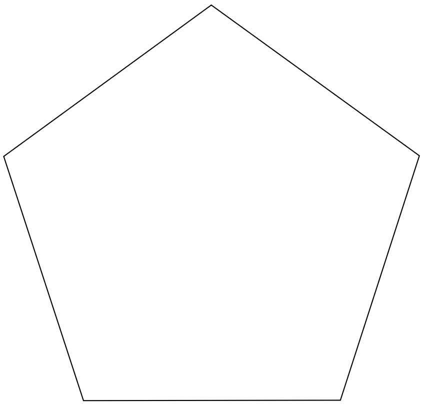
In this group we have:

$$r_h \circ r_v = t_\pi \tag{6.2.48}$$

(which is commutative!), $t_\pi \circ t_\pi$ is the rotation of angle 2π, which is the same application as the identity application, therefore $t_\pi \circ t_\pi = \text{id}$.

Thus, the symmetry group of this letter is indeed commutative and the composition law is internal. It is indeed a group.

E3. The regular pentagon:



has a group of symmetries of 10 elements, namely, more precisely 5 rotations id, $t_{2\pi/5}, t_{4\pi/5}, t_{6\pi/5}, t_{8\pi/5}$ and also 5 reflections along the 5-axis symmetry. It is therefore a group of symmetries of order 5 corresponding to cyclic group $\mathbb{Z}/5\mathbb{Z}$.

Remark

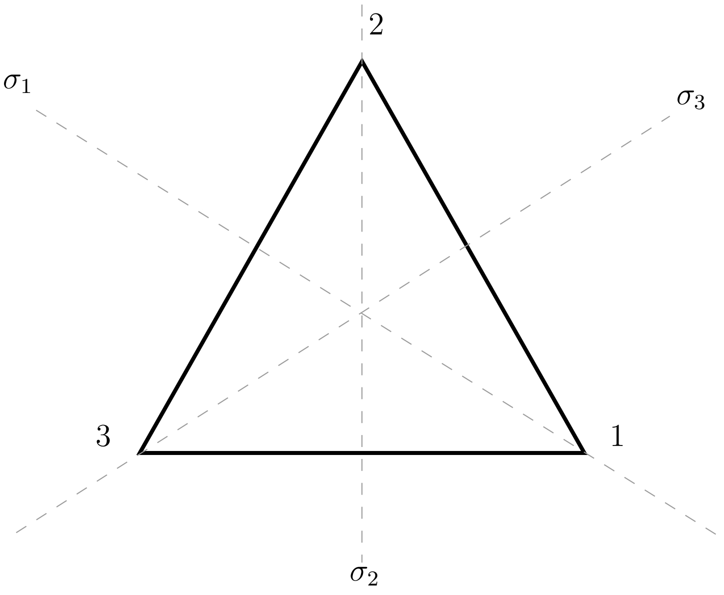
More generally, the group of symmetries of a regular n-gon (where n is odd) has exactly $2n$ elements. This group is named "dihedral group of order n" and is most often denoted by D_{2n} (be careful because some authors do not multiply by a factor of 2 so that the index is then directly the order and not the number of elements).

The pentagon has therefore D_{10} for dihedral group and $\mathbb{Z}/5\mathbb{Z}$ is a "distinct subgroups" (we'll come on this notion of subgroup later below).

E4. The dihedral group D_6 of order 3 of the isometries of an equilateral triangle (regular polygon) has 6 elements which we will denote (so that the writing is less heavy):

$$D_6 = \{\text{id}, t_{2\pi/3}, t_{4\pi/3}, \sigma_1, \sigma_2, \sigma_3\} \tag{6.2.49}$$

where $\sigma_1, \sigma_2, \sigma_3$ are the symmetries relatively to the three bisectors (mediators respectively). The compositions table below, named in general a "Cayley table", of this dihedral group also shows that this group is non-commutative:

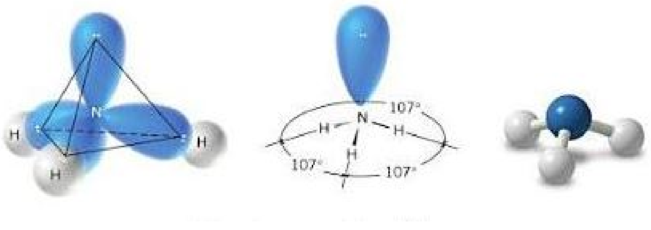


$\nearrow D_6$	id	$t_{2\pi/3}$	$t_{4\pi/3}$	σ_1	σ_2	σ_3
id	id	$t_{2\pi/3}$	$t_{4\pi/3}$	σ_1	σ_2	σ_3
$t_{2\pi/3}$	$t_{2\pi/3}$	$t_{4\pi/3}$	id	σ_3	σ_1	σ_2
$t_{\pi/3}$	$t_{4\pi/3}$	id	$t_{2\pi/3}$	σ_2	σ_3	σ_1
σ_1	σ_1	σ_2	σ_3	id	$t_{2\pi/3}$	$t_{4\pi/3}$
σ_2	σ_2	σ_3	σ_1	$t_{4\pi/3}$	id	$t_{2\pi/3}$
σ_3	σ_3	σ_1	σ_2	$t_{2\pi/3}$	$t_{4\pi/3}$	id

Table 6.8: **Symmetries of dihedral group of order 3**

We will return back later on this example when we will introduce a little further below the concept of a distinct group in our study of permutations groups.

E5. Let's look at one last example applied to chemistry by enumerating the symmetry operations that leave the ammonia molecule NH_3 (tetrahedron) invariant.



The transformation group contains 6 elements: the identity id, C_3 that is the rotation of $2\pi/3$, C_3^2 that is the rotation of $4\pi/3$ (which we will denote after by C_{-3}) both along the z-axis (therefore perpendicular to the xy-plane...) and 3 axes of symmetry $\sigma_1, \sigma_2, \sigma_3$ of symmetries/reflection each passing through the middle of one of the base edges in the middle of the opposite edge as shown in the figure below (pyramid view from above):

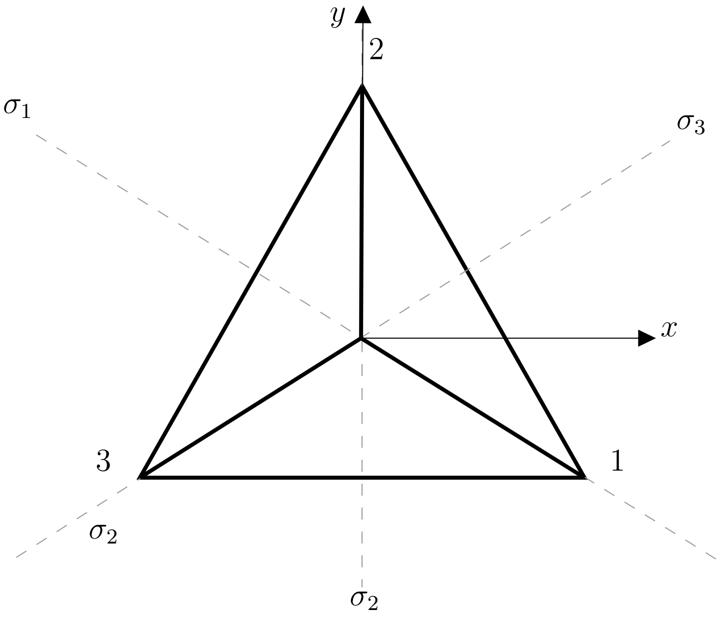


Figure 6.22: **Operations leaving invariant a tetrahedron**

The combination of the various elements of symmetries show that the compositions table is (which proves that the law is internal and we are working effectively in a group):

↗	id	σ_1	σ_2	σ_3	C_3	C_{-3}
id	id	σ_1	σ_2	σ_3	C_3	C_{-3}
σ_1	σ_1	id	C_{-3}	C_3	σ_3	σ_2
σ_2	σ_2	C_3	id	C_{-3}	σ_1	σ_3
σ_3	σ_3	C_{-3}	C_3	id	σ_2	σ_1
C_3	C_3	σ_2	σ_3	σ_1	C_{-3}	id
C_{-3}	C_{-3}	σ_3	σ_1	σ_2	id	C_3

Table 6.9: **Compositions of transformations of the tetrahedron**

Attention to the order of operations in the above table, we first apply the line element and afterwards the column element!

We note that the group is not commutative.

6.2.1.3.1 Orbits and Stabilizers

We will now see two definitions we meet again in crystallography (their name is not innocent!).

Definition (#6.2.188): The orbit of an element x of E is given by:

$$\text{Orb}_x = \{g \cdot x, g \in G\} \tag{6.2.50}$$

The orbit of x is the set of all positions (in E) likely to be occupied by the image of x under the action of G. The orbits obviously form a partition of E.

✍**Example:**

Let us consider a set E on which a group G will act, by:

$$E = \{S_0, S_1, S_2, S_3, S_4, S_5\} \tag{6.2.51}$$

the set of all 6 vertices of a hexagon on which we do act the group $G = \{\text{id}, t_{2\pi/3}, t_{4\pi/3}\}$. We see already trivially see that G is a group!

But now let us, consider an element of E, for example S_0.

Its orbit will be by definition:

$$\text{Orb}_{S_0} = \{\text{id}(S_0)S_0, t_{2\pi/2}(S_0) = S_2, t_{4\pi/3}(S_0) = S_4\} \tag{6.2.52}$$

Definition (#6.2.189): The stabilisator of x of an element of E is the set:

$$\text{Stab}_x = \{g \in G | g \cdot x = x\} \tag{6.2.53}$$

of all elements that let x invariant under their action. It is a subgroup of G.

✍**Example:**

To continue with our previous example. Its stabilisator is reduced to:

$$\text{Stab}_{S_0} = \{\text{id}\} \tag{6.2.54}$$

6.2.1.4 Permutations Groups

Symmetric groups have significant importance in some areas of Quantum Physics but also in mathematics as part of Linear Algebra (for the theory of the determinant as we will see in the corresponding section) and in Galois Theory (see further below) and also in Error Correcting Codes (see corresponding section for the example used with VISA credit cards). So these must be also pay special attention!

Let us first recall (see section Probabilities page 525) that in a set $\{1, \ldots, n\}$ there are $n!$ possible permutations. Mathematicians say, rightly, that there are $n!$ bijections and name this number "order of the permutations of the group".

✍**Example:**

Given for example the set $\{1,2,3\}$. This set has $3!$ possible permutations that are denoted in the context of the permutation groups as follows:

$$\{(1),(1\,2),(1\,3),(2\,3),(1\,2\,3),(1\,3\,2)\} \tag{6.2.55}$$

This must be read in the order: identity application id, 1 takes on 2 or 2 on 1 (in terms of positions!), 1 takes on 3 or 3 on 1, 2 takes on 3 or 3 on 2, 1 takes on 2 that takes on 3 that takes on 1, 1 takes on 3 that takes on 2 that takes on 1.

$$\begin{aligned}
&\begin{pmatrix}1 & 2 & 3\\ 1 & 2 & 3\end{pmatrix}\rightarrow(1) && \begin{pmatrix}1 & 2 & 3\\ 2 & 1 & 3\end{pmatrix}\rightarrow(1,2)\\
&\begin{pmatrix}1 & 2 & 3\\ 3 & 2 & 1\end{pmatrix}\rightarrow(1,3) && \begin{pmatrix}1 & 2 & 3\\ 1 & 3 & 2\end{pmatrix}\rightarrow(2,3)\\
&\begin{pmatrix}1 & 2 & 3\\ 3 & 1 & 2\end{pmatrix}\rightarrow(1,2,3) && \begin{pmatrix}1 & 2 & 3\\ 2 & 3 & 1\end{pmatrix}\rightarrow(1,3,2)
\end{aligned} \tag{6.2.56}$$

We can easily observe that the composition of two permutations is not commutative:

$$\begin{aligned}(1,\ 2)\circ(1,\ 3)&=\{1,2,3\}\\(1,\ 3)\circ(1,\ 2)&=\{3,1,2\}\end{aligned} \tag{6.2.57}$$

and that the composition of two permutations is an internal law:

$$(1\,2)\circ(1\,3\,2)=\{1,3,2\}=(2\,3) \tag{6.2.58}$$

with a neutral element that is indeed the identity id. So we do have well a non-commutative group. Let us recall also the reader that certain elements of the group, if well chosen, can form a subgroup. This is the example of:

$$\{(1),(1\,2)\} \tag{6.2.59}$$

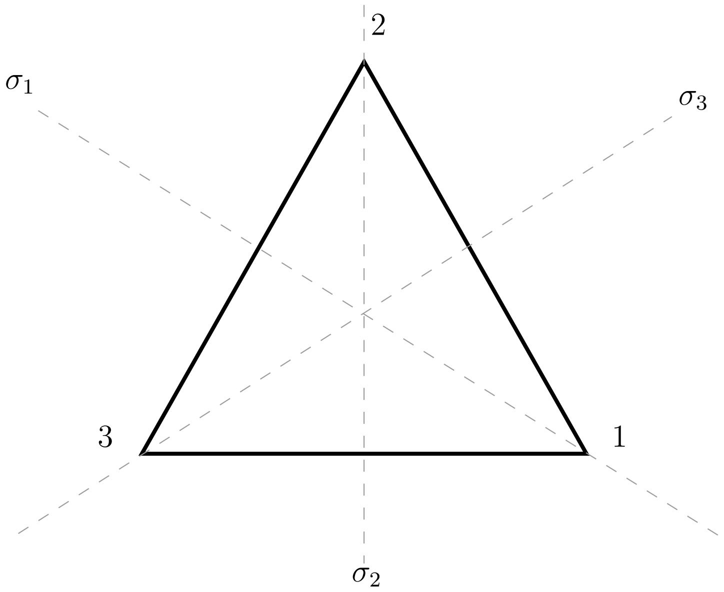
which is a sub-group of S_3 (it must be easy to the reader to check that it has all the properties of a group).

Definition (#6.2.190): A subgroup H of a group G is named "distinct group" if, for every g of G and every h of H, we have that ghg^{-1} is element of H. The mathematicians name this an "inner automorphism"...

Let us first consider interesting introducing geometric example after which we will come back to this definition with S_3.

✍**Example:**

We have seen earlier the elements of the dihedral symmetry group of order 3 of the equilateral triangle. Geometrically they all correspond to displacements in the plane in which the triangle is located. We got for recall of the following table of compositions:



$\nearrow D_6$	*id*	$t_{2\pi/3}$	$t_{4\pi/3}$	σ_1	σ_2	σ_3
id	id	$t_{2\pi/3}$	$t_{4\pi/3}$	σ_1	σ_2	σ_3
$t_{2\pi/3}$	$t_{2\pi/3}$	$t_{4\pi/3}$	id	σ_3	σ_1	σ_2
$t_{\pi/3}$	$t_{4\pi/3}$	id	$t_{2\pi/3}$	σ_2	σ_3	σ_1
σ_1	σ_1	σ_2	σ_3	id	$t_{2\pi/3}$	$t_{4\pi/3}$
σ_2	σ_2	σ_3	σ_1	$t_{4\pi/3}$	id	$t_{2\pi/3}$
σ_3	σ_3	σ_1	σ_2	$t_{2\pi/3}$	$t_{4\pi/3}$	id

First, we easily see using this table that we have:

- The sub-group made of $\{\text{id}\}$ of order 1
- The sub-group made of $\{\text{id}, t_{2\pi/3}, t_{4\pi/3}\}$ of order 3
- The sub-group made of $\{\text{id}, \sigma_1\}$ of order 2
- The sub-group made of $\{\text{id}, \sigma_2\}$ of order 2

- The sub-group made of $\{\text{id}, \sigma_3\}$ of order 2

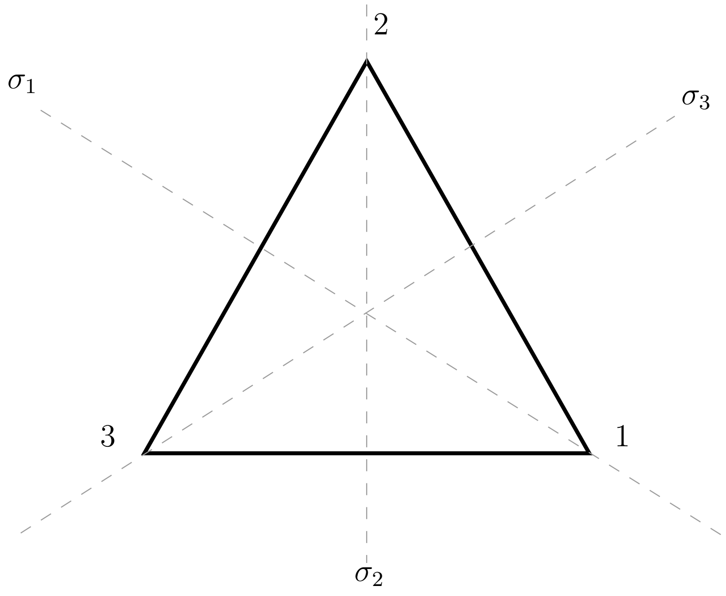
Among these five subgroups, let us see which one are distincted sub-groups (this is relatively easy to see using the table of compositions above):

- The sub-group made of $\{\text{id}\}$
- The sub-group made of $\{\text{id}, t_{2\pi/3}, t_{4\pi/3}\}$

We will now see a remarkable thing! By numbering with $1, 2$ and 3 the vertices of the equilateral triangle and taking the rotations clockwise, we can identify the elements of D_6 to the following elements of S_3:

$$\begin{gathered}
\text{id} = \begin{pmatrix} 1 & 2 & 3 \\ 1 & 2 & 3 \end{pmatrix} \rightarrow (1) \quad t_{2\pi/3} = \begin{pmatrix} 1 & 2 & 3 \\ 2 & 3 & 1 \end{pmatrix} \rightarrow (1,2,3) \quad t_{4\pi/3} = \begin{pmatrix} 1 & 2 & 3 \\ 1 & 3 & 2 \end{pmatrix} \rightarrow (1,3,2) \\
\sigma_1 = \begin{pmatrix} 1 & 2 & 3 \\ 3 & 1 & 2 \end{pmatrix} \rightarrow (2,3) \quad \sigma_2 = \begin{pmatrix} 1 & 2 & 3 \\ 3 & 2 & 1 \end{pmatrix} \rightarrow (1,3) \quad \sigma_3 = \begin{pmatrix} \rightarrow 1 & 2 & 3 \\ 2 & 1 & 2 \end{pmatrix} \rightarrow (1,2)
\end{gathered} \tag{6.2.60}$$

and rebuild the same table of compositions (copy of the previous one but just with the notation change ... hehe!):



$\nearrow S_3$	(1)	(1 2 3)	(1 3 2)	(1 2)	(1 3)	(2 3)
(1)	(1)	(1 2 3)	(1 3 2)	(1 2)	(1 3)	(2 3)
(1 2 3)	(1 2 3)	(1 3 2)	(1)	(2 3)	(1 2)	(1 3)
(1 3 2)	(1 3 2)	(1)	(1 2 3)	(1 3)	(2 3)	(1 2)
(1 2)	(1 2)	(1 3)	(2 3)	(1)	(1 2 3)	(1 3 2)
(1 3)	(1 3)	(2 3)	(1 2)	(1 3 2)	(1)	(1 2 3)
(2 3)	(2 3)	(1 2)	(1 3)	(1 2 3)	(1 2 3)	(1)

Well ... this little interlude closed, let us return to the distincted subgroup of S_3 (as it will be important for our introduction to Galois groups) and let us first recall that:

$$G=\{(1),(1\ 2),(1\ 3),(2\ 3),(1\ 2\ 3),(1\ 3\ 2)\} \tag{6.2.61}$$

and we see that the distinct subgroup consists of:

$$H=\{(1),(1\ 2\ 3),(1\ 3\ 2)\} \tag{6.2.62}$$

Definition (#6.2.191): For any subgroup H stable by the inner automorphisms of a group G, we name "index of H in G" the quotient of the order of the group G by the order of the subgroup H and we denote it by $[G/H]$.

✍**Example:**

The index of the subgroup $\{(1),(12)\}$ in the group S_3 is $6/2$ that is to say 3.

This concept will be very helpful to us during our introduction to Galois Theory.

Let us consider now the particular permutation σ to introduce the subject from a different but equivalent angle:

$$\{1,2,3,4\}\xrightarrow{\sigma}\{3,2,4,1\} \tag{6.2.63}$$

As we know the mathematicians are accustomed to note that, at first, in the form:

$$\begin{pmatrix}1&2&3&4\\3&2&4&1\end{pmatrix} \tag{6.2.64}$$

with:

$$\sigma(1)=3,\sigma(2)=2,\sigma(3)=4,\sigma(4)=1 \tag{6.2.65}$$

Hence:

$$\begin{pmatrix}1&2&3&4\\\sigma(1)&\sigma(2)&\sigma(3)&\sigma(4)\end{pmatrix} \tag{6.2.66}$$

Given σ and τ, two permutations, it is natural to look at their composition $\tau\circ\sigma$ (recall that this means that first we apply σ and afterwards τ as for the composition of functions).

Therefore if:

$$\sigma=\begin{pmatrix}1&2&3&4\\3&2&4&1\end{pmatrix}\quad\text{and}\quad\tau=\begin{pmatrix}1&2&3&4\\2&1&4&3\end{pmatrix} \tag{6.2.67}$$

Then:

$$\tau\circ\sigma=\begin{pmatrix}1&2&3&4\\4&1&3&2\end{pmatrix} \tag{6.2.68}$$

and:

$$\sigma\circ\tau=\begin{pmatrix}1&2&3&4\\4&2&1&3\end{pmatrix} \tag{6.2.69}$$

Now the idea is to interpret the composition as a multiplication of permutations. This multiplication is then non-commutative as we have seen in the previous example. We have generally $\sigma\circ\tau\neq\tau\circ\sigma$.

Each bijection has an inverse (reciprocal function). In our example it is obviously:

$$\sigma^{-1}=\begin{pmatrix}1&2&3&4\\4&2&1&3\end{pmatrix}\tag{6.2.70}$$

Geometrically, to calculate the inverse σ^{-1} of an element σ, we just need to take the reflection of the drawing of σ in a horizontal axis as shown in the left side of the figure below:

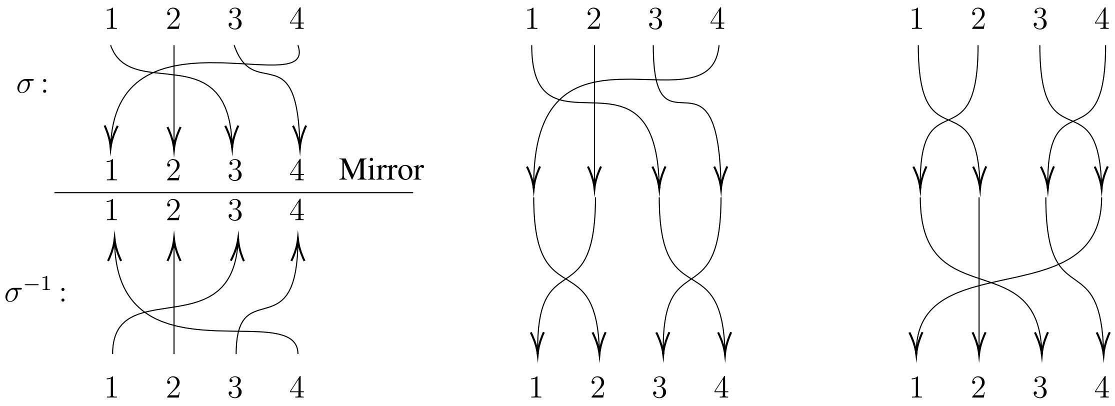


Figure 6.23: **Examples of compositions and inverse of permutations**

We may represent a permutation σ as a permutation matrix, i.e., the matrix that maps:

$$\sigma:\begin{pmatrix}1\\2\\\vdots\\n\end{pmatrix}\mapsto\begin{pmatrix}\sigma(1)\\\sigma(2)\\\vdots\\\sigma(n)\end{pmatrix}\tag{6.2.71}$$

An $n\times n$ matrix is a permutation matrix if and only if all its entries are zeros and ones, each column has exactly one 1, and each row has exactly one 1. In this instance, we have:

$$\sigma=\begin{bmatrix}0&0&1&0\\0&1&0&0\\0&0&0&1\\1&0&0&0\end{bmatrix}\tag{6.2.72}$$

Definitions (#6.2.192):

D1. The set of permutations of a set with n elements, with this structure of multiplication, is named the "group of permutations of order n" or "group of substitutions of order n", and is denoted by S_n or $S(n)$.

D2. We say that an element σ of S_n is a "cycle of order k", or simply a "k-th cycle" if there exists $a_1,a_2,\ldots,a_k\in\{1,\ldots,n\}$ such that:

- σ send a_1 on a_2, a_2 on $a_3,\ldots,a_{k-1}$, and a_k on a_1.

- σ fix all other elements of S_n

and we denote the cycle as following:

$$\sigma=(a_1,a_2,\ldots,a_k) \tag{6.2.73}$$

✍**Example:**

Perhaps, for a better understanding let us our previous example of S_4:

$$\begin{pmatrix} 1 & 2 & 3 & 4 \\ 3 & 2 & 4 & 1 \end{pmatrix} \tag{6.2.74}$$

This symmetric group is a 3-cycle denoted $\sigma=(1\,3\,4)$ because in order: 1 send on 3, 3 send on 4 and 4 send on 1 (and 2 is not mentioned as it remains fixed). We can also write this in the following equivalent ways: $\sigma=(3\,4\,1)$ or also $\sigma=(4\,1\,3)$.

D3. The order of a k-cycle is k (hence the name!).

✍**Example:**

Indeed if we take again our $\sigma=(1\,3\,4)$, then we have:

$$\sigma^2=(1\,4\,3) \quad \text{and} \quad \sigma^3=\text{id} \tag{6.2.75}$$

D4. We say that a permutation σ is a "cycle" if there exists $k\in\mathbb{N}$ such as that σ is a k-cycle.

Warning! Any permutation must be written as a product of disjoint cycles (that is to say, a number that appears in a cycle should not appear in another cycle).

✍**Example:**

For example, in S_9, we have:

$$\sigma=\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ 5 & 2 & 8 & 3 & 7 & 1 & 6 & 4 & 9 \end{pmatrix}=(1\;5\;7\;6)(3\;8\;4) \tag{6.2.76}$$

So this service is a product of a 4-cycle and of a 3-disjoint cycle.

We also let the reader see for himself that the cyclic group generated by σ (which in this case is a subgroup of S_9) is of order 12 (12-cycle)...

Remark

Mathematicians can prove that if σ is an element that has a decomposition into c disjoint cycles of length $n_1,n_2,\ldots,n_c$ then the order of σ is the least common multiple of the orders of all disjoint cycles that compose it.

We also assume intuitive that in the common vocabulary, a 2-cycle into S_n is also named a "transposition".

Let us go a little further. We propose to show by example that the set of all transpositions generates S_n. In other words, any permutation is written as a product of transpositions!

✍**Example:**

Let us return to our example (it is an even permutation):

$$\sigma = \begin{pmatrix} 1 & 2 & 3 & 4 \\ 3 & 2 & 4 & 1 \end{pmatrix} = (1\;3\;4) = (1\;3)(4\;1) \tag{6.2.77}$$

In general, a k-cycle is thus written as the product of $k-1$ transpositions.

Theorem 6.6. As the permutations of a finite set form a group, this means (among other things) that there is therefore always an integer k, such that p applied k time is the identity transformation (that is to say, the operation that does not change anything).

Proof 6.6.1. If G is a finite group and that $g \in G$, we consider the sequence of items (recall that in a group there is only one an operation and therefore the square, cube, etc. means we compose this operation!):

$$g, g^2, g^3, \ldots \tag{6.2.78}$$

For example, in the permutation groups, the operation is the composition of permutations.

Since G is finite and that this sequence is infinite, there are necessarily two elements that are equal in the sequence... So there are two different n and m such that:

$$g^n = g^m \tag{6.2.79}$$

Assuming that $n < m$, the previous equality is simplified and we get:

$$g^{m-n} = e \tag{6.2.80}$$

where e is the neutral element of the group.

■ Q.E.D.

We will see that the permutations being bijective, we can create on finite groups, compositions of permutations operations that always end up returning to the initial state (identity application id)!!!

✍**Examples:**

E1. In a list of 5 items, we exchange the first and the third, and, at the same time, we pass the second in position 4, this that is in position 4 in put in position 5 and the one in position 5 is put on position 2. And we reiterate. This gives:

$$ABCDE \rightarrow CEABD \rightarrow ADCEB \rightarrow CBADE \rightarrow AECBD \rightarrow CDAEB \rightarrow ABCDE \tag{6.2.81}$$

We returned to the starting point after 6 steps.

E2. Let us consider the "Photomaton transformation" of the image of Mona Lisa of size 256 by 256 pixels:

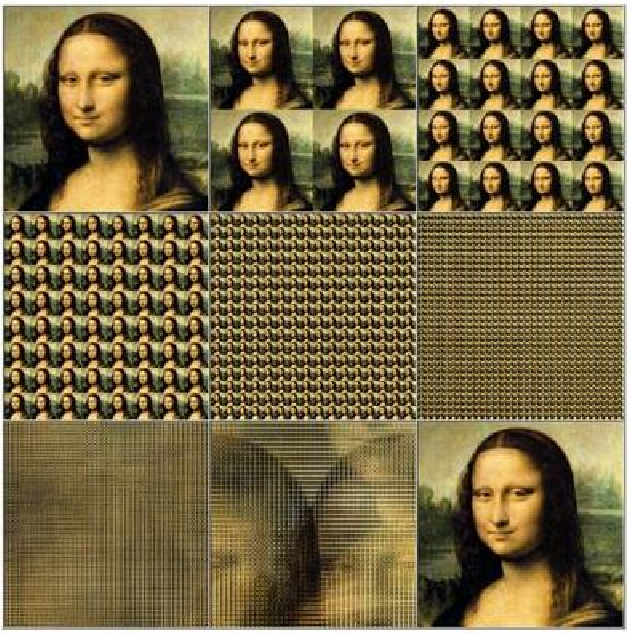

Figure 6.24: **Photomaton transformation**

We could thing that each image was obtained from the previous by reducing the size of the image half, which gave four similar pieces that we have placed in square to obtain an image having the same size as original image. But in fact it is not!!!! The number of pixels has been preserved (no pixel is duplicated!!!) and we actually just moved the pixels by permutation to get four images that do not actually contain all the information of the original image but only a part!

By repeating the procedure 8 times we always fall back on the original image regardless of the original image. The question is to understand why?

Let us consider that the original image is a square with a size of 16 pixels wide by 16 pixels high (but you can also apply what follows with a rectangular image of any size and you will see that it works also!). Each pixel of a line (the process is exactly the same for columns!) is identified by a coordinate along the X axis going from 0 to 15.

Thus we have at the beginning a sequence of numbers where the pixel coordinates correspond to their x coordinate:

$$0\ 1\ 2\ 3\ 4\ 5\ 6\ 7\ 8\ 9\ 10\ 11\ 12\ 13\ 14\ 15$$

We then do the permutation that consist to denote by k the position of a pixel and to do:

$$\text{permutation:}\begin{cases} x \text{ is even:} & 2k \rightarrow k \\ x \text{ is odd:} & 2k+1 \rightarrow 8+k \end{cases} \tag{6.2.82}$$

This then gives the first permutation:

$$\begin{array}{c} 0\;1\;2\;3\;4\;5\;6\;7\;8\;9\;10\;11\;12\;13\;14\;15 \\ \downarrow \text{Permutation } 1 \\ 0\;2\;4\;6\;8\;10\;12\;14\;1\;3\;5\;7\;9\;11\;13\;15 \\ \downarrow \text{Permutation } 2 \\ 0\;4\;8\;12\;1\;5\;9\;13\;2\;6\;10\;14\;3\;7\;11\;15 \\ \downarrow \text{Permutation } 3 \\ 0\;8\;1\;9\;2\;10\;3\;11\;4\;12\;5\;13\;6\;14\;7\;15 \\ \downarrow \text{Permutation } 4 \\ 0\;1\;2\;3\;4\;5\;6\;7\;8\;9\;10\;11\;12\;13\;14\;15 \end{array}$$

Thus, for an image of 16 by 16 pixels, it takes four permutations, which corresponds to $2^4=16$. So for an image of 256 pixels, we have $256=2^8$, hence the fact that we need 8 permutation to find back the original Mona Lisa with:

$$\text{permutation:}\begin{cases} x \text{ is even:} & 2k \rightarrow k \\ x \text{ is odd:} & 2k+1 \rightarrow 128+k \end{cases} \tag{6.2.83}$$

Thus, in the general case of an image of width L in number of pixels counting from 1, the transformation is:

$$\text{permutation:}\begin{cases} x \text{ is even:} & 2k \rightarrow k \\ x \text{ is odd:} & 2k+1 \rightarrow E^{+}\left[\dfrac{L}{2}\right]+k \end{cases} \tag{6.2.84}$$

where $E^{+}[\ldots]$ is the upper (nearest) integer value in the case where L is odd.

The reader will also have maybe notice something interesting if we return to our example with the image of 16 pixels ... Indeed, let us take the third pixel from the left of coordinate x equal to 2. In binary, its initial position is then 0010. After the first permutation, its x coordinate is equal to 1, or in binary: 0001. After the second permutation, the x coordinate is equal to 8, or in binary: 1000, etc. In fact we see that every permutation can be summarized in binary by shifting the bits to the right.

Definition (#6.2.193): Given $\sigma \in S_n$ a permutation. We say that σ is an "even permutation" if, in a writing of σ as product of transpositions, there is an even number of transpositions. We say the obviously that σ is an "odd permutation" if, in a writing of σ as product of transposition, there is an odd number of transpositions.

Let us end with a small complement... We know that S_3 is a group of permutations of order 3

and therefore with $3!=6$ possible permutations.

If we list the 6 permutations we saw what we get:

$$\{(1),(1\,2),(1\,3),(2\,3),(1\,2\,3),(1\,3\,2)\} \tag{6.2.85}$$

Among these only some can be written as an even product of transpositions:

$$(1\,2\,3)=(1\,2)(3\,1) \quad \text{and} \quad (1\,3\,2)=(1\,3)(2\,1) \tag{6.2.86}$$

The even permutations form with the identity permutation, a subgroup (not commutative!) we name the "alternating group of order n" and that we denote by AN. It is easy to check with the previous example.

6.2.2 Galois Theory

In abstract algebra, Galois theory, named after Évariste Galois, provides a connection between field theory and group theory. Using Galois theory, certain problems in field theory can be reduced to group theory, which is, in some sense, simpler and better understood.

Originally, Galois used permutation groups to describe how the various roots of a given polynomial equation are related to each other.

The birth and development of Galois theory was caused by the following question, whose answer is known as the "Abel–Ruffini theorem": Why is there no formula for the roots of a fifth (or higher) degree polynomial equation in terms of the coefficients of the polynomial, using only the usual algebraic operations (addition, subtraction, multiplication, division) and application of radicals (square roots, cube roots, etc)?.

Galois theory not only provides a beautiful answer to this question, it also explains in detail why it is possible to solve equations of degree four or lower in the above manner, and why their solutions take the form that they do. Further, it gives a conceptually clear, and often practical, means of telling when some particular equation of higher degree can be solved in that manner.

Galois theory originated in the study of symmetric functions: the coefficients of a monic polynomial are (up to sign) the elementary symmetric polynomials in the roots. For instance:

$$(x-a)(x-b)=x^2-(a+b)x+ab \tag{6.2.87}$$

where 1, $a+b$ and ab are the elementary polynomials of degree 0, 1 and 2 in two variables.

We tried to make this part of the book as easy as possible. So we hope our goal is reach if you understand what follows. Let us now begin!!!

6.2.2.1 Elementary symmetric and Invariant Polynomials

Definition (#6.2.194): The "kth elementary symmetric polynomial in n variables", denoted $s_k(x_k,\ldots,x_n)$ is the sum of all possible degree k monomials in n variables with each x_i appearing NO MORE THAN ONCE IN EACH MONOMIAL. Formally, for $k \leq n$:

$$s_k(x_1,\ldots,x_n) = \sum_{1\leq i_1<\ldots<i_k\leq n} x_{i_1}x_{i_2}\ldots x_{i_k} \tag{6.2.88}$$

A polynomial is said "invariant under S_n" if and only if it is a polynomial in the elementary symmetric functions $s_1,\ldots,s_n$.

Therefore:

$$\begin{aligned}
s_0(x_1,x_2,\ldots,x_n) &= 1,\\
s_1(x_1,x_2,\ldots,x_n) &= \sum_{1\leq j\leq n} x_j,\\
s_2(x_1,x_2,\ldots,x_n) &= \sum_{1\leq j<k\leq n} x_jx_k,\\
s_3(x_1,x_2,\ldots,x_n) &= \sum_{1\leq j<k<l\leq n} x_jx_kx_l\\
&\vdots\\
s_n(x_1,x_2,\ldots,x_n) &= x_1x_2\ldots x_n
\end{aligned} \tag{6.2.89}$$

✍**Example:**

For $n=1$:

$$s_1(x_1) = x_1, \tag{6.2.90}$$

For $n=2$:

$$\begin{aligned}
s_1(x_1,x_2) &= x_1+x_2\\
s_2(x_1,x_2) &= x_1x_2
\end{aligned} \tag{6.2.91}$$

For $n=3$:

$$\begin{aligned}
s_1(x_1,x_2,x_3) &= x_1+x_2+x_3,\\
s_2(x_1,x_2,x_3) &= x_1x_2+x_1x_3+x_2x_3,\\
s_3(x_1,x_2,x_3) &= x_1x_2x_3
\end{aligned} \tag{6.2.92}$$

For $n=4$:

$$\begin{aligned}
s_1(x_1,x_2,x_3,x_4) &= x_1+x_2+x_3+x_4\\
s_2(x_1,x_2,x_3,x_4) &= x_1x_2+x_1x_3+x_1x_4+x_2x_3+x_2x_4+x_3x_4\\
s_3(x_1,x_2,x_3,x_4) &= x_1x_2x_3+x_1x_2x_4+x_1x_3x_4+x_2x_3x_4\\
s_4(x_1,x_2,x_3,x_4) &= x_1x_2x_3x_4
\end{aligned} \tag{6.2.93}$$

Now consider the equation:

$$ax^2+bx+c=0 \tag{6.2.94}$$

It can be rewritten as:

$$1\cdot x^2+\frac{b}{a}x+\frac{c}{a}=0 \tag{6.2.95}$$

or as we know the Vieta relations with two roots, the latter can be rewritten:

$$1\cdot x^2-(r_1+r_2)x+r_1r_2=(x-r_1)(x-r_2)=0 \tag{6.2.96}$$

That is to say:

$$s_0\cdot x^2-s_1x+s_2=0 \tag{6.2.97}$$

Similarly, for a third-degree polynomial:

$$\begin{aligned}&ax^3+bx^2+cx+d=\\&a(x-r_1)(x-r_2)(x-r_3)=a[x^3-(r_1+r_2+r_3)x^2+(r_1r_2+r_1r_3+r_2r_3)x-r_1r_2r_3]\\&=a[s_0x^3-s_1x^2+s_2x-s_3]\end{aligned} \tag{6.2.98}$$

and therefore:

$$s_1=r_1+r_2+r_3=-\frac{b}{a}\quad s_2=r_1r_2+r_1r_3+r_2r_3=\frac{c}{a}\quad s_3=r_1r_2r_3=-\frac{d}{a} \tag{6.2.99}$$

The elementary symmetric polynomials appear when we expand a linear factorization of a monic polynomial. We have the identity:

$$\prod_{i=1}^{n}(x-r_i)=x^n-s_1(r_1,\ldots,r_n)x^{n-1}+s_2(r_1,\ldots,r_n)x^{n-2}+\cdots+(-1)^ns_n(r_1,\ldots,r_n) \tag{6.2.100}$$

That is, when we substitute numerical values for the variables $r_1,r_2,\ldots,r_n$, we get the monic univariate polynomial (with variable x) whose roots are the values substituted for $r_1,r_2,\ldots,r_n$ and whose coefficients are up to their sign the elementary symmetric polynomials. These relations between the roots and the coefficients of a polynomial are named "General Vieta's formulas" for which we have already see two special cases in the section of Calculus and that we will generalize further below.

Theorem 6.7. If $r_1,r_2,\ldots,r_n$ are the roots of a degree n polynomial, then:

$$\boxed{\prod_{i=1}^{n}(x-r_i)=x^n+\sum_{i=1}^{n}(-1)^is_i(r_1,\ldots,r_n)x^{n-i}} \tag{6.2.101}$$

Proof 6.7.1. We will prove this by induction on the degree of the polynomial. If our polynomial is of degree $n=1$ with root r, the left hand side is $x-r$, and the right hand side is $x-s_1(r)=$

$x-r$, so the equation holds for $n=1$. Suppose the equation holds for all polynomials of degree n. Let $P(x)$ be of degree $n+1$ with roots $r_1,\dots,r_{n+1}$.

Then, we can write:

$$P(x)=(x-r_{n+1})\prod_{i=1}^{n}(x-a_i)=(x-r_{n+1})\left(x^n+\sum_{i=1}^{n}(-1)^i s_i x^{n-i}\right)\tag{6.2.102}$$

where we let s_i denote $s_i(r_1,\dots,r_n)$ for brevity. By multiplying out the right hand side:

$$\begin{aligned}P(x)&=(x-r_{n+1})(x^n+\sum_{i=1}^{n}(-1)^i s_i x^{n-i})\\&=x^{n+1}+x\sum_{i=1}^{n}(-1)^i s_i x^{n-i}-r_{n+1}x^n-r_{n+1}\sum_{i=1}^{n}(-1)^i s_i x^{n-i}\\&=x^{n+1}+\sum_{i=1}^{n}(-1)^i s_i x^{n-i+1}-r_{n+1}x^n+r_{n+1}\sum_{i=1}^{n}(-1)^{i+1} s_i x^{n-i}\\&=x^{n+1}+\sum_{i=1}^{n}(-1)^i s_i x^{n-i+1}-r_{n+1}x^n+\sum_{i=1}^{n}(-1)^{i+1} s_i r_{n+1} x^{n-i}\\&=x^{n+1}+\sum_{i=1}^{n}(-1)^i s_i x^{n-i+1}-r_{n+1}x^n+\sum_{i=1}^{n-1}(-1)^{i+1} s_i r_{n+1} x^{n-i}+(-1)^{n+1}s_n r_{n+1}\\&=x^{n+1}+(-1)s_1x^n+\sum_{i=1}^{n-1}(-1)^{i+1} s_{i+1} x^{n-i}-r_{n+1}x^n+\sum_{i=1}^{n-1}(-1)^{i+1} s_i r_{n+1} x^{n-i}+(-1)^{n+1}s_n r_{n+1}\\&=x^{n+1}+(-1)s_1x^n-r_{n+1}x^n+\sum_{i=1}^{n-1}(-1)^{i+1}(s_{i+1}+s_i r_{n+1})x^{n-i}+(-1)^{n+1}s_n r_{n+1}\\&=x^{n+1}-(r_{n+1}+s_1)x^n+\sum_{i=1}^{n-1}(-1)^{i+1}(s_{i+1}+s_i r_{n+1})x^{n-i}+(-1)^{n+1}s_n r_{n+1}\end{aligned}\tag{6.2.103}$$

Since:

$$s_1+r_{n+1}=(r_1+\ldots+r_n)+r_{n+1}=s_1(r_1,\dots,r_{n+1})\tag{6.2.104}$$

and:

$$s_n r_{n+1}=(r_1 r_2\ldots r_n)r_{n+1}=s_{n+1}(r_1,\dots,r_{n+1})\tag{6.2.105}$$

So we get:

$$\begin{aligned}P(x)&=x^{n+1}-(r_{n+1}+s_1)x^n+\sum_{i=1}^{n-1}(-1)^{i+1}(s_{i+1}+s_i r_{n+1})x^{n-i}+(-1)^{n+1}s_n r_{n+1}\\&=x^{n+1}-s_1(r_1,\dots,r_{n+1})x^n+\sum_{i=1}^{n-1}(-1)^{i+1}(s_{i+1}+s_i r_{n+1})x^{n-i}+(-1)^{n+1}s_{n+1}(r_1,\dots,r_{n+1})\end{aligned}\tag{6.2.106}$$

Now it remains that if we can prove that:

$$s_{i+1}+s_i a_{n+1}=s_{i+1}(a_1,\ldots,a_{n+1}) \tag{6.2.107}$$

for all the other i, we conclude the equation holds for $n+1$, hence for all n.

Remember that by definition:

$$s_k(x_1,\ldots,x_n)=\sum_{i\leq i_1<\ldots<i_k\leq n} x_{i_1}x_{i_2}\ldots x_{i_k} \tag{6.2.108}$$

Then:

$$s_{i+1}(r_1,\ldots,r_{n+1})=\sum_{1\leq j_1<\ldots<j_{i+1}\leq n+1} r_{j_1}r_{j_2}\ldots r_{j_{n+1}} \tag{6.2.109}$$

By separating the sum with respect to monomials divisible by r_{n+1}, we see the above is equal to (most of time the best is to check this be using one the previous examples given earlier):

$$\begin{gathered}\sum_{1\leq j_1<\ldots<j_{i+1}\leq n+1} r_{j_1}r_{j_2}\ldots r_{j_{i+1}}=\\ \sum_{1\leq j_1<\ldots<j_{i+1}\leq n} r_{j_1}r_{j_2}\ldots r_{j_{i+1}}+r_{n+1}\sum_{1\leq j_1<\ldots<j_i\leq n} r_{j_1}r_{j_2}\ldots r_{j_i}=s_{i+1}(r_1,\ldots,r_{n+1})+r_{n+1}s_i(r_1,\ldots,r_n)\end{gathered} \tag{6.2.110}$$

so it is clear the relation we wanted holds.

■ Q.E.D.

6.2.2.2 General Vieta's formulas

If we write the second degree equation as following:

$$a_2x^2+a_1x+a_0=0 \tag{6.2.111}$$

We already know that:

$$s_1=r_1+r_2=-\frac{a_1}{a_2} \qquad s_2=r_1r_2=\frac{a_0}{a_2} \tag{6.2.112}$$

And also for a third degree polynomial we saw just before in the examples that if we have:

$$a_3x^3+a_2x^2+a_1x+a_0=0 \tag{6.2.113}$$

then:

$$s_1=r_1+r_2+r_3=-\frac{a_2}{a_3} \quad s_2=r_1r_2+r_1r_3+r_2r_3=\frac{a_1}{a_3} \quad s_3=r_1r_2r_3=-\frac{a_0}{a_3} \tag{6.2.114}$$

We can easily see a pattern emerging that is:

$$\boxed{s_k=\sum_{i\leq i_1<\ldots<i_k\leq n} r_{i_1}r_{i_2}\ldots r_{i_k}=(-1)^k\frac{a_{n-k}}{a_k}} \tag{6.2.115}$$

6.3. Differential and Integral Calculus

DIFFERENTIAL CALCULUS is one of the most exciting and vast field of mathematics and there is colossal literature on the subject. The results initiated by scientists as Fermat, Newton, Leibniz, Euler and company since the late 117th century (holocene calendar) found absolutely implications in all areas of physics, computer science, electronics, chemistry, finance, biology and mathematics itself.

Mathematicians have written such a lot of theorems since the birth of differential calculus in the mid-116th century (holocene calendar) that the validation of a sample of these theorems is sometimes tricky because requiring for some of them a whole life to be covered (it is a problem that the community of mathematicians recognizes) and checked (so that sometimes nobody checks...).

This fact know, we have chosen here to present only the items absolutely necessary to the understanding of the fundamental tools for the engineer. The purists will excuse us for the moment not to present some theorems that seem indispensable to them but we will prepare once we will have more time...

We will mainly study in what follows what mathematicians like to precisely name (and they are right!): the general cases of real functions of one real variable. More complex functions (several real or complex variables, continuous or discrete) will come once this first part is finished. But the reader can already found theorems with complex variables in the section of Complex Analysis.

Remark

We will not prove in this textbook all the primitives and derivatives of all possible functions because as there are an infinite number of possible functions, there is also an infinite number of derivatives and primitives! It is the role of teachers in educational institutions to train students to apply and understand the reasoning of derivations and integration by applications on known functions (the Internet probably never replace the school at this level).

6.3.1 Differential Calculus

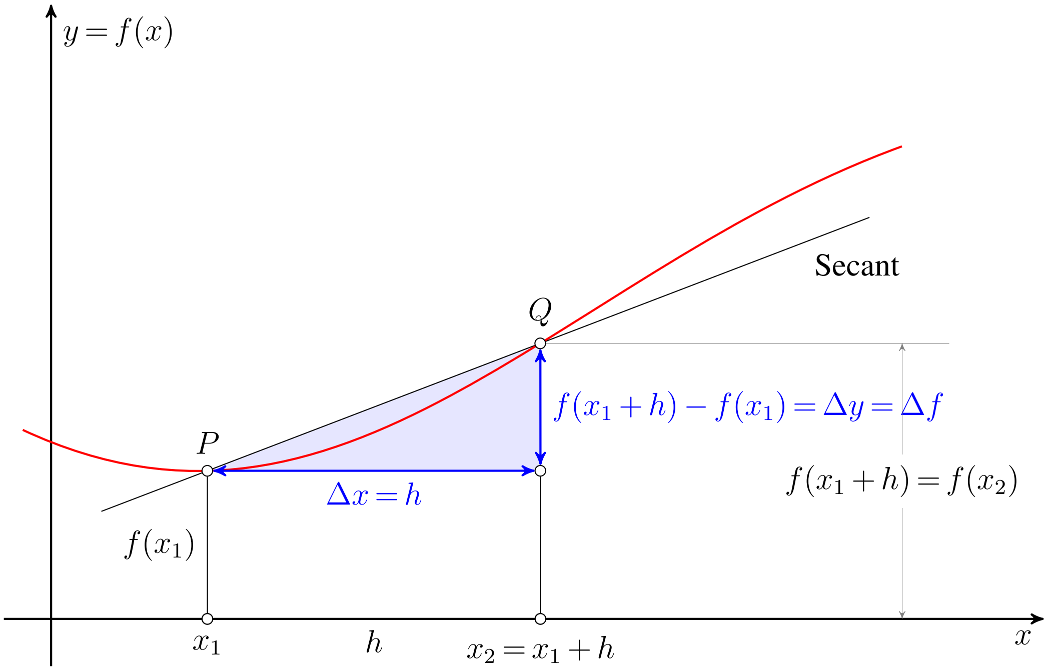
Let f be a real function of one real variable x denoted $f(x)$ (we restrict ourselves to this case for now and we will study the partial derivatives in any number of dimensions later) continue in at least one interval where the horizontal axis contains the value a.

Definitions (#6.3.195):

D1. We name "average slope", or "directing coefficient" the report of the orthogonal projection of two points $x_1 \neq x_2$ of the function f not necessarily continuous on the x-axis and y-axis as:

$$\frac{\Delta f}{\Delta x}=\frac{f(x_2)-f(x_1)}{x_2-x_1}=\frac{f(x_1+h)-f(x_1)}{(x_1+h)-(x_1)}\underset{x_1:=a}{=}\frac{f(a+h)-f(a)}{h} \tag{6.3.1}$$

What can be represented graphically as follows with a specific function:



Remark

Δ named "delta" expresses the fact that we take a difference of the same amount.

We assume as obvious (without proof) that two functions whose slopes are the same in the same interval of definition, are parallel (on a plane).

Remark

We will prove in the chapter of Analytical Geometry page 2804 that two functions whose slopes multiplication is equal -1 are perpendicular.

D2. We name "derivative on a" or "instantaneous slope" or "first derivative", the limit when h tends to 0 (if the limits exists) of the ratio of the orthogonal projection of two points $x_1 \neq x_2$ infinitely close of a continuous function f (in the sense that it does not contain "holes") on the x-axis and y-axis so that:

$$\boxed{\frac{\Delta f}{\Delta x}\underset{h\to 0}{=}\frac{\mathrm{d}f_a}{\mathrm{d}x}=\lim_{h\to 0}=\frac{f(a+h)-f(h)}{h}=f'(a)} \tag{6.3.2}$$

This relation is sometimes named "Newton's difference quotient".

A graphical interpretation gives us that $f'(a)$ is quite obviously the directing coefficient (the slope of the tangent at the point of abscissa a).

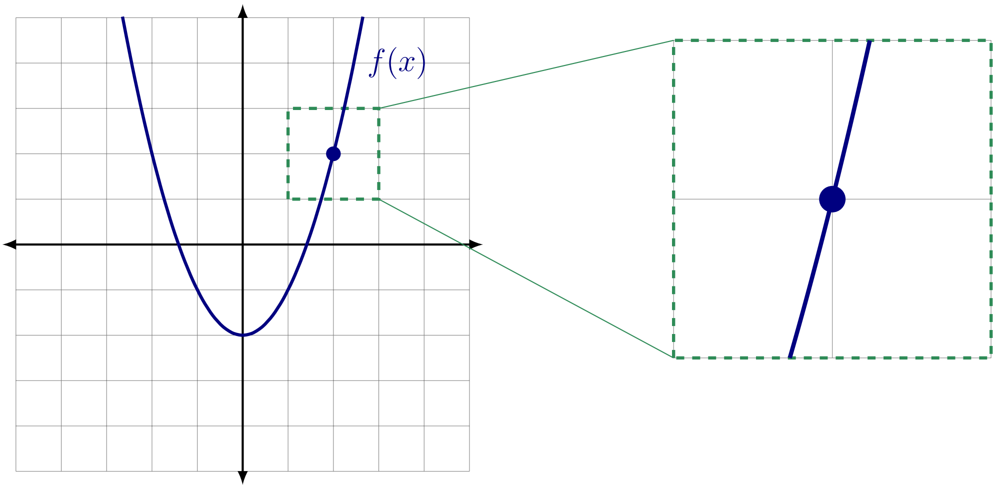


Figure 6.25: A continuous function at the limit looks always like a tangent (author: Lauren K. Williams)

The "tangent" to a curve Γ at a point A is the limit position, when it exists, of the secant line AB when point B of the curve tends towards point A. To be made perfectly rigorous, this definition requires the introduction of notions of topology allowing the calculation of such a limit as we will see in the section of Functional Analysis at page 2226.

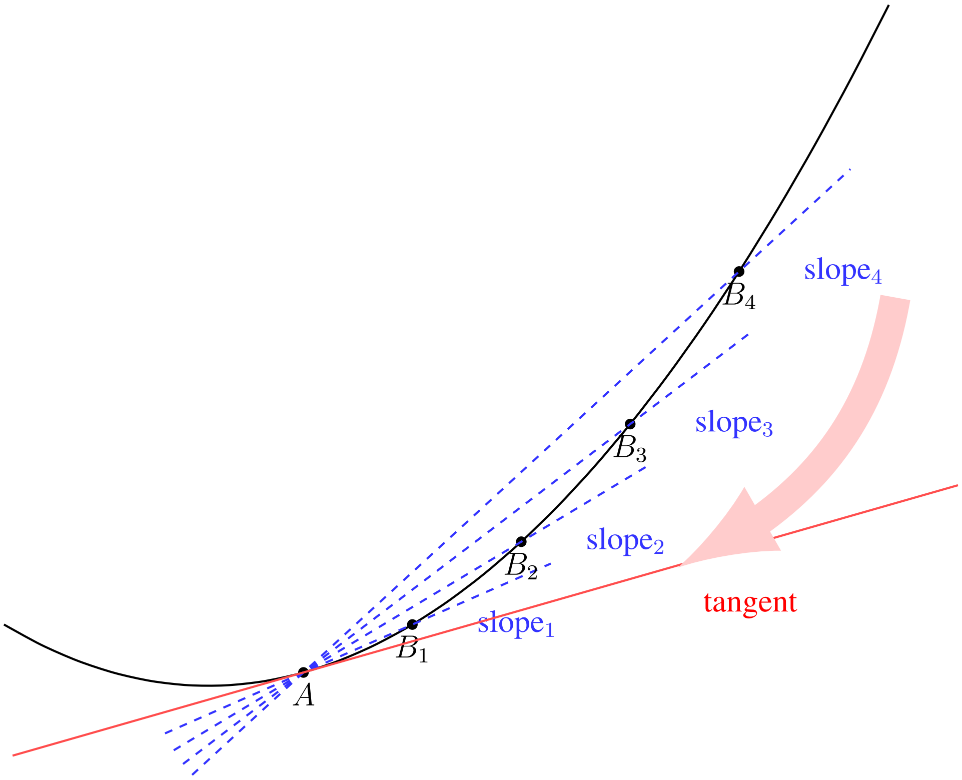

Figure 6.26: Secant vs Tangent

Remarks

R1. The letter d (written upright, not italicized as recommended by the ISO 80000-2 international standard: *Quantities and units - Part 2: Mathematical signs and symbols to be used in the natural sciences and technology*) means here a "differential" and expresses the fact that we take an infinitesimal difference of the same amount.

R2. We refer the reader to the section of Functional Analysis (page 2226) for the definition of a continuous function.

D3. Let f be a function defined on an interval I and differentiable at every point a of I. The function that to any real number of I associates the number $f'(a)$ is named the "derivative function of f on I" and is denoted by f'.

Remark

About the notations of the derivatives... physicists adopt depending on their mood various possible notations. Thus, consider the real function $f(x)$ with one real variable x you can find in the literature and in this textbook the following notations for the first derivative:

$$\frac{\mathrm{d}}{\mathrm{d}x}f(x)=\frac{\mathrm{d}f(x)}{\mathrm{d}x}=\mathrm{d}_x f(x)=\dot{f}(x)=f'(x) \tag{6.3.3}$$

or implicitly assuming that f is a function of x (this gives the opportunity to reduce the size of developments):

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}x}f=\frac{\mathrm{d}f}{\mathrm{d}x}=\mathrm{d}_x f(x)=\dot{f}=f'} \tag{6.3.4}$$

We can in the same way define 2nd order derivatives (derivative of a derivative), the derivatives of order 3 (derivative from a derivative of order 2) and so on. We will frequently meet such derivatives in physics or in pure mathematics for functional analysis.

Note that the derivatives of order two have a very important interpretation in physics and in the field of optimization (see section Numerical Methods page 6673). Indeed, if the sign of the first derivative is positive and then becomes negative (going trough the value of zero) when x increases, then we easily guess we travel through a local maximum of a function (the point where the derivative is zero) and that if the sign of the first derivative becomes negative and positive when x increases, so we travel a local minimum of the function (the point where the derivative is zero). In other words, when the slope changes sign (becomes zero by changing the sign) function passes through an extremum (maximum or minimum) and the tangent is "horizontal" in this point: parallel to the x-axis. We speak then of "turning point":

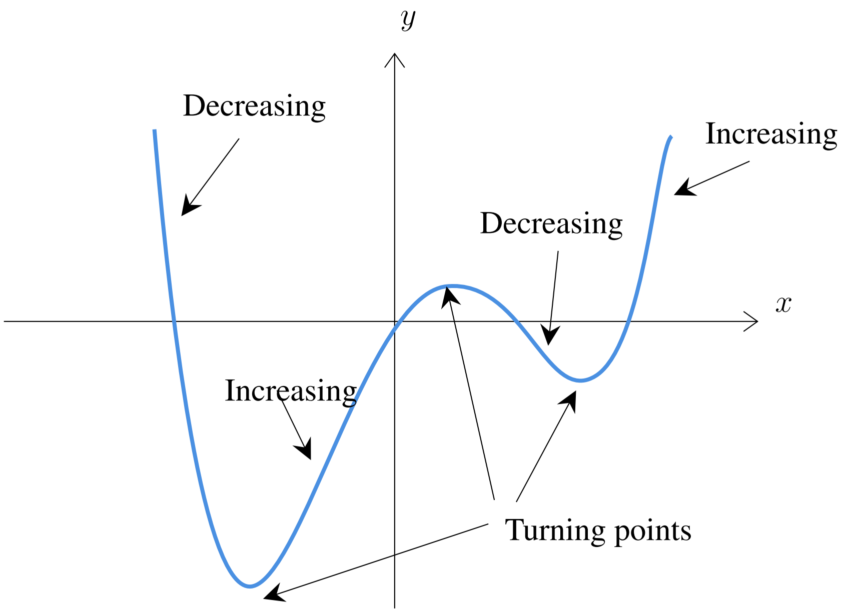

Figure 6.27: **Turning point explicitly highlighted**

But when the 2nd order derivative is zero, that means that the curvature of the function is reversing. We speak then about an "inflection point":

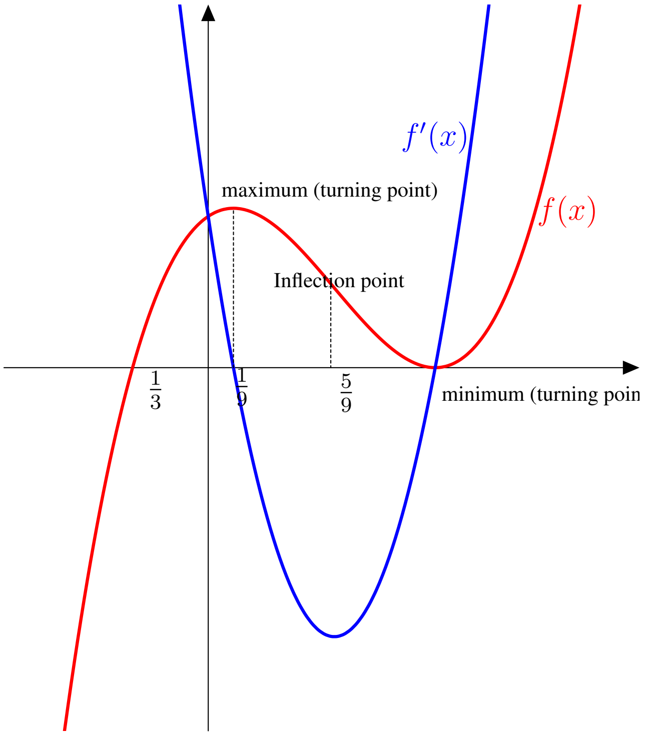

Figure 6.28: **Turning point and inflection point of** $3x^3-5x^2+x+1$

So a very important thing that should always keep in mind (!!!) when you write that the derivative of a function is null, is that we can have a derivative which vanishes at a point without being an extremum (remember that we name this an "inflection point"). To check whether it is really an extremum, we can calculate the second derivative to eliminate the case of an inflection point (because in a inflection point the second derivative will not be null). Otherwise we must use a table of variations to ensure that we are dealing with a maximum or minimum like for example with the function x^3-3x^2+2:

x	$-\infty$		0		2		$+\infty$
f'		$+$	0	$-$	0	$+$	
f							

Which corresponding plot is (with Maple™ 4.00b):

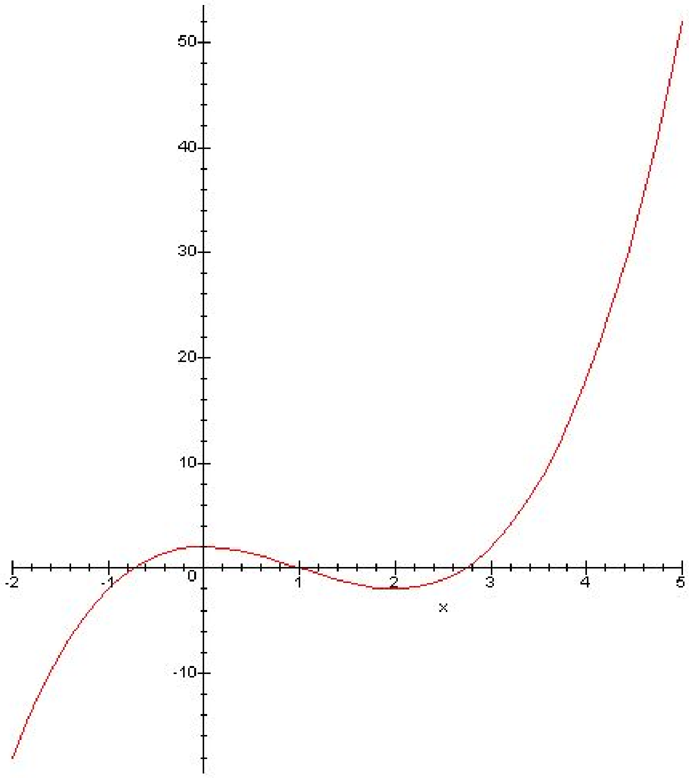

Figure 6.29: **Plot of function** x^3-3x^2+2

Another example with $f(x)=x^4-4x^3+11$ (with Maple™ 4.00b too):

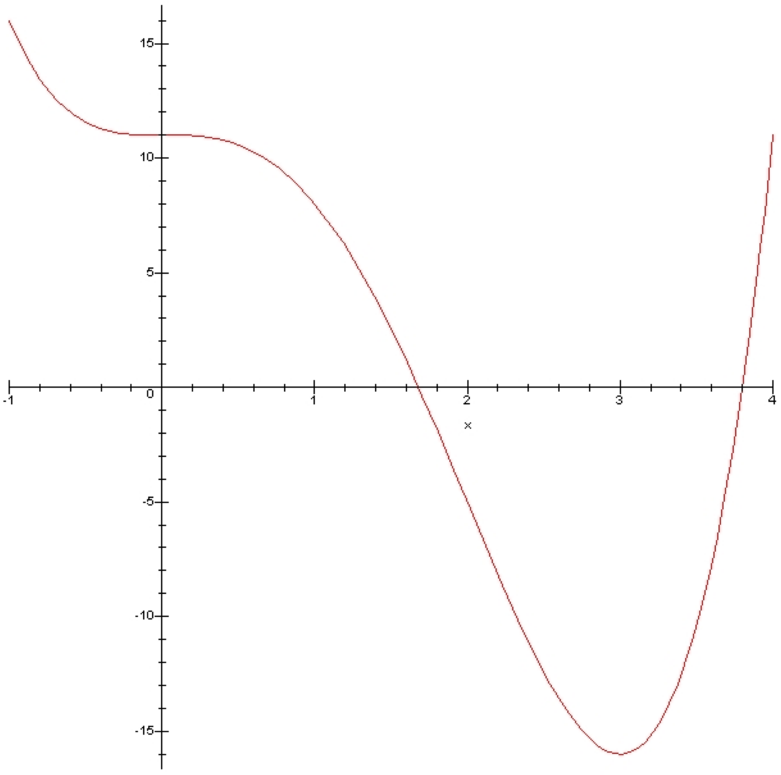

Figure 6.30: **Plot of function** $x^4 - 4x^3 + 11$

With a more detailed variation table:

x	$-\infty$		0		2		3		$+\infty$
$f'(x)$		$-$	0	$-$		$-$	0	$+$	
$f''(x)$		$+$	0	$-$	0	$+$		$+$	
$f(x)$	$+\infty$	↘	11 Σ.K.	↘	-5 Σ.K.	↘	-16 T.E.	↗	$+\infty$

Here is a very entertaining example of a function with its first and second derivatives in Maple™ 4.00:

```
>plot([tanh(x),diff(tanh(x),x),diff(tanh(x),x$2)],x=-5...5,
color=[red,green,blue]);
```

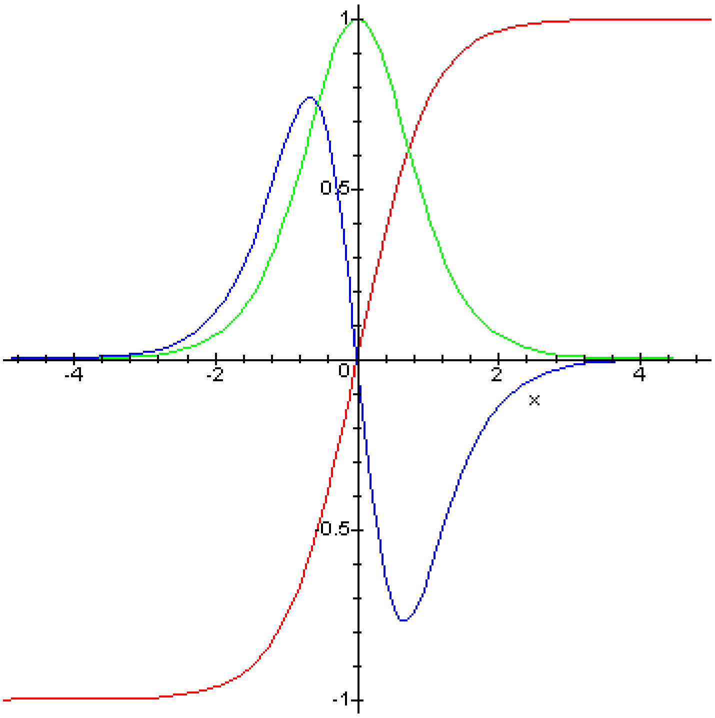

Figure 6.31: **Plot of the hyperbolic tangent function, its first and second derivatives**

The "second derivative" or "second order derivative" is given by:

$$\boxed{f''(x)=\lim_{h\to 0}\dfrac{f(x+h)-2f(x)+f(x-h)}{h^2}} \tag{6.3.5}$$

Indeed, using the Taylor series expansions (see page 1723) of $f(x+h)$ and $f(x-h)$:

$$\begin{aligned}f(x+h)&=f(x)+f'(x)h+f''(x)\frac{h^2}{2}+f'''(x)\frac{h^3}{3!}+\cdots\\ f(x-h)&=f(x)-f'(x)h+f''(x)\frac{h^2}{2}-f'''(x)\frac{h^3}{3!}+\cdots\end{aligned} \tag{6.3.6}$$

Adding the above relations gives:

$$\frac{f(x+h)-2f(x)+f(x-h)}{h^2}=f''(x)+2\frac{f''''(x)}{4!}h^2+\cdots \tag{6.3.7}$$

taking the limit of the above equation as h goes to zero gives the desired result:

$$f''(x)=\lim_{h\to 0}\frac{f(x+h)-2f(x)+f(x-h)}{h^2} \tag{6.3.8}$$

Remark

Two good functions to easy remember the property of the second derivative is $f(x)=x^2$ and $f(x)=-x^2$. As you know the first has a global minimum and the second a global maximum and if you calculate the second derivative for the first one you get a positive constant and a negative constant for the second.

A very important inflection point in business and science is the inflection point of the Normal distribution (see section Statistics page 692).

Given the function of the univariate Gauss distribution:

$$f(x)=\frac{1}{2\sqrt{2\pi}}e^{-\frac{(x-\mu)^2}{2\sigma^2}} \tag{6.3.9}$$

The points of inflections occur when the second derivative $f''(x)=0$. Then we have to calculate it. First:

$$f'(x)=-\frac{(x-\mu)}{\sigma^2\sqrt{2\pi}}e^{-\frac{(x-\mu)^2}{2\sigma^2}} \tag{6.3.10}$$

Hence:

$$f''(x)=\frac{(x-\mu-\sigma)(x-\mu+\sigma)}{\sigma^2\sqrt{2\pi}}e^{-\frac{(x-\mu)^2}{2\sigma^2}} \tag{6.3.11}$$

We put it equal to zero:

$$0=\frac{(x-\mu-\sigma)(x-\mu+\sigma)}{\sigma^2\sqrt{2\pi}}e^{-\frac{(x-\mu)^2}{2\sigma^2}} \tag{6.3.12}$$

Therefore we have two possible situations:

$$0=(x-\mu-\sigma) \qquad \text{and} \qquad 0=(x-\mu+\sigma) \tag{6.3.13}$$

Hence the two inflection points occur at:

$$x=\mu\pm\sigma \tag{6.3.14}$$

or one standard deviation above and below the mean.

Now, following a problem of understanding of one of our reader in one of the chapters of this textbook, let us specify a technique often used by physicists. Consider a derivative of order 2 as:

$$\ddot{f}=f''=\frac{\mathrm{d}^2f(x)}{\mathrm{d}x}=\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\mathrm{d}f(x)}{\mathrm{d}x}\right)=\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\mathrm{d}}{\mathrm{d}x}f(x)\right) \tag{6.3.15}$$

If we look at the $\dfrac{\mathrm{d}}{\mathrm{d}x}$ as a differential operator (what it is!) we can obviously write:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\mathrm{d}}{\mathrm{d}x}f(x)\right)=\frac{\mathrm{d}}{\mathrm{d}x}\frac{\mathrm{d}}{\mathrm{d}x}(f(x))=\left(\frac{\mathrm{d}}{\mathrm{d}x}\right)^2f(x) \tag{6.3.16}$$

Finally we have:

$$\frac{\mathrm{d}^2f(x)}{\mathrm{d}x}=\left(\frac{\mathrm{d}}{\mathrm{d}x}\right)^2f(x) \tag{6.3.17}$$

and so it comes after simplification by $f(x)$:

$$\boxed{\frac{\mathrm{d}^2}{\mathrm{d}x}=\left(\frac{\mathrm{d}}{\mathrm{d}x}\right)^2} \tag{6.3.18}$$

otherwise we can not have this equality if the operator acts explicitly on a function in a math or any physical relation.

This may seem obvious to some but sometimes less so for others ... and it is clearly useful to clarify this because it is often used in the sections of Special Relativity, General Relativity, Corpuscular Quantum Physics and Wave Quantum Physics.

Let us now indicate and prove two properties intuitively obvious of derivative which will be essential for us several times some proofs in this textbook (for example in the section of Numerical Methods or just simple in this section...).

Theorem 6.8. Consider first two real numbers $a<b$ and f a continuous real-valued function on the closed interval $[a,b]$ and differentiable on the open interval $]a,b[$ such that $f(a)=f(b)$. So we want to prove that there is obviously at least one element $c\in]a,b[$ such that $f'(c)=0$ (this is typically the case of polynomial functions!).

This property is named "Rolle's theorem" and therefore it explicitly shows that there is at least one element where the derivative of f is zero when we browsing its path we return back to the same value images for two distinct values of the abscissas (pre-images), that is to say that there exists at least one point where the tangent is horizontal.

Proof 6.8.1. First, if f is constant, the result is immediate... Otherwise, as f is continuous on the closed interval $[a,b]$ it admits at least one minimum or maximum considering that we rely on the assumption that $f(a)=f(b)$ and that f is not constant. The extrema is reached at a point c belonging to the open interval $]a,b[$ (the fact of taking an open interval allows in some cases to avoid having an extrema again in a or b).

Suppose as a first case that $f(c)$ is global maximum in the interval. The derivative of the function f between c and a second point a has a known sign:

- For h strictly positive and such that $c+h$ still belongs to the interval $[a,b]$:

  $$\frac{f(c+h)-f(c)}{h}<0 \tag{6.3.19}$$

  Considering the limit when h tends to 0, the derivative valuation on $f'(c)$ is thus negative.

- For h strictly negative and such that $c+h$ still belongs to the interval $[a,b]$:

  $$\frac{f(c+h)-f(c)}{h}>0 \tag{6.3.20}$$

  Considering the limit when h tends to 0, the derivative valuation on $f'(c)$ is thus positive.

Ultimately, the derivative of f is zero at point c.

The proof is analogous if $f(c)$ is a minimum in the interval, with the signs of derivatives that are opposite.

■ Q.E.D.

It should be quite obvious to the reader that in the general case, the change of basis doesn't conserve the norm!

Let us now consider two real numbers a,b and $f(x)$ a continuous function on $[a,b]$ (that is to say $\mathcal{C}([a,b])$) and differentiable on $]a,b[$.

Theorem 6.9. So we propose to show that there is at least one real number $c \in]a,b[$ such that:

$$f(b)-f(a)=f'(c)(b-a) \tag{6.3.21}$$

This can also be written as follows:

$$f(x_0+k)-f(x_0)=f'(x_0+s\cdot k)k \tag{6.3.22}$$

with $s\in]0,1[$.

Since the term on the left represents a finite increase of the term on the right, then this result is named "mean value theorem" or better "theorem of finite increments".

Geometrically this means that on at least one point c of the graph of the function $f(x)$, there is a tangent with a director coefficient of:

$$\frac{f(b)-f(a)}{b-a} \tag{6.3.23}$$

Graphically this gives:

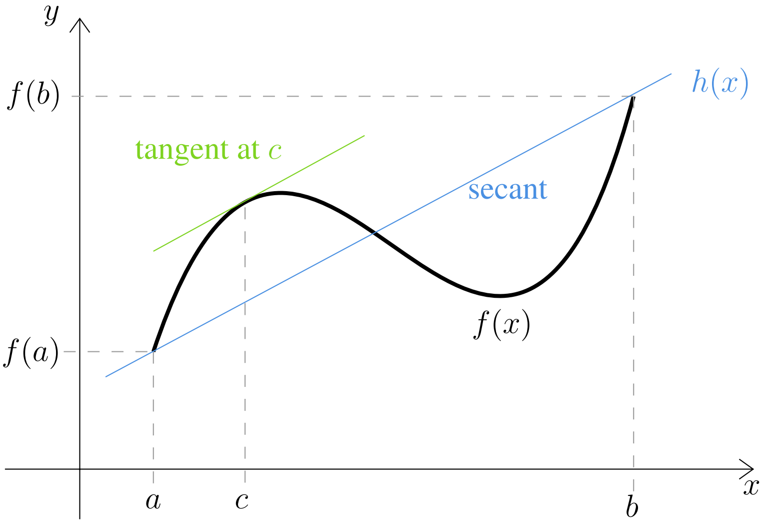

Figure 6.32: **Graphical representation of Rolle's theorem**

Proof 6.9.1. We first have:

$$h(x)=(x-a)\frac{f(b)-f(a)}{b-a}+f(a) \tag{6.3.24}$$

because the slope of $h(x)$ is obviously:

$$\frac{f(b)-f(a)}{b-a} \tag{6.3.25}$$

and as we must have $f(a)$ when $x=a$ it follows the relation given previously.

Then, to show that such a c value exists, the idea is to bring the two points a and b in the same ordinate making this brings us back to Rolle's theorem and for that, we define a function $g(x)$ by:

$$g(x)=f(x)-h(x)=f(x)-\left[(x-a)\frac{f(b)-f(a)}{b-a}+f(a)\right] \tag{6.3.26}$$

which is such that indeed $g(a)=g(b)$ ... is in this case equal to 0 (but this value is not relevant).

Therefore, the Rolle's theorem discussed above indicates that there is a point between a and b where the derivative of $g(x)$ is zero such that $g'(c)=0$. And by seeing that:

$$g'(x)=f'(x)-\frac{f(b)-f(a)}{b-a} \tag{6.3.27}$$

we get:

$$g'(c)=f'(c)-\frac{f(b)-f(a)}{b-a}=0 \tag{6.3.28}$$

Therefore after simplification:

$$f(b)-f(a)=f'(c)(b-a) \tag{6.3.29}$$

■ Q.E.D.

Using this little theorem and mathematical tools introduced earlier, we can build a little theorem useful and powerful physics.

Definition (#6.3.196): We name "Hôpital's rule" (also sometimes named "Bernoulli's rule") the method that uses the derivative in order to determine the boundaries difficult to calculate with most quotients which often appear in physics (the rule is named after the 117th-century - according to holocene calendar - French mathematician Guillaume de l'Hôpital. Although the rule is often attributed to l'Hôpital, the theorem was first introduced to him in 11694 by the Swiss mathematician Johann Bernoulli).

Proof 6.9.2. Consider two functions $f(x)$ and $g(x)$ and such that $f(a)=g(a)=0$ so we can write:

$$\frac{f(x)}{g(x)}=\frac{f(x)}{g(x)}\frac{x-a}{x-a}=\frac{f(x)}{x-a}\frac{x-a}{g(x)}=\frac{f(x)-f(a)}{x-a}\frac{x-a}{g(x)-g(a)} \tag{6.3.30}$$

Then according to the definition of the derivative:

$$\lim_{x\to a}\frac{f(x)}{g(x)}=\lim_{x\to a}\frac{f(x)-f(a)}{x-a}\frac{x-a}{g(x)-g(a)}=\frac{f(a+h)-f(a)}{(a+h)-h}\frac{(a+h)-h}{g(a+h)-g(a)}=\frac{f'(a)}{g'(a)} \tag{6.3.31}$$

■ Q.E.D.

We can generalize this previous result initially based on a little too strong constraint:

$$f(a)=g(a)=0 \tag{6.3.32}$$

Proof 6.9.3. Let us recall that according to the mean value theorem, if $f(x)$ is differentiable on an interval $]a,b[$ and continuous on $[a,b]$ then there is a real c in the interval $[a,b]$ such that:

$$f'(c)=\frac{f(b)-f(a)}{b-c} \tag{6.3.33}$$

If the theorem is true for two functions satisfying the same constraints then we have two functions such as:

$$f'(c)=\frac{f(b)-f(a)}{b-c} \quad \text{and} \quad g'(c)=\frac{f(b)-f(a)}{b-c} \tag{6.3.34}$$

If $g'(c)$ is not zero then we have the right to write the ratio (some name this the "generalized mean value theorem"...):

$$\frac{f'(c)}{g'(c)}=\frac{f(b)-f(a)}{b-a}\frac{b-a}{g(b)-g(a)}=\frac{f(b)-f(a)}{g(b)-g(a)} \tag{6.3.35}$$

which without losing validity as c is in the range $[a,x]$ can be written:

$$\frac{f'(c)}{g'(c)}=\frac{f(x)-f(a)}{g(x)-g(a)} \tag{6.3.36}$$

Therefore, when $x\rightarrow a$ that implies the range $[a,x]$ is always smaller and thus $c\rightarrow a$ we have:

$$\begin{aligned}\lim_{x\rightarrow a}&=\frac{f'(c)}{g'(c)}=\frac{f(a+h)-f(a)}{g(a+h)-g(a)}=\frac{f(a+h)-f(a)}{(a+h)-a}\frac{(a+h)-a}{g(a+h)-g(a)}\\&=\frac{f'(a)}{g'(a)}\end{aligned} \tag{6.3.37}$$

So we just proved now that in the first simplified proof of l'Hôpital's rule of the relation:

$$\frac{f(a+h)-f(a)}{(a+h)-a}\frac{(a+h)-a}{g(a+h)-g(a)}=\frac{f'(a)}{g'(a)} \tag{6.3.38}$$

we had is true in general and that it is not necessary that $f(a)=g(a)=0$ is true for the result to be fair!

■ Q.E.D.

Remark

The result can be generalized, still under the same condition, with:

$$\lim_{x\to a}\frac{f(x)}{g(x)}=\lim_{x\to a}\frac{f'(x)}{g'(x)}=\lim_{x\to a}\frac{f''(x)}{g''(x)}=\ldots=\lim_{x\to a}\frac{f^{(k)}(x)}{g^{(k)}(x)}=\lim_{x\to a}\frac{f^{(k+1)}(x)}{g^{(k+1)}(x)} \tag{6.3.39}$$

✍**Examples:**

E1. We want to calculate:

$$\lim_{x\to 2}\frac{x^2+x-6}{x^2-4} \tag{6.3.40}$$

There is two ways to solve that! First we can factorize:

$$\lim_{x\to 2}\frac{x^2+x-6}{x^2-4}=\lim_{x\to 2}\frac{(x+3)(x-2)}{(x+2)(x-2)}=\lim_{x\to 2}\frac{x+3}{x-2}=\frac{5}{4} \tag{6.3.41}$$

Or using l'Hôpital's rule (we see that the assumption $f(2)=g(2)=0$ is satisfied!):

$$\lim_{x\to 2}\frac{x^2+x-6}{x^2-4}=\lim_{x\to 2}\frac{2x+1}{2x}=\frac{5}{4} \tag{6.3.42}$$

But we see that we can't applied l'Hôpital's rule twice as assumptions would not be met.

E2. We want to calculate:

$$\lim_{x\to +\infty}\frac{x^2-4}{2+x-4x^2} \tag{6.3.43}$$

We obviously can't apply l'Hôpital's rule as $f(+\infty)\neq g(+\infty)\neq 0$. The factorization technique will also fail. We have to use a power trick.

We divide by the highest denominator power:

$$\lim_{x\to +\infty}\frac{x^2-4}{2+x-4x^2}=\lim_{x\to +\infty}\frac{1-\dfrac{4}{x^2}}{\dfrac{2}{x^2}+\dfrac{1}{x}-4}=-\frac{1}{4} \tag{6.3.44}$$

We will also caution here the previous "divide by highest power rule" is applicable in the specific scenario where you are taking a limit at infinity or minus infinity AND the limit expression is of the form $P(x)/Q(x)$ where both P and Q are linear combinations of powers of x and the largest power of x appearing in the entire expression is non-negative.

Caution!!! L'Hôpital's Rule is only for single-variable functions. In multivariable calculus, pathdependence must be checked. This limit depends on the path taken, so the limit does not exist.

6.3.1.1 Differentials

We noted earlier what is a differential d. But there are actually several different types of differential of a function (note that we distinguish the masculine and feminine gender of the word):

1. Differentials
2. Partial differentials
3. Total exact differentials
4. Total inexact differentials

Remember as seen at the beginning of this section hat we name "differential $\mathrm{d}f$" of an univariate function the relation given by:

$$\boxed{\mathrm{d}f = f'\mathrm{d}x} \tag{6.3.45}$$

However, to express the effect of changing all the variables of a multivariate function f, we must use another type of differential which we name the "total differential" (derived into two subfamilies: total exact differential and total inexact differential).

Take, for example, a function $f(x,y)$ of the two variables x and y. The increase $\mathrm{d}f$ of the function f, for a finite increase of x to $x+\Delta x$ and of y to $y+\Delta y$ is obviously given by:

$$\Delta f(x) = f(x+\Delta x),y+\Delta y) - f(x,y) \tag{6.3.46}$$

we can also write:

$$\Delta f(x) = f(x+\Delta x),y+\Delta y) - f(x,y+\Delta y) + f(x,y+\Delta y) - f(x,y) \tag{6.3.47}$$

Or also:

$$\Delta f(x) = \frac{f(x+\Delta x),y+\Delta y) - f(x,y+\Delta y)}{\Delta x}\Delta x + \frac{f(x,y+\Delta y) - f(x,y)}{\Delta y}\Delta y \tag{6.3.48}$$

For infinitely small increments of x and y:

$$\mathrm{d}f = \lim_{\Delta x\to 0}\left(\frac{f(x+\Delta x),y+\Delta y) - f(x,y+\Delta y)}{\Delta x}\Delta x\right) + \lim_{\Delta y\to 0}\left(\frac{f(x,y+\Delta y) - f(x,y)}{\Delta y}\Delta y\right) \tag{6.3.49}$$

Let us therefore focus on the two terms when going to the limit:

$$\frac{f(x+\mathrm{d}x),y+\mathrm{d}y) - f(x,y+\mathrm{d}y)}{\mathrm{d}x} \quad \text{and} \quad \frac{f(x,y+\mathrm{d}y) - f(x,y)}{\mathrm{d}y} \tag{6.3.50}$$

The first term on the left, we see it clearly, finally gives the change in x of the function $f(x,y)$ by having y fixed on the variation. We denote therefore this by (if the fixed variables are trivial we do note write them):

$$\left(\frac{\partial f}{\partial x}\right)_y = \left(\frac{\partial f}{\partial x}\right) = \frac{f(x+\mathrm{d}x),y+\mathrm{d}y) - f(x,y+\mathrm{d}y)}{\mathrm{d}x} \tag{6.3.51}$$

and even:

$$\left(\frac{\partial f}{\partial y}\right)_x = \left(\frac{\partial f}{\partial y}\right) = \frac{f(x,y+\mathrm{d}y) - f(x,y)}{\mathrm{d}y} \tag{6.3.52}$$

Remark

When a variable is fixed to study the variation of the other, some authors and teachers of older generations like to say, "all things being equal f varies in function of ... as ...". In short, it is an expression that can be found in other areas of mathematics (such as multivariate linear regressions) but that is disappearing...

Both expressions:

$$\left(\frac{\partial f}{\partial x}\right)_y \quad \text{and} \quad \left(\frac{\partial f}{\partial y}\right)_x \tag{6.3.53}$$

are what we name "partial differential" or just "partial derivative" (whose practical application case of the simplest and probably the most interesting and pedagogically relevant example available today in this entire book is the supply chain Wilson's model with rupture presented in the section of Quantitative Management).

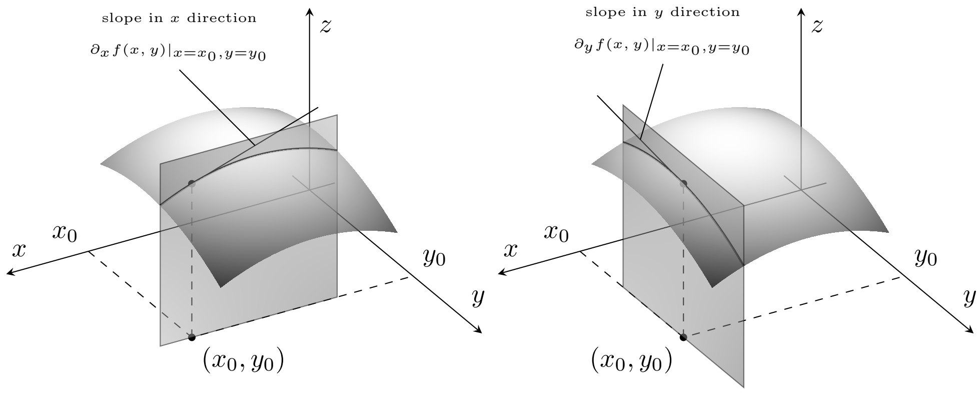

Figure 6.33: **Partial derivative illustrated**

✍**Example:**

Consider $f(x,y)=x^2+y^3+e^{xy^2}$. Computing the partial derivative is equivalent to computing the regular derivative with the other variables treated as constants. e.g.:

$$\left.\frac{\partial f}{\partial x}\right|_y = 2x+y^2e^{xy^2}$$

Second and mixed partial derivatives can also be computed:

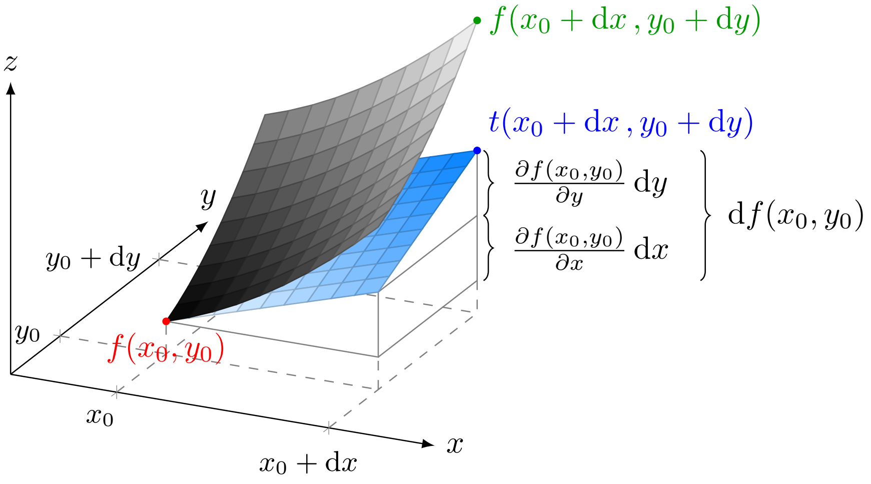
$$\begin{gathered}\frac{\partial^2 f}{\partial x^2}=2+y^4e^{xy^2}\\ \frac{\partial^2 f}{\partial y\partial x}=\frac{\partial}{\partial y}\left(\frac{\partial f}{\partial x}\right)=2ye^{xy^2}+2xy^3e^{xy^2}\end{gathered}$$

It is often cumbersome to write out the variables that are kept constant. If all other variables are being held constant, we simply don't write them out, and just say $\frac{\partial f}{\partial x}$.

We have therefore:

$$\boxed{\mathrm{d}f=\frac{\partial f}{\partial x}\mathrm{d}x+\frac{\partial f}{\partial y}\mathrm{d}y} \tag{6.3.54}$$

that is the "differential of f". The thermodynamicists them often talk of "total exact differential of f" or just "exact differential of f" or even simple "total derivative" and also "exterior derivative".



$f(x_0+\mathrm{d}x\,,y_0+\mathrm{d}y)$
z
$t(x_0+\mathrm{d}x\,,y_0+\mathrm{d}y)$
$\frac{\partial f(x_0,y_0)}{\partial y}\,\mathrm{d}y$
$\frac{\partial f(x_0,y_0)}{\partial x}\,\mathrm{d}x$
$\mathrm{d}f(x_0,y_0)$
y
$y_0+\mathrm{d}y$
y_0
$f(x_0,y_0)$
x_0
x
$x_0+\mathrm{d}x$

Figure 6.34: Total differential illustrated

There is also a shorter way (a matter of notation) to get the same result by considering an arbitrary displacement in any direction $(x,y)\rightarrow(x+\delta x,y+\delta y)$.

We have:

$$\begin{aligned}\delta f&=f(x+\delta x,y+\delta y)-f(x,y)\\&=f(x+\delta x,y+\delta y)-f(x+\delta x,y)+f(x+\delta x,y)-f(x,y)\\&=f_y(x+\delta x,y)\delta y+o(\delta y)+f_x(x,y)\delta x+o(\delta x)\\&=(f_y(x,y)+o(1))\,\delta y+o(\delta y)+f_x(x,y)\delta x+o(\delta x)\\&=\frac{\partial f}{\partial x}\delta x+\frac{\partial f}{\partial y}\delta y+o(\delta x,\delta y)\end{aligned} \tag{6.3.55}$$

If we take the limit as $\delta x,\delta y\rightarrow 0$ we fall back on the above boxed relation.

The previous relation is a special case of what mathematicians name very generally a "differential form":

$$\boxed{\mathrm{d}f=M(x,y)\mathrm{d}x+N(x,y)\mathrm{d}y} \tag{6.3.56}$$

we will come back about this a little further below...

It is customary to write:

$$\vec{F}=\begin{pmatrix}M(x,y)\\N(x,y)\end{pmatrix} \tag{6.3.57}$$

that is to say under vector field way.

It is important to remember the form of the total derivative because we will meet it again almost everywhere in special operators in quantum physics, in fluid mechanics, in electrodynamics, in thermodynamics, in economy, etc.

Geometrically, the partial derivatives can be interpreted as follows: the function $f(x,y)$ defines typically a surface in $\mathbb{R}$ whose intersection with the plane $y=y_0$ is a curve given by $f(x,y_0)$.

The partial derivative $\partial_x f$ is then the slope of this curve at every point x. We then have naturally the following function for the slope at the point (x_0,y_0):

$$f(x,y_0)=f(x_0,y_0)+\frac{\partial f}{\partial x}(x_0,y_0)(x-x_0) \tag{6.3.58}$$

Similarly, the tangent to the curve $f(x_0,y)$ will be given by:

$$f(x_0,y)=f(x_0,y_0)+\frac{\partial f}{\partial y}(x_0,y_0)(y-y_0) \tag{6.3.59}$$

The plane locally tangent to the point (x_0,y_0) determined by its two tangents is then given by:

$$f(x_0,y_0)=f(x_0,y_0)+\frac{\partial f}{\partial x}(x_0,y_0)(x-x_0)+\frac{\partial f}{\partial y}(x_0,y_0)(y-y_0) \tag{6.3.60}$$

Reorganizing the terms as:

$$f(x_0,y_0)-f(x_0,y_0)=\frac{\partial f}{\partial x}(x_0,y_0)(x-x_0)+\frac{\partial f}{\partial y}(x_0,y_0)(y-y_0) \tag{6.3.61}$$

We recognize:

$$\mathrm{d}f=\frac{\partial f}{\partial x}\mathrm{d}x+\frac{\partial f}{\partial y}\mathrm{d}y \tag{6.3.62}$$

Thus, for example, the surface represented by the function:

$$f(x,y)=e^{-x^2-y^2} \tag{6.3.63}$$

is shown below with the two tangents passing through the point:

$$(x_0,y_0)=(0.3,0.1) \tag{6.3.64}$$

and that respective equations are:

$$\begin{aligned}f(x,y_0)=f(x_0,y_0)+\frac{\partial f}{\partial x}(x_0,y_0)(x-x_0)&=e^{-x^2-y^2}\Big|_{0.3,0.1}-2xe^{-x^2-y^2}\Big|_{0.3,0.1}(x-x_0)\\&\cong 0.905-0.543(x-0.3)=-0.543x+1.0679\end{aligned} \tag{6.3.65}$$

and:

$$\begin{aligned}f(x_0,y)=f(x_0,y_0)+\frac{\partial f}{\partial y}(x_0,y_0)(y-y_0)&=e^{-x^2-y^2}\Big|_{0.3,0.1}-2ye^{-x^2-y^2}\Big|_{0.3,0.1}(y-y_0)\\&\cong 0.905-0.181(x-0.1)=-0.181x+0.9231\end{aligned} \tag{6.3.66}$$

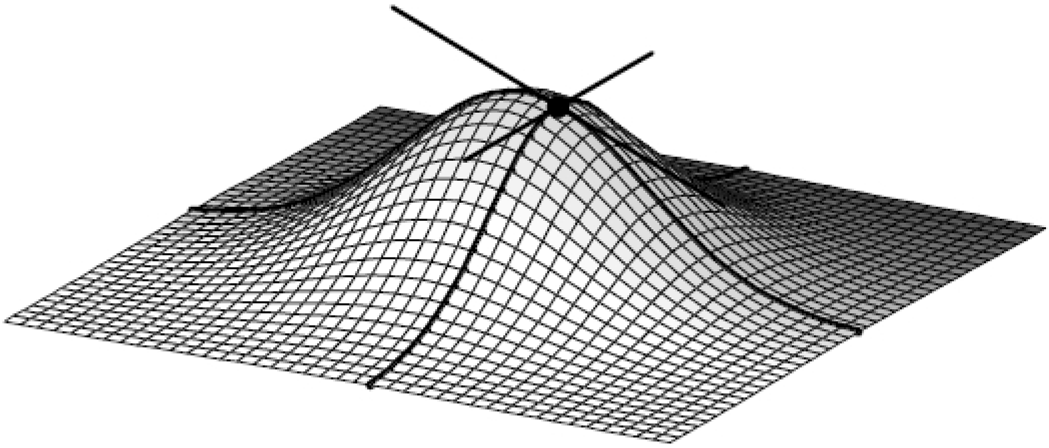


Figure 6.35: **Both partial derivatives tangents of the function at the point of interest**

The "tangent plane" at this point is then given by:

$$\begin{aligned} f(x_0,y_0) &= f(x_0,y_0)+\frac{\partial f}{\partial x}(x_0,y_0)(x-x_0)+\frac{\partial f}{\partial y}(x_0,y_0)(y-y_0) \\ &\cong 0.905-0.543(x-0.3)-0.181(y-0.1)=-0.543x-0.181y+1.086 \end{aligned} \tag{6.3.67}$$

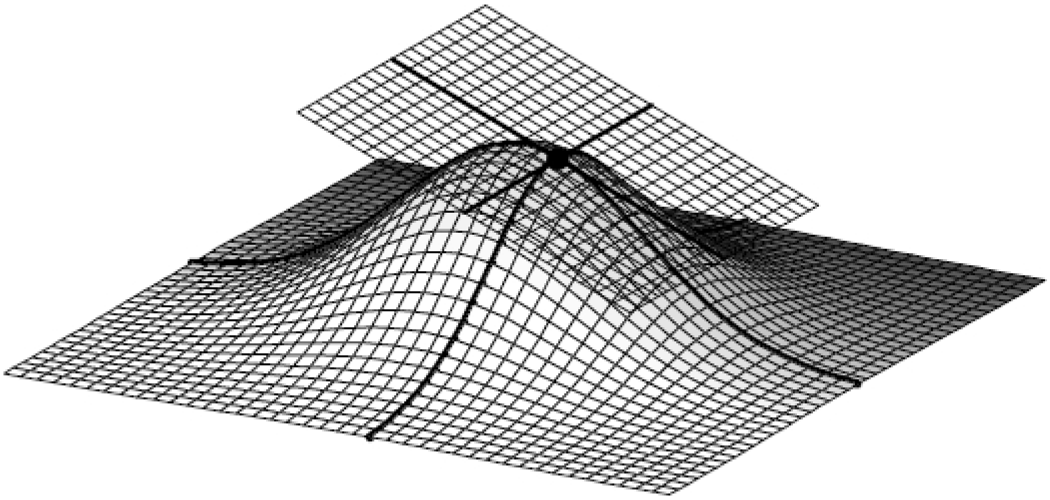

Figure 6.36: **The two tangents of the function at the point of interest with the tangent plane**

Remark

Similarly, for a function of more than two variables, for example $f(x,y,z)$, the total derivative $\mathrm{d}f$ is given by:

$$\mathrm{d}f=\left(\frac{\partial f}{\partial x}\right)_{y,z}\mathrm{d}x+\left(\frac{\partial f}{\partial y}\right)_{x,z}\mathrm{d}y+\left(\frac{\partial f}{\partial z}\right)_{x,y}\mathrm{d}z=\frac{\partial f}{\partial x}\mathrm{d}x+\frac{\partial f}{\partial y}\mathrm{d}y+\frac{\partial f}{\partial z}\mathrm{d}z \tag{6.3.68}$$

In the above equation, the differential $\mathrm{d}f$ was calculated from the expression of the function f. Since there is a function f satisfying an expression $\mathrm{d}f$, the differential $\mathrm{d}f$ is then, as we know, named the "total exact derivative".

We take the opportunity to make an important indication on the use of partial derivatives by physicists (and therefore in many chapter of this textbook). We have seen that if f depends on two variables x,y we have:

$$\mathrm{d}f=\dfrac{\partial f}{\partial x}\mathrm{d}x+\dfrac{\partial f}{\partial y}\mathrm{d}y \tag{6.3.69}$$

and if it depends of only one variable we have then:

$$\mathrm{d}f=\dfrac{\partial f}{\partial x}\mathrm{d}x \tag{6.3.70}$$

And therefore in the univariate case:

$$\dfrac{\mathrm{d}f}{\mathrm{d}x}=\dfrac{\partial f}{\partial x} \tag{6.3.71}$$

this is why many physicists mixed the two notations...

Now you have to know however that there are also total exact derivative that no functions satisfies. In this case, we speak about "total inexact derivative" and for determining whether a total derivative is exact or inexact, we use the properties of partial derivatives (very important case in thermodynamics!!!).

Given the famous general differential form (notation used typically in differential geometry):

$$\mathrm{d}z=M(x,y)\mathrm{d}x+N(x,y)\mathrm{d}y \tag{6.3.72}$$

where $M(x,y)$ and $N(x,y)$ are functions of the variables x and y. If $\mathrm{d}z$ is an exact total differential, then:

$$\mathrm{d}z=\dfrac{\partial z}{\partial x}\mathrm{d}x+\dfrac{\partial z}{\partial y}\mathrm{d}y \tag{6.3.73}$$

this requires verbatim that:

$$M(x,y)=\dfrac{\partial z}{\partial x}\qquad N(x,y)=\dfrac{\partial z}{\partial y} \tag{6.3.74}$$

or, by performing a second partial derivative that:

$$\dfrac{\partial}{\partial y}\dfrac{\partial z}{\partial x}=\dfrac{\partial^2 z}{\partial x\partial y}=\dfrac{\partial}{\partial y}M(x,y)=\dfrac{\partial M}{\partial y}\qquad \dfrac{\partial}{\partial x}\dfrac{\partial z}{\partial y}=\dfrac{\partial^2 z}{\partial x\partial y}=\dfrac{\partial}{\partial x}N(x,y)=\dfrac{\partial N}{\partial x} \tag{6.3.75}$$

so that the differential form is an exact total derivative.

Before continuing, we need a result given by the "Schwarz's theorem" (but which was proved in the late 117th century by one of the Bernoulli brothers) which is the following:

Theorem 6.10. Given a function f, if:

$$f,\dfrac{\partial f}{\partial x},\dfrac{\partial f}{\partial y},\dfrac{\partial^2 f}{\partial x\partial y},\dfrac{\partial^2 f}{\partial y\partial x} \tag{6.3.76}$$

are continuous (we must really check that this assumption is true!) then we get a very important result in practice:

$$\dfrac{\partial^2 f}{\partial x\partial y}(x_0,y_0)=\dfrac{\partial^2 f}{\partial y\partial x}(x_0,y_0) \tag{6.3.77}$$

for every $(x_0,y_0)\in U$ where U is the domain of definition where f is continuous (and therefore assumed to be differentiable).

Proof 6.10.1. We consider the expression:

$$H=f(x_0+k,y_0+h)-f(x_0+k,y_0)-f(x_0,y_0+h)+f(x_0,y_0) \tag{6.3.78}$$

Let us write:

$$\begin{aligned}g(x)&:=f(x,y_0+h)-f(x,y_0)\\ w(x)&:=f(x_0+k,y)-f(x_0,y)\end{aligned} \tag{6.3.79}$$

Then we have:

$$H=g(x_0+k)-g(x_0)=w(y_0+h)-w(y_0) \tag{6.3.80}$$

By the mean value theorem:

$$\begin{aligned}H&=g(x_0+k)-g(x_0)=kg'(x_0+sk)\\ H&=w(y_0+h)-w(y_0)=hw'(y_0+th)\end{aligned} \tag{6.3.81}$$

With $s,t\in]0,1[$. By taking the definitions of w and g we get:

$$\begin{aligned}H&=kg'(x_0+sk)=k\left(\frac{\partial f}{\partial x}(x_0+sk,y_0+h)-\frac{\partial f}{\partial x}(x_0+sk,y_0)\right)\\ H&=hw'(y_0+th)=h\left(\frac{\partial f}{\partial y}(x_0+k,y_0+th)-\frac{\partial f}{\partial y}(x_0,y_0+th)\right)\end{aligned} \tag{6.3.82}$$

by applying the again the mean value theorem to both sides in brackets we find:

$$\begin{aligned}H&=kh\frac{\partial^2 f}{\partial y\partial x}(x_0+sk,y_0+\tilde{s}h)\\ H&=hk\frac{\partial^2 f}{\partial x\partial y}(x_0+\tilde{t}k,y_0+th)\end{aligned} \tag{6.3.83}$$

With $\tilde{s},\tilde{t}\in]0,1[$. To finish we see that we have:

$$\frac{\partial^2 f}{\partial y\partial x}(x_0+sk,y_0+\tilde{s}h)=\frac{\partial^2 f}{\partial x\partial y}(x_0+\tilde{t}k,y_0+th) \tag{6.3.84}$$

and by continuity when $k,h\rightarrow 0$, we have:

$$\frac{\partial^2 f}{\partial y\partial x}(x_0,y_0)=\frac{\partial^2 f}{\partial x\partial y}(x_0,y_0) \tag{6.3.85}$$

More simply written:

$$\boxed{\frac{\partial^2 f}{\partial y\partial x}=\frac{\partial^2 f}{\partial x\partial y}} \tag{6.3.86}$$

So if f is expressed in a total derivative form therefore the cross differentials are equal (the reciprocal is not necessarily true!).

■ Q.E.D.

By induction on the number of variables we can prove in the general case (that is long but it is possible we will do it if it needs to be done and we have the time...).

So finally getting back to our original problem, we have:

$$\frac{\partial^2 z}{\partial x \partial y}=\frac{\partial^2 z}{\partial y \partial x} \tag{6.3.87}$$

Which finally gives us the "Schwarz condition":

$$\frac{\partial M}{\partial y}=\frac{\partial N}{\partial x} \tag{6.3.88}$$

This is the condition that must be met for a differential form to be an exact total differential and the condition that it should not meet to be a non-total exact differential!!! This is a very important property for the study of Thermodynamics (see corresponding section)!

In order not to confuse the two types of differentials, we use the symbol δ to represent a non-total exact differential:

$$\delta z=M\mathrm{d}x+N\mathrm{d}y \tag{6.3.89}$$

and d for a total exact differential:

$$\mathrm{d}z=M\mathrm{d}x+N\mathrm{d}y \tag{6.3.90}$$

The distinction is extremely important because only the total exact differentials that satisfy:

$$\frac{\partial M}{\partial y}=\frac{\partial N}{\partial x} \tag{6.3.91}$$

have an integral that depends only on the limits of integration (since all the variables change at the same time). Therefore non-total exact differentials depend only on the limits of integration, meaning that:

$$\int\limits_{z_1}^{z_2} \delta z \neq z_2-z_1 \tag{6.3.92}$$

and therefore on a closed path we can have:

$$\oint_\gamma \delta z \neq 0 \tag{6.3.93}$$

While for total exact differentials:

$$\int\limits_{z_1}^{z_2} \mathrm{d}z=\Delta z \tag{6.3.94}$$

and therefore (see detailed proof later when we will deal with curvilinear integrals):

$$\oint_\gamma \mathrm{d}z=0 \tag{6.3.95}$$

In other words, the variation of a function whose differential is total exact, does not depend on the path followed, but only of the initial and final states as it can be expressed as the gradient of a function (see the proof by example in the section of Electrostatics when we check that the electrostatic potential difference is independent of the path). We name such a function that satisfies an exact total differential in physics a "state function" and in mathematics a "holomorphic function" (see section Complex Analysis page 2399), that is, i.e. a function whose value depends only on the present and future state, not its history.

This distinction is very important and especially in thermodynamics where it should be determined whether a physical quantity is a total exact differential (a "state function"!) or not to know how systems evolve.

✍**Example:**

An important example of differential form in thermodynamics, is the elementary work δW of a force exerted on a body in motion in the plane Oxy, we have:

$$\delta W = \vec{F} \circ \mathrm{d}\vec{r} = F_x \mathrm{d}x + F_y \mathrm{d}y \tag{6.3.96}$$

The forces F_x, F_y are not necessarily derived from the same potential $U(x,y)$ such that:

$$\frac{\partial U}{\partial x} = \frac{\partial U}{\partial y} \tag{6.3.97}$$

therefore δW is indeed in this special case a non-total exact differential!

Finally something maybe important to keep in mind?!:

- Suppose $y = f(x,w)$, while in turn $x = g(t)$ and $w = h(t)$. How does y change when t changes?

  $$\frac{\mathrm{d}y}{\mathrm{d}t} = \frac{\partial y}{\partial x}\frac{\mathrm{d}x}{\mathrm{d}t} + \frac{\partial y}{\partial \omega}\frac{\mathrm{d}\omega}{\mathrm{d}t} \tag{6.3.98}$$

  Notice that if we assume $y = f(x, w(x))$ (a direct dependency!) but with x having no implicit dependencies, the above relation becomes:

  $$\frac{\mathrm{d}y}{\mathrm{d}x} = \frac{\partial y}{\partial x}\frac{\partial x}{\partial x} + \frac{\partial y}{\partial \omega}\frac{\partial \omega}{\partial x} \tag{6.3.99}$$

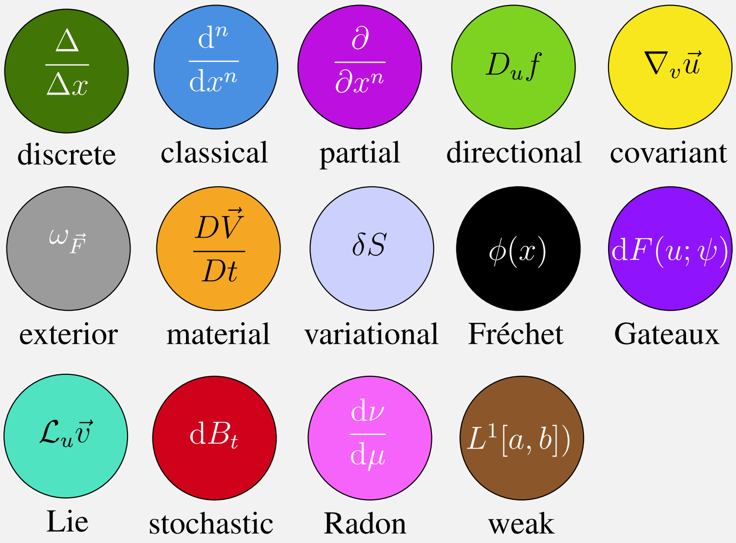
- Suppose $y = f(x,w)$, while in turn $x = g(t,s)$ and $w = h(t,s)$. How does y change when t changes?

  $$\begin{aligned}\frac{\partial y}{\partial t} &= \frac{\partial y}{\partial x}\frac{\partial x}{\partial t} + \frac{\partial y}{\partial \omega}\frac{\partial \omega}{\partial t}\\ \frac{\partial y}{\partial s} &= \frac{\partial y}{\partial x}\frac{\partial x}{\partial x} + \frac{\partial y}{\partial \omega}\frac{\partial \omega}{\partial s}\end{aligned} \tag{6.3.100}$$

Notice that the first bullet point is the "total derivative" when the second bullet point is the "partial total derivative".

Remark

For information there are plenty of different types of derivatives in mathematics:



$\frac{\Delta}{\Delta x}$
discrete
$\frac{\mathrm{d}^n}{\mathrm{d}x^n}$
classical
$\frac{\partial}{\partial x^n}$
partial
$D_u f$
directional
$\nabla_v \vec{u}$
covariant
$\omega_{\vec{F}}$
exterior
$\frac{D\vec{V}}{Dt}$
material
δS
variational
$\phi(x)$
Fréchet
$\mathrm{d}F(u;\psi)$
Gateaux
$\mathcal{L}_u \vec{v}$
Lie
$\mathrm{d}B_t$
stochastic
$\frac{\mathrm{d}\nu}{\mathrm{d}\mu}$
Radon
$L^1[a,b])$
weak

Figure 6.37: Most common types of derivatives in mathematics

in this textbook we will use and introduce only a few of them for practical purposes like the discrete, classical, the partial, covariant, stochastic, material and variational derivatives.

6.3.1.1.1 Implicit functions

It frequently happens, particularly in Thermodynamics, that certain variables, let's call them x, y, and z, are not independent, but linked by a relation of the form $g(x,y,z)=0$. In this case, each variable is implicitly defined in terms of the other two, and we can write:

$$x=x(y,z)\quad y=y(x,z)\quad \text{and}\quad z=z(x,y) \tag{6.3.101}$$

Even if we cannot explicitly define these functions, it is possible to relate their partial derivatives. Indeed, let us consider the function $x=x(y,z)$ and write its total differential:

$$\mathrm{d}x=\left.\frac{\partial x}{\partial y}\right|_z \mathrm{d}y+\left.\frac{\partial x}{\partial z}\right|_y \mathrm{d}z \tag{6.3.102}$$

For example, we can deduce from this $\mathrm{d}y$:

$$\mathrm{d}y=\frac{1}{(\partial x/\partial y)_z}\mathrm{d}x-\frac{(\partial x/\partial z)_y}{(\partial x/\partial y)_z}\mathrm{d}z \tag{6.3.103}$$

Let's identify this relationship with the expression for the total differential of $y(x,z)$:

$$\mathrm{d}y=\left.\frac{\partial y}{\partial x}\right|_z \mathrm{d}x+\left.\frac{\partial y}{\partial z}\right|_x \mathrm{d}z \tag{6.3.104}$$

We deduce from this:

$$\left.\frac{\partial y}{\partial x}\right|_z=\frac{1}{\left.\frac{\partial x}{\partial y}\right|_z} \tag{6.3.105}$$

and:

$$\left.\frac{\partial y}{\partial z}\right|_x = -\frac{(\partial x/\partial z)_y}{(\partial x/\partial y)_z} \qquad (6.3.106)$$

therefore:

$$\left.\frac{\partial x}{\partial y}\right|_z \cdot \left.\frac{\partial y}{\partial z}\right|_x \cdot \left.\frac{\partial z}{\partial x}\right|_y = -1 \qquad (6.3.107)$$

named "triangular relation". Note in passing that the fact that this product equals -1 and not $+1$ shows that a partial derivative cannot be treated as a fraction!

✍**Example:**

As we will prove it in the Thermodynamics section, the equation of state of a van der Waals gas is given by:

$$\left(p+\frac{a}{V^2}\right)(V-b) = RT \qquad (6.3.108)$$

where a, b, and R are three positive constants. We wish to calculate the isobaric thermal expansion coefficient of this gas, defined by:

$$\alpha \overset{\text{def}}{=} \left.\frac{1}{V}\frac{\partial V}{\partial T}\right|_p \qquad (6.3.109)$$

The first instinct is to look for the expression $V(T,p)$. However, a quick examination of the equation reveals tedious calculations since V is obtained by solving a cubic equation. It is therefore much more efficient to use the triangular relationship:

$$\left.\frac{\partial V}{\partial T}\right|_p \cdot \left.\frac{\partial T}{\partial p}\right|_V \cdot \left.\frac{\partial p}{\partial V}\right|_T = -1 \qquad (6.3.110)$$

Indeed, the derivatives $\partial T/\left.\partial p\right|_V$ and $\partial p/\left.\partial V\right|_T$ are easily calculated:

$$T = \frac{p(V-b)}{R} + \frac{a(V-b)}{RV^2} \qquad (6.3.111)$$

hence:

$$\left.\frac{\partial T}{\partial p}\right|_V = \frac{V-b}{R} \qquad (6.3.112)$$

and:

$$p = \frac{RT}{V-b} - \frac{a}{V^2} \qquad (6.3.113)$$

so therefore:

$$\left.\frac{\partial p}{\partial V}\right|_T = -\frac{RT}{(V-b)^2} + \frac{2a}{V^3} \qquad (6.3.114)$$

Thus, the triangular relationship allows us to get:

$$\left.\frac{\partial V}{\partial T}\right|_p=\frac{\left.\frac{\partial T}{\partial p}\right|_V}{\left.\frac{\partial p}{\partial V}\right|_T}=\frac{(V-b)V^3}{TV^3-\frac{2a}{R}(V-b)^2} \tag{6.3.115}$$

which gives:

$$\alpha=\frac{(V-b)V^2}{TV^3-\frac{2a}{R}(V-b)^2} \tag{6.3.116}$$

6.3.1.2 Usual Derivatives

We will prove in details here the most common univariate derivatives (around a small thirty) and some of their major properties that we will meet in theoretical physics and mathematics (in fact, we will used them all in respectively the chapters on Mechanics, Engineering, Atomistic, Social Mathematics, etc.). The list below is not exhaustive at this time but the proofs being generalized, they can be applied to many other similar cases (that we will apply / meet throughout almost all this textbook).

1. Derivative of $f(x)=x^n$:

   First start with a particular case, the derivative of x^3:

$$\lim_{h\to 0}\frac{(a+h)^3-a^3}{h}=\lim_{h\to 0}\frac{a^3+3a^2h+3ah^2+h^3-a^3}{h}=\lim_{h\to 0}3a^2+3ah+h^2=3a^2 \tag{6.3.117}$$

   Therefore the derivative of the cubic function is $3a^2$.

   We can generalize this result for any positive or negative integer n and we will see that the function f defined on $\mathbb{R}$ by $f(x)=x^n$ is differentiable and that its derivative f' is given by $f'(x)=nx^{n-1}$.

$$\begin{aligned}\lim_{h\to 0}\frac{(a+h)^n-a^n}{h}&=\lim_{h\to 0}\frac{\sum\limits_{k=0}^{n}C_n^ka^kh^{n-k}-a^n}{h}=\lim_{h\to 0}\frac{\sum\limits_{k=0}^{n-1}C_n^ka^kh^{n-k}+a^n-a^n}{h}\\&=\lim_{h\to 0}\frac{\sum\limits_{k=0}^{n-1}C_n^ka^kh^{n-k}}{h}=\lim_{h\to 0}\sum_{k=0}^{n-1}C_n^ka^kh^{n-k-1}\\&=\lim_{h\to 0}\sum_{k=0}^{n-2}\left(C_n^ka^kh^{n-k-1}+C_n^{n-1}a^{n-1}\right)=C_n^{n-1}a^{n-1}=\frac{n!}{(n-1)!}a^{n-1}\\&=na^{n-1}\end{aligned} \tag{6.3.118}$$

Therefore we have (a few examples can be helpful to understand the scope of this result!):

$$\begin{aligned}
&f(x)=x^2\Rightarrow f'(x)=2x^1=2x\\
&f(x)=x^{-1}\Rightarrow f'(x)=-x^{-2}\\
&f(x)=\sqrt{x}\Rightarrow f'(x)=-\frac{1}{2}x^{-\frac{1}{2}}
\end{aligned}\tag{6.3.119}$$

So we see that having determined the derivative of a function of the form x^n, we also determined the derivative of any function that is written in such a form:

$$f(x)=\frac{1}{x^n}=x^{-n}\quad\text{and}\quad f(x)=\sqrt[n]{x}=x^{1/n}\tag{6.3.120}$$

However, the following functions:

$$f(x)=\frac{1}{x^n}\quad\text{and}\quad f(x)=\sqrt[n]{x}\tag{6.3.121}$$

are not differentiable in the $x=0$ because the function is not more defined on this point (division by zero). Furthermore, relatively to the root function (not integer power), the derivative is not defined in $\mathbb{R}_-^*$.

Remark

It is immediate from the results above that if $f(x)=x^n$ for n being a positive integer then $f^{(k)}(x)=x^{n-k}\,n!/(n-k)!$ for $k\leq n$.

2. Derivative of $f(x)=c^{te}$:

The previous result gives an interesting immediate result for constant functions such as:

$$f(x)=c^{te}=c^{te}x^0\tag{6.3.122}$$

it is then not difficult to determine that the derivative is simply:

$$f'(x)=c^{te}0x^{0-1}=0\tag{6.3.123}$$

So the derivative of any constant function is zero (it is important to remember that result when we will study the properties of integrals) !!!

3. Derivative of $f(x)=\cos(x)$:

Given any real fixed number a, then (be careful it is useful to know the remarkable trigonometric relations that we proved in the section Trigonometry!):

$$\begin{aligned}
f'(x)&=\lim_{h\to 0}\frac{\cos(a+h)-\cos(a)}{h}=\lim_{h\to 0}\frac{-2\sin\left(\dfrac{a+h+a}{2}\right)\sin\left(\dfrac{a+h-a}{2}\right)}{h}\\
&=\lim_{h\to 0}\frac{-2\sin\left(\dfrac{2a+h}{2}\right)\sin\left(\dfrac{h}{2}\right)}{h}=\lim_{h\to 0}\left(-2\sin\left(\frac{2a+h}{2}\right)\right)\frac{1}{2}\lim_{h\to 0}\left(\frac{\sin\left(\dfrac{h}{2}\right)}{\dfrac{h}{2}}\right)\\
&=-2a\sin(a)\frac{1}{2}=-\sin(a)
\end{aligned}\tag{6.3.124}$$

Because using l'Hôpital's rule (or by seeing that $\sin(x)$ can be assimilate by a straight line function $f(x)=x$ near $x=0$):

$$\lim_{h\to 0}\frac{\sin(x)}{x}=1 \tag{6.3.125}$$

So to summarize:

$$f(x)=\cos(x)\Rightarrow f'(x)=-\sin(x) \tag{6.3.126}$$

4. Derivative of $f(x)=\sin(x)$:

   Given any real fixed number a, then (be careful again it is useful to know the remarkable trigonometric relations that we proved in the section Trigonometry!):

$$\begin{aligned} f'(x)&=\lim_{h\to 0}\frac{\sin(a+h)-\sin(a)}{h}=\lim_{h\to 0}\frac{2\cos\left(\dfrac{a+h+a}{2}\right)\sin\left(\dfrac{a+h-a}{2}\right)}{h}\\ &=\lim_{h\to 0}\frac{2\cos\left(\dfrac{2a+h}{2}\right)\sin\left(\dfrac{h}{2}\right)}{h}=\lim_{h\to 0}\left(2\cos\left(\frac{2a+h}{2}\right)\right)\frac{1}{2}\lim_{h\to 0}\left(\frac{\sin\left(\dfrac{h}{2}\right)}{\dfrac{h}{2}}\right)\\ &=2a\cos(a)\frac{1}{2}=\cos(a) \end{aligned} \tag{6.3.127}$$

   Because using l'Hôpital's rule (or by seeing that $\sin(x)$ can be assimilate by a straight line function $f(x)=x$ near $x=0$):

$$\lim_{h\to 0}\frac{\sin(x)}{x}=1 \tag{6.3.128}$$

   So to summarize:

$$f(x)=\sin(x)\Rightarrow f'(x)=\cos(x) \tag{6.3.129}$$

5. Derivative of $f(x)=\log_b(x)$:

   We begin by writing that:

$$y+\Delta y=\log_b(x+\Delta x) \tag{6.3.130}$$

   Therefore:

$$\Delta y=\log_b(x+\Delta x)-y=\log_b(x+\Delta x)-\log_b(x)=\log_b\left(\frac{x+\Delta x}{x}\right)=\log_b\left(1+\frac{\Delta x}{x}\right) \tag{6.3.131}$$

   Therefore:

$$\frac{\Delta y}{\Delta x}=\frac{1}{\Delta x}\log_b\left(1+\frac{\Delta x}{x}\right) \tag{6.3.132}$$

Multiply and divide by x the term in the right member of the last previous equality:

$$\frac{\Delta y}{\Delta x}=\frac{1}{x}\frac{x}{\Delta x}\log_b\left(1+\frac{\Delta x}{x}\right)=\frac{1}{x}\log_b\left(\left(1+\frac{\Delta x}{x}\right)^{\frac{x}{\Delta x}}\right) \tag{6.3.133}$$

Denote the quantity $\dfrac{\Delta x}{x}$ by α. It is obvious that $\alpha\rightarrow 0$ when Δx tends to zero for a given x. Consequently:

$$\frac{\Delta y}{\Delta x}=\frac{1}{x}\log_b\left((1+\alpha)^{\frac{1}{\alpha}}\right) \tag{6.3.134}$$

However, we find here again an another historical origin from Euler's constant (see the section Functional Analysis page 2289 for the proof), that is:

$$\lim_{\alpha\rightarrow 0}(1+\alpha)^{\frac{1}{\alpha}}=e \tag{6.3.135}$$

Therefore:

$$f'(x)=\lim_{\alpha\rightarrow 0}\frac{\Delta y}{\Delta x}=\lim_{\alpha\rightarrow 0}\frac{1}{x}\log_b\left((1+\alpha)^{\frac{1}{\alpha}}\right)=\frac{1}{x}\log_b(e) \tag{6.3.136}$$

An important special case is the case where $b=e$. Then we have the famous result:

$$y=\ln(x)\Rightarrow y'=\frac{1}{x} \tag{6.3.137}$$

6. Derivative of a sum of functions:

   Let us now consider u and v two functions. The sum function $s=u+v$ is derivable over any interval where u and v are differentiable, we will denote by s' the derivative of the sum. Let us now see what is its expression.

   Let a be a real number and u,v two defined and differentiable functions on a:

$$\begin{aligned}s'&=\lim_{h\rightarrow 0}\frac{(u+v)(a+h)-(u+v)(a)}{h}=\lim_{h\rightarrow 0}\frac{u(a+h)+v(a+h)-u(a)-v(a)}{h}\\&=\lim_{h\rightarrow 0}\frac{u(a+h)-u(a)+v(a+h)-v(a)}{h}=\lim_{h\rightarrow 0}\frac{u(a+h)-u(a)}{h}+\lim_{h\rightarrow 0}\frac{v(a+h)-v(a)}{h}\\&=u'(a)+v'(a)\end{aligned} \tag{6.3.138}$$

   So the derivative of a sum is the sum of the derivatives.

   This result can be generalized for a sum of any number of functions.

7. Derivative of a product of functions (named the "product rule"):

   Let us now consider u and v two functions. The product function $p=uv$ is derivable over any interval where u and v are differentiable, we will denote by p' the derivative of the product. Let us now see what is its expression.

   Let a be a real number and u,v two defined and differentiable functions on a:

$$\lim_{h\to 0}\frac{(uv)(a+h)-(uv)(a)}{h}=\lim_{h\to 0}\frac{u(a+h)v(a+h)-u(a)v(a)}{h} \tag{6.3.139}$$

We add to this last relation two terms whose sum is zero such as:

$$\begin{aligned}p' &= \lim_{h\to 0}\frac{u(a+h)v(a+h)-u(a)v(a)}{h}\\ &= \lim_{h\to 0}\frac{u(a+h)v(a+h)-u(a)v(a+h)+u(a)v(a+h)-u(a)v(a)}{h}\\ &= \lim_{h\to 0}\frac{u(a+h)v(a+h)-u(a)v(a+h)}{h}+\lim_{h\to 0}\frac{u(a)v(a+h)-u(a)v(a)}{h}\\ &= \lim_{h\to 0}\frac{u(a+h)-u(a)}{h}v(a+h)+\lim_{h\to 0}\frac{v(a+h)-v(a)}{h}u(a)\\ &= \lim_{h\to 0}\frac{u(a+h)-u(a)}{h}\lim_{h\to 0}v(a+h)+\lim_{h\to 0}\frac{v(a+h)-v(a)}{h}\lim_{h\to 0}u(a)\\ &= u'(a)v(a)+u(a)v'(a)\end{aligned} \tag{6.3.140}$$

Hence the well known result:

$$p=u'v+uv' \tag{6.3.141}$$

But there is a more general formulation than the first derivative of a product:

Theorem 6.11. Consider for this purpose always our two functions u and v, n times differentiable on an interval I. Then the uv product is n times differentiable on I and:

$$\boxed{(uv)^{(n)}=\sum_{k=0}^{n}C_k^n u^{(k)}v^{(n-k)}} \tag{6.3.142}$$

and this constitutes the "Leibniz differentiation rule for products" that we used in the section of Calculus for the study of Legendre polynomials and also Laguerre polynomials (which we are themselves essential to our study of Quantum Chemistry).

The proof of this expression is very similar to that made for the Newton's binomial theorem (see section Calculus page 1364).

Proof 6.11.1. Either:

$$(uv)^{(0)}=uv \tag{6.3.143}$$

On the other hand:

$$(uv)^{(0)}=\sum_{k=0}^{0}C_k^0 u^k v^{(0-k)}=u^{(0)}v^{(0)}=uv \tag{6.3.144}$$

The relation is thus at least well initialized.

The proof is made by induction. Thus, the goal is to show that for $\forall n\geq 0\in\mathbb{N}$ if:

$$(uv)^{(n)}=\sum_{k=0}^{n}C_k^n u^k v^{(n-k)} \tag{6.3.145}$$

then:

$$(uv)^{(n+1)}=\sum_{k=0}^{n+1}C_k^{n+1}u^k v^{(n+1-k)} \tag{6.3.146}$$

We have therefore:

$$\begin{aligned}(uv)^{(n+1)}&=\left((uv)^{(n+1)}\right)'=\sum_{k=0}^{n}C_k^n\left(u^{(k)}v^{(n-k)}\right)'\\&=\sum_{k=0}^{n}C_k^n\left(\left(u^{(k)}\right)'v^{(n-k)}+u^{(k)}\left(v^{(n-k)}\right)'\right)\\&=\sum_{k=0}^{n}C_k^n\left(u^{(k+1)}v^{(n-k)}+u^{(k)}v^{(n-k+1)}\right)\\&=\sum_{k=0}^{n}C_k^n u^{(k+1)}v^{(n-k)}+\sum_{k=0}^{n}C_k^n u^{(k)}v^{(n+1-k)}\end{aligned} \tag{6.3.147}$$

We'll do now a change of variable in the first sum to not have the term in $k+1$ again. We put for this purpose $j=k+1$:

$$\sum_{k=0}^{n}C_k^n u^{(k+1)}v^{(n-k)}=\sum_{j=1}^{n+1}C_{j-1}^n u^{(j)}v^{(n-(j-1))} \tag{6.3.148}$$

If we go back to the letter k, we have:

$$\sum_{k=0}^{n}C_k^n u^{(k+1)}v^{(n-k)}=\sum_{k=1}^{n+1}C_{k-1}^n u^{(k)}v^{(n+1-k)} \tag{6.3.149}$$

So we have:

$$(uv)^{(n+1)}=\sum_{k=1}^{n+1}C_{k-1}^n u^{(k)}v^{(n+1-k)}+\sum_{k=0}^{n}C_k^n u^{(k)}v^{(n+1-k)} \tag{6.3.150}$$

We want to combine this two sums. For this, we discard the terms in excess in each:

$$\begin{aligned}(uv)^{(n+1)}=&C_{n+1-1}^n u^{(n+1)}v^{(n+1-(n+1))}+\sum_{k=1}^{n}C_{k-1}^n u^{(k)}v^{(n+1-k)}\\&+\sum_{k=1}^{n}C_k^n u^{(k)}v^{(n+1-k)}+C_0^n u^{(0)}v^{(n+1-0)}\end{aligned} \tag{6.3.151}$$

This therefore gives:

$$\begin{aligned}(uv)^{(n+1)}&=u^{(n+1)}v^{(0)}+\sum_{k=1}^{n}C_{k-1}^n u^{(k)}v^{(n+1-k)}+\sum_{k=1}^{n}C_k^n u^{(k)}v^{(n+1-k)}+u^{(0)}v^{(n+1)}\\&=u^{(n+1)}v^{(0)}+\sum_{k=1}^{n}(C_{k-1}^n+C_k^n)u^{(k)}v^{(n+1-k)}+u^{(0)}v^{(n+1)}\end{aligned} \tag{6.3.152}$$

According to Pascal's formula (see section Probabilities page 529), we have:

$$C_{k-1}^{n}+C_{k}^{n}=C_{k}^{n+1} \tag{6.3.153}$$

Therefore:

$$(uv)^{(n+1)}=u^{(n+1)}v^{(0)}+\sum_{k=1}^{n}C_{k}^{n+1}u^{(k)}v^{(n+1-k)}+u^{(0)}v^{(n+1)} \tag{6.3.154}$$

But we have at the same time:

$$u^{(n+1)}v^{(0)}=C_{n+1}^{n+1}u^{(n+1)}v^{(n+1-(n+1))} \qquad u^{(0)}v^{(n+1)}=C_{0}^{n+1}u^{(0)}v^{(n+1-0)} \tag{6.3.155}$$

Therefore:

$$\begin{aligned}(uv)^{(n+1)}&=C_{n+1}^{n+1}u^{(n+1)}v^{(n+1-(n+1))}+\sum_{k=1}^{n}C_{k}^{n+1}u^{(k)}v^{(n+1-k)}+C_{0}^{n+1}u^{(0)}v^{(n+1-0)}\\&=\sum_{k=0}^{n+1}C_{k}^{n+1}u^{(k)}v^{(n+1-k)}\end{aligned} \tag{6.3.156}$$

■ Q.E.D.

8. Derivative of a ratio of two differentiable functions (named the "quotient rule"):

   Let $f(x)=g(x)/h(x)$. Applying the definition of the derivative and properties of limits gives the following proof:

$$\begin{aligned}f'(x)&=\lim_{k\to 0}\frac{f(x+k)-f(x)}{k}\\&=\lim_{k\to 0}\frac{\dfrac{g(x+k)}{h(x+k)}-\dfrac{g(x)}{h(x)}}{k}\\&=\lim_{k\to 0}\frac{g(x+k)h(x)-g(x)h(x+k)}{k\cdot h(x)h(x+k)}\\&=\lim_{k\to 0}\frac{g(x+k)h(x)-g(x)h(x+k)}{k}\cdot\lim_{k\to 0}\frac{1}{h(x)h(x+k)}\\&=\left(\lim_{k\to 0}\frac{g(x+k)h(x)-g(x)h(x)+g(x)h(x)-g(x)h(x+k)}{k}\right)\cdot\frac{1}{h(x)^2}\\&=\left(\lim_{k\to 0}\frac{g(x+k)h(x)-g(x)h(x)}{k}-\lim_{k\to 0}\frac{g(x)h(x+k)-g(x)h(x)}{k}\right)\cdot\frac{1}{h(x)^2}\\&=\left(h(x)\lim_{k\to 0}\frac{g(x+k)-g(x)}{k}-g(x)\lim_{k\to 0}\frac{h(x+k)-h(x)}{k}\right)\cdot\frac{1}{h(x)^2}\\&=\frac{g'(x)h(x)-g(x)h'(x)}{h(x)^2}\end{aligned} \tag{6.3.157}$$

   We can also do the proof using implicit differentiation. Indeed, let $f(x)=g(x)/h(x)$, so $g(x)=f(x)h(x)$. The product rule proved just earlier above gives:

$$g'(x)=f'(x)h(x)+f(x)h'(x) \tag{6.3.158}$$

Solving for $f'(x)$ and substituting back for $f(x)$ gives:

$$f'(x)=\frac{g'(x)-f(x)h'(x)}{h(x)}=\frac{g'(x)-\dfrac{g(x)}{h(x)}\cdot h'(x)}{h(x)}=\frac{g'(x)h(x)-g(x)h'(x)}{h(x)^2} \tag{6.3.159}$$

9. Derivative of a composite univariate function:

   Let us consider the composite function $f=g\circ u=g(u(x))$ of two functions g and u differentiable, the first in $u(a)$, the second in a. We have therefore:

$$f'=\lim_{h\to 0}\frac{g\circ u(a+h)-g\circ u(a)}{h}=\lim_{h\to 0}\frac{g(u(a+h))-g(u(a))}{h} \tag{6.3.160}$$

   Let us put now $k=u(a+h)-u(a)$ then we have:

$$\lim_{h\to 0} k=0 \tag{6.3.161}$$

   Let us continue our previous development:

$$\begin{aligned}f'&=\lim_{h\to 0}\frac{g(u(a+h))-g(u(a))}{h}=\lim_{h\to 0}\frac{g(k+u(a)))-g(u(a))}{h}\\&=\lim_{h\to 0}\frac{g(u(a)+k)-g(u(a))}{k}\frac{k}{h}=\lim_{h\to 0}\frac{g(u(a)+k)-g(u(a))}{k}\lim_{h\to 0}\frac{k}{h}\\&=\lim_{h\to 0}\frac{g(u(a)+k)-g(u(a))}{k}\lim_{h\to 0}\frac{u(a+h)-u(a)}{h}=\frac{\mathrm{d}g}{\mathrm{d}u}\frac{\mathrm{d}u}{\mathrm{d}x}\\&=g'(u(a))u'(a)\end{aligned} \tag{6.3.162}$$

   Thus the derivative of a composite function is given by the derivative of the function, multiplied by the "inner derivative". Furthermore, this type of derivation is very important because often used in physics under the name of "(univariate) chain derivation" or simply "(univariate) chain rule".

   Let's see what it is. The previous obtained relation can be rewritten in another more common way:

$$y=f(g(x))\Rightarrow y'=f'g'=\frac{\mathrm{d}f}{\mathrm{d}g}\frac{\mathrm{d}g}{\mathrm{d}x} \tag{6.3.163}$$

   Or typically when we have multiple functions that multiplies each other:

$$y=f(g(x))h(j(x))\Rightarrow y'=\frac{\mathrm{d}f}{\mathrm{d}g}\frac{\mathrm{d}g}{\mathrm{d}x}+\frac{\mathrm{d}h}{\mathrm{d}j}\frac{\mathrm{d}j}{\mathrm{d}x} \tag{6.3.164}$$

   We then speak of "power chain rule".

10. Derivative of a composite bivariate function:

   Theorem 6.12. The t derivative of the composite function $z=f(x(t),y(t))$ is:

$$\frac{\mathrm{d}}{\mathrm{d}t}[f(x(t),y(t))]=\frac{\partial f(x(t),y(t))}{\partial x}\frac{\mathrm{d}x(t)}{\mathrm{d}t}+\frac{\partial f(x(t),y(t))}{\partial y}\frac{\mathrm{d}y(t)}{\mathrm{d}t} \tag{6.3.165}$$

   We assume in this theorem and its applications that $x=x(t)$ and $y=y(t)$ have first derivatives at t and that $z=f(x,y)$ has continuous first order derivatives in an open circle centered at $(x(t),y(t))$.

Proof 6.12.1. We fix t and set $(x,y)=(x(t),y(t))$. We consider non-zero Δt so small that $(x(t+\Delta t),y(t+\Delta t))$ is in the circle where f has continuous first derivatives and set $\Delta x=x(t+\Delta t)-x(t)$ and $\Delta y=y(t+\Delta t)-y(t)$. Then by definition of the derivative:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}[f(x(t),y(t))]&=\lim_{\Delta t\to 0}\frac{f(x(t+\Delta t),y(t+\Delta t))-f(x(t),y(t))}{\Delta t}\\&=\lim_{\Delta t\to 0}\frac{f(x+\Delta x,y+\Delta y)-f(x,y)}{\Delta t}\\&=\lim_{\Delta t\to 0}\frac{[f(x+\Delta x),y)-f(x,y)]+[f(x+\Delta x,y+\Delta y)-f(x+\Delta x,y)]}{\Delta t}\end{aligned}\tag{6.3.166}$$

We can apply the "mean value theorem" that states (see the proof further below during our study of integral calculus):

$$f(b)-f(a)=f'(c)(b-a)\tag{6.3.167}$$

to the expression in the first set of square brackets on the right of the last equality above where y is constant and to the expression in the second set of square brackets where x is constant. We conclude that there is a number c_1 between x and $x+\Delta x$ and a number c_2 between y and $y+\Delta y$ such that:

$$\begin{aligned}f(x+\Delta x,y)-f(x,y)&=\frac{\partial f(x,y)}{\partial x}(c_1,y)\Delta x\\f(x+\Delta x,y+\Delta y)-f(x+\Delta x,y)&=\frac{\partial f(x,y)}{\partial x}(x+\Delta x,c_2)\Delta y\end{aligned}\tag{6.3.168}$$

We add the both relations above and divide by Δt to get:

$$\frac{f(x+\Delta x,y+\Delta y)-f(x,y)}{\Delta t}=\frac{\partial f(x,y)}{\partial x}(c_1,y)\frac{\Delta x}{\Delta t}+\frac{\partial f(x,y)}{\partial x}(x+\Delta x,c_2)\frac{\Delta y}{\Delta t}\tag{6.3.169}$$

The functions $x=x(t)$ and $y=y(t)$ are continuous at t because they have derivatives at that point. Consequently, as $\Delta t\to 0$, the numbers Δx and Δy both tend to zero and the circle including the constants c_i collapses to the point (x,y), Because the partial derivatives of f are continuous, the term $\partial_x f(c_1,y+\Delta y)$ tends to $\partial_x f(x,y)$ and the term $\partial_y f(x,c_2)$ tends to $\partial_y f(x,y)$ as $\Delta t\to 0$. Moreover:

$$\frac{\Delta x}{\Delta t}\to x'(t)\qquad\frac{\Delta y}{\Delta t}\to y'(t)\tag{6.3.170}$$

as $\Delta t\to 0$, so the above relation becomes:

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}t}[f(x(t),y(t))]=\frac{\partial f(x(t),y(t))}{\partial x}\frac{\mathrm{d}x(t)}{\mathrm{d}t}+\frac{\partial f(x(t),y(t))}{\partial y}\frac{\mathrm{d}y(t)}{\mathrm{d}t}}\tag{6.3.171}$$

named the "multivariate chain rule" (but in reality it is only the bivariate case...) and that is veeeeery important for study physics.

The latter relation is sometimes written:

$$\frac{\mathrm{d}}{\mathrm{d}t}[f(x(t),y(t))]=\partial_x f(x(t),y(t))\frac{\mathrm{d}x(t)}{\mathrm{d}t}+\partial_y f(x(t),y(t))\frac{\mathrm{d}y(t)}{\mathrm{d}t}\tag{6.3.172}$$

■ Q.E.D.

11. Derivative of an inverse function:

    Theorem 6.13. If the function f is continuous, strictly monotonic over an interval I, derivable over I, then the reciprocal function f^{-1} is derivable on the interval $f(I)$ and admits for derivative function:

    $$\forall y \in f(I) \qquad (f^{-1})'(y) = \frac{1}{f(f^{-1}(y))'} \tag{6.3.173}$$

    Proof 6.13.1. Indeed we can write:

    $$x \overset{f}{\mapsto} y = f(x) \overset{f^{-1}}{\longmapsto} x = f^{-1}(y) \tag{6.3.174}$$

    That is to say (identity application):

    $$x = f^{-1}(y) = f^{-1}(f(x)) = f^{-1} \circ f(x) \tag{6.3.175}$$

    By application of the derivation of composite functions seen just above we have:

    $$(f^{-1}(f(x)))' = (f^{-1}(y))' f'(x) = (x)' = 1 \tag{6.3.176}$$

    Therefore:

    $$(f^{-1}(y))' = \frac{1}{f'(x)} = \frac{1}{f'(f^{-1}(y))} \tag{6.3.177}$$

    For a variable x, it is more common to write for the derivative of the inverse function as following:

    $$(f^{-1}(x))' = \frac{1}{f'(y)} \tag{6.3.178}$$

■ Q.E.D.

12. Derivative of $|x|$:

    By definition:

    $$\frac{\mathrm{d}}{\mathrm{d}x}|x| = \frac{\mathrm{d}}{\mathrm{d}x}\sqrt{x^2} = \frac{\mathrm{d}}{\mathrm{d}x}\left(x^2\right)^{\frac{1}{2}} \tag{6.3.179}$$

    By applying the chain rule for derivatives, we get:

    $$\frac{\mathrm{d}}{\mathrm{d}x}|x| = \frac{1}{2}\left(x^2\right)^{-\frac{1}{2}} \cdot 2x = \frac{x}{\sqrt{x^2}} \tag{6.3.180}$$

    Therefore:

    $$\frac{\mathrm{d}}{\mathrm{d}x}|x| = \frac{x}{|x|} \tag{6.3.181}$$

    Or in another way (from the definition of derivative):

    $$\begin{aligned}\left.\frac{\mathrm{d}|x|}{\mathrm{d}x}\right|_{x=0} &= \lim_{x\to 0}\frac{|x|-0}{x-0}\\ &= \begin{cases}\lim_{x\to 0^+}\frac{x}{x} & : x > 0\\ \lim_{x\to 0^-}\frac{-x}{x} & : x < 0\end{cases} \qquad \text{Definition of Absolute Value}\\ &= \begin{cases}1 & : x > 0\\ -1 & : x < 0\end{cases}\end{aligned}$$

13. Derivative of $\arccos(x)$:

    Using the previous result of the reciprocal function and the derivative of $\cos(x)$ proved above, we can calculate the derivative of the function $\arccos(x)$:

$$(f^{-1}(x))'=(\arccos(x))=\frac{1}{f'(y)}=\frac{1}{-\sin(y)}=\frac{-1}{\sin(y)}=\frac{1}{\sqrt{1-\cos^2(y)}}=\frac{-1}{\sqrt{1-x^2}} \tag{6.3.182}$$

14. Derivative of $\arcsin(x)$:

    Using the previous result of the reciprocal function and the derivative of $\sin(x)$ proved above, we can calculate the derivative of the function $\arcsin(x)$:

$$(f^{-1}(x))'=(\arcsin(x))=\frac{1}{f'(y)}=\frac{1}{\cos(y)}=\frac{1}{\sqrt{1-\sin^2(y)}}=\frac{1}{\sqrt{1-x^2}} \tag{6.3.183}$$

15. Derivative from a quotient of two functions:

    Consider that function:

$$f=\frac{u}{v} \tag{6.3.184}$$

is derivable over any interval where u and v are differentiable functions and wherein the function v is not null.

The function f can be considered as the product of two functions: the function u and the function $1/v$. A product of two functions is differentiable if each is differentiable, it is necessary that the function u is differentiable and the function $1/v$ is also derivable which is the case when v is differentiable and not null.

$$\left(\frac{u}{v}\right)'=\left(u\frac{1}{v}\right)'=u'\frac{1}{v}+u\left(\frac{-v'}{v^2}\right)=\frac{u'v-uv'}{v^2} \tag{6.3.185}$$

16. Derivative of the function $\tan(x)$:

    By definition (see section Trigonometry page 2508), $\forall x\neq k\dfrac{\pi}{2}, k\in\mathbb{Z}$:

$$f(x)=\tan(x)=\frac{\sin(x)}{\cos(x)} \tag{6.3.186}$$

and then applying the derivative rule for a quotient as proved above, we have:

$$f'(x)=\frac{\cos^2(x)+\sin^2(x)}{\cos^2(x)}=\frac{1}{\cos^2(x)} \tag{6.3.187}$$

or:

$$f'(x)=\frac{\cos^2(x)+\sin^2(x)}{\cos^2(x)}=1+\frac{\sin^2(x)}{\cos^2(x)}=1+\tan^2(x) \tag{6.3.188}$$

17. Derivative of the function $\cot(x)$:

    By definition (see section Trigonometry page 2508),$\forall x \neq k\pi, k \in \mathbb{Z}$:

$$f(x)=\cot(x)=\frac{1}{\tan(x)} \tag{6.3.189}$$

    and therefore (applying once again the rule of the derivative of a quotient as proved previously):

$$f'(x)=\cot'(x)=-\frac{1+\tan^2(x)}{\tan^2(x)}=-\frac{1}{\tan^2(x)}-1=-(\cot^2(x)+1) \tag{6.3.190}$$

    or:

$$\cot'(x)=-\frac{1}{\tan^2(x)}-1=-\frac{\cos^2(x)}{\sin^2(x)}-1=-\frac{\cos^2(x)+\sin^2(x)}{\sin^2(x)}=-\frac{1}{\sin^2(x)} \tag{6.3.191}$$

18. Derivative of the function $\arctan(x)$:

    We use the properties of the derivative of reciprocal functions proved previously:

$$\forall x \in \mathbb{R} \quad f'(x)=\arctan'(x)=\frac{1}{1+\tan^2(\arctan(x))}=\frac{1}{1+x^2} \tag{6.3.192}$$

19. Derivative of the function $\text{arccot}(x)$:

    We also use the properties of the derivative of reciprocal functions proved previously:

$$\forall x \in \mathbb{R} \quad f'(x)=\text{arccot}'(x)=\frac{1}{-(1+\cot^2(\text{arccot}(x)))}=-\frac{1}{1+x^2} \tag{6.3.193}$$

20. Derivative of e^x:

    We will prove in our study of Theoretical Computing (see section of the same name 6301) that the "Euler number" can be calculated from the series:

$$e^x=\sum_{k=0}^{+\infty}\frac{x^k}{k!} \tag{6.3.194}$$

    which converges on $\mathbb{R}$. By derivating term by term this series that converges, we get:

$$\forall x \in \mathbb{R} \quad f'(x)=\sum_{k=0}^{+\infty}k\frac{x^{k-1}}{k!}=\sum_{k=1}^{+\infty}\frac{x^{k-1}}{(k-1)!}=e^x \tag{6.3.195}$$

    Thus the exponential is its own derivative. So now we can afford to study the derivatives of some hyperbolic trigonometric functions (see section Trigonometry page 2532) and many other specific cases (see all other chapters of the book).

21. Derivative of $\sinh(x)$:

    Remember (see section Trigonometry page 2508):

$$\sinh(x)=\frac{1}{2}\left(e^x-e^{-x}\right) \tag{6.3.196}$$

    So trivially:

$$\sinh'(x)=\frac{1}{2}\left(e^x+e^{-x}\right) \tag{6.3.197}$$

22. Derivative of $\cosh(x)$:

    Remember (see section Trigonometry page 2508):

    $$\cosh(x)=\frac{1}{2}\left(e^x+e^{-x}\right) \quad (6.3.198)$$

    So trivially:

    $$\cosh'(x)=\frac{1}{2}\left(e^x-e^{-x}\right)=\sinh(x) \quad (6.3.199)$$

23. Derivative of $\tanh(x)$:

    Remember (see section Trigonometry page 2508):

    $$\tanh(x)=\frac{\sinh(x)}{\cosh(x)} \quad (6.3.200)$$

    Therefore by applying the derivative from a quotient we get:

    $$\tanh'(x)=\frac{\cosh^2(x)-\sinh^2(x)}{\cosh^2(x)}=\frac{1}{\cosh^2(x)} \quad (6.3.201)$$

    or:

    $$\tanh'(x)=\frac{\cosh^2(x)-\sinh^2(x)}{\cosh^2(x)}=1-\frac{\sinh^2(x)}{\cosh^2(x)}=1-\tanh^2(x) \quad (6.3.202)$$

24. Derivative of $\coth(x)$:

    Remember (see section Trigonometry page 2508):

    $$\forall x\neq 0 \qquad \coth(x)=\frac{\cosh(x)}{\sinh(x)}=\frac{1}{\tanh(x)} \quad (6.3.203)$$

    Therefore by applying the derivative from a quotient we get:

    $$\coth'(x)=-\frac{1-\tanh^2(x)}{\tanh^2(x)}=1-\frac{1}{\tanh^2(x)}=1-\coth^2(x) \quad (6.3.204)$$

25. Derivative of arcsinh(x):

    We also use the properties of the derivative of reciprocal functions proved previously:

    $$\text{arcsinh}'(x)=\frac{1}{\cosh(\text{arcsinh}(x))} \quad (6.3.205)$$

    But (see section Trigonometry page 2508):

    $$1=\cosh^2(\text{arcsinh}(x))-\sinh^2(\text{arcsinh}(x))=\cosh^2(\text{arcsinh}(x))-x^2 \quad (6.3.206)$$

    and therefore:

    $$1+x^2=\cosh^2(\text{arcsinh}(x)) \quad (6.3.207)$$

    Since $\cosh(x)$ takes only positive values, we have:

    $$\cosh(\text{arcsinh}(x))=\sqrt{1+x^2} \quad (6.3.208)$$

    Then finally:

    $$\text{arcsinh}'(x)=\frac{1}{\cosh(\text{arcsinh}(x))}=\frac{1}{\sqrt{1+x^2}} \quad (6.3.209)$$

26. Derivative of $\text{arccosh}(x)$:

    We also use the properties of the derivative of reciprocal functions proved previously:

    $$\forall x > 1 \quad \text{arccosh}'(x) = \frac{1}{\sinh(\text{arccosh}(x))} \tag{6.3.210}$$

    But (see section Trigonometry page 2508):

    $$1 = \cosh^2(\text{arccosh}(x)) - \sinh^2(\text{arccosh}(x)) = x^2 - \sinh^2(\text{arccosh}(x)) \tag{6.3.211}$$

    and therefore:

    $$-1 + x^2 = \sinh^2(\text{arccosh}(x)) \tag{6.3.212}$$

    Since $\text{arccosh}(x)$ takes only positive values so do $\sinh(x)$, then we have:

    $$\sinh(\text{arccosh}(x)) = \sqrt{x^2 - 1} \tag{6.3.213}$$

    Then finally:

    $$\forall x > 1 \quad \text{arccosh}'(x) = \frac{1}{\sinh(\text{arccosh}(x))} = \frac{1}{\sqrt{x^2 - 1}} \tag{6.3.214}$$

27. Derivative of $\text{arctanh}(x)$:

    We also use the properties of the derivative of reciprocal functions proved previously:

    $$\forall x \in [-1, 1] \quad \text{arctanh}'(x) = \frac{1}{1 - \tanh^2(\text{arctanh}(x))} = \frac{1}{1 - x^2} \tag{6.3.215}$$

28. Derivative of $\text{arccoth}(x)$:

    We also use the properties of the derivative of reciprocal functions proved previously:

    $$\forall |x| > 1 \quad \text{arccoth}'(x) = \frac{1}{1 - \coth^2(\text{arccoth}(x))} = \frac{1}{1 - x^2} \tag{6.3.216}$$

29. Derivative of a^x with $a > 0$:

    $$f(x) = a^x = e^{\ln(a^x)} = e^{x \ln(a)} \tag{6.3.217}$$

    So (derivative of a composite function):

    $$f'(x) = \ln(a) e^{x \ln(a)} = a^x \ln(a) \tag{6.3.218}$$

30. We are aware of the chain rules for the derivative of a product of function. But what about the power that is quite frequent in physics?

    Indeed, the derivative of $f(x)^{g(x)}$ is considered by many as one of the most versatile derivative!

    First, to make the proof, it should be obvious that:

    $$\frac{\mathrm{d}}{\mathrm{d}x} x^n = n x^{n-1} \tag{6.3.219}$$

and:

$$\frac{\mathrm{d}}{\mathrm{d}x}a^x=\ln(a)a^x \tag{6.3.220}$$

are just special cases of the derivative of $f(x)^{g(x)}$.

To solve:

$$\frac{\mathrm{d}}{\mathrm{d}x}f(g)^{g(x)} \tag{6.3.221}$$

we need to play a little trick to make the differentiation easier. And nothing is as easy as:

$$\frac{\mathrm{d}}{\mathrm{d}x}e^x=e^x \tag{6.3.222}$$

So since $x=e^{\ln(x)}$ we will use that to our advantage.

We start with:

$$\frac{\mathrm{d}}{\mathrm{d}x}f(g)^{g(x)}=\frac{\mathrm{d}}{\mathrm{d}x}\left(e^{\ln\left(f(x)^{g(x)}\right)}\right) \tag{6.3.223}$$

We know that:

$$\ln\left(f(x)^{g(x)}\right)=g(x)\ln(f(x)) \tag{6.3.224}$$

so we plug that in to get this:

$$\frac{\mathrm{d}}{\mathrm{d}x}f(g)^{g(x)}=\frac{\mathrm{d}}{\mathrm{d}x}\left(e^{g(x)\ln(f(x))}\right) \tag{6.3.225}$$

Now all we have to do is differentiate the right-hand side!

Remember that:

$$\frac{\mathrm{d}}{\mathrm{d}x}e^{f(x)}=e^{f(x)}\frac{\mathrm{d}}{\mathrm{d}x}f(x) \tag{6.3.226}$$

Then:

$$\frac{\mathrm{d}}{\mathrm{d}x}e^{g(x)\ln(f(x))}=e^{g(x)\ln(f(x))}\frac{\mathrm{d}}{\mathrm{d}x}\left(g(x)\ln(f(x))\right) \tag{6.3.227}$$

That is equivalent as to write:

$$\frac{\mathrm{d}}{\mathrm{d}x}f(x)^{g(x)}=f(x)^{g(x)}\frac{\mathrm{d}}{\mathrm{d}x}\left(g(x)\ln(f(x))\right) \tag{6.3.228}$$

Now all we have to do is differentiate the right-hand side. This is the simple multiplication rule:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(g(x)\ln(f(x))\right)=\frac{\mathrm{d}g(x)}{\mathrm{d}x}\ln(f(x))+g(x)\frac{\mathrm{d}\ln(x)}{\mathrm{d}x} \tag{6.3.229}$$

And then we need to differentiate the natural log:

$$\frac{\mathrm{d}\ln(x)}{\mathrm{d}x}=\frac{1}{f(x)}\frac{\mathrm{d}f(x)}{\mathrm{d}x} \tag{6.3.230}$$

So we plug that in to get this:

$$\frac{\mathrm{d}}{\mathrm{d}x}f(x)^{g(x)}=f(x)^{g(x)}\left[\frac{\mathrm{d}g(x)}{\mathrm{d}x}\ln(f(x))+\frac{g(x)}{f(x)}\frac{\mathrm{d}f(x)}{\mathrm{d}x}\right] \tag{6.3.231}$$

And then we distribute $f(x)^{g(x)}$ to get:

$$\frac{\mathrm{d}}{\mathrm{d}x}f(x)^{g(x)}=f(x)^{g(x)}\frac{\mathrm{d}g(x)}{\mathrm{d}x}\ln(f(x))+f(x)^{g(x)}\frac{g(x)}{f(x)}\frac{\mathrm{d}f(x)}{\mathrm{d}x} \tag{6.3.232}$$

Then if we simplify:

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}x}f(x)^{g(x)}=f(x)^{g(x)}\frac{\mathrm{d}g(x)}{\mathrm{d}x}\ln(f(x))+f(x)^{g(x)-1}g(x)\frac{\mathrm{d}f(x)}{\mathrm{d}x}} \tag{6.3.233}$$

So some application examples give us:

$$\frac{\mathrm{d}}{\mathrm{d}x}x^n=nx^{n-1}\frac{\mathrm{d}}{\mathrm{d}x}x \tag{6.3.234}$$

Indeed, all we have to do is set $f(x)=x$ and $g(x)=n$ and we get:

$$\frac{\mathrm{d}}{\mathrm{d}x}x^n=x^n\frac{\mathrm{d}n}{\mathrm{d}x}\ln(x)+x^{n-1}n\frac{\mathrm{d}n}{\mathrm{d}x}=x^n\cdot 0\cdot\ln(x)+x^{n-1}n\cdot 1=x^{n-1}n \tag{6.3.235}$$

Or another application:

$$\frac{\mathrm{d}}{\mathrm{d}x}a^x \tag{6.3.236}$$

all we have to do is set $f(x)=a$ and $g(x)=x$ and we get:

$$\frac{\mathrm{d}}{\mathrm{d}x}a^x=a^x\frac{\mathrm{d}x}{\mathrm{d}x}\ln(a)+a^{x-1}x\frac{\mathrm{d}x}{\mathrm{d}x}=a^2\cdot 1\cdot\ln(a)+a^{x-1}x\cdot 0=a^x\cdot\ln(a) \tag{6.3.237}$$

31. For the fun (we don't use this derivative anywhere in this textbook on any practical case), let us calculate the derivative of x^x.

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}x}\left[x^x\right]&=\frac{\mathrm{d}}{\mathrm{d}x}\left[\mathrm{e}^{\ln(x)x}\right]=\mathrm{e}^{x\ln(x)}\cdot\frac{\mathrm{d}}{\mathrm{d}x}[x\ln(x)]\\&=\left(\frac{\mathrm{d}}{\mathrm{d}x}[x]\cdot\ln(x)+x\cdot\frac{\mathrm{d}}{\mathrm{d}x}[\ln(x)]\right)\mathrm{e}^{x\ln(x)}\\&=\mathrm{e}^{x\ln(x)}\left(1\ln(x)+\frac{1}{x}x\right)=\mathrm{e}^{x\ln(x)}(\ln(x)+1)=x^x(\ln(x)+1)\end{aligned} \tag{6.3.238}$$

To summarize for the most important one (some will be proved later in this textbook):

$f(x)$	$f'(x)$	Condition
c^{te}	0	None
x^n	nx^{n-1}	None
$\cos(x)$	$-\sin(x)$	$x \in \mathbb{R}$
$\sin(x)$	$\cos(x)$	$x \in \mathbb{R}$
$\log_b(x)$	$\dfrac{1}{x}\log_b(e)$	$x > 0, b > 0, b \neq 1$
$u(x)+v(x)$	$u'(x)+v'(x)$	None
$u(x)v(x)$	$u'(x)v(x)+u(x)v'(x)$	None
$u(x)v(x)$	$u'(x)v(x)+u(x)v'(x)$	None
$u(x)/v(x)$	$\dfrac{u'(x)v(x)-u(x)v'(x)}{v(x)^2}$	$v(x) \neq 0, v'(x) \neq 0$
$\lvert x \rvert$	$x/\lvert x \rvert$	
$v \circ u = v(u(x))$	$\dfrac{\mathrm{d}v}{\mathrm{d}u}\dfrac{\mathrm{d}u}{\mathrm{d}x}$	None
$\frac{\mathrm{d}}{\mathrm{d}t}[f(x(t),y(t))]$	$\frac{\partial f(x(t),y(t))}{\partial x}\frac{\mathrm{d}x(t)}{\mathrm{d}t}+\frac{\partial f(x(t),y(t))}{\partial y}\frac{\mathrm{d}y(t)}{\mathrm{d}t}$	None
$f^{-1}(y)$	$\frac{1}{f(f^{-1}(y))'}$	None
$\arccos(x)$	$\frac{-1}{\sqrt{1-x^2}}$	$1 \geq x \geq -1$
$\arcsin(x)$	$\frac{1}{\sqrt{1-x^2}}$	$1 \geq x \geq -1$
$\tan(x)$	$1+\tan^2(x)$	$\forall x \neq k\frac{\pi}{2}, k \in \mathbb{Z}$
$\cot(x)$	$-\left(\cot^2(x)+1\right) = -\frac{1}{\sin^2(x)}$	$\forall x \neq k\pi, k \in \mathbb{Z}$
$\arctan(x)$	$\frac{1}{1+x^2}$	$\forall x \in \mathbb{R}$
$\mathrm{arccot}(x)$	$-\frac{1}{1+x^2}$	$\forall x \in \mathbb{R}$
e^x	e^x	None
$\sinh(x)$	$\frac{1}{2}\left(e^x+e^{-x}\right)$	None
$\cosh(x)$	$\frac{1}{2}\left(e^x-e^{-x}\right) = \sinh(x)$	None
$\coth(x)$	$1-\frac{1}{\tanh^2(x)} = 1-\coth^2(x)$	$\forall x \neq 0$
$\mathrm{arcsinh}(x)$	$\frac{1}{\cosh(\mathrm{arcsinh}(x))} = \frac{1}{\sqrt{1+x^2}}$	None
$\mathrm{arccosh}(x)$	$\frac{1}{\sinh(\mathrm{arccosh}(x))} = \frac{1}{\sqrt{x^2-1}}$	$\forall x > 1$
$\mathrm{arctanh}(x)$	$\frac{1}{1-\tanh^2(\mathrm{arctanh}(x))} = \frac{1}{1-x^2}$	$\forall x \in [-1,1]$
$\mathrm{arccoth}(x)$	$\frac{1}{1-\coth^2(\mathrm{arccoth}(x))} = \frac{1}{1-x^2}$	$\forall \lvert x \rvert > 1$
a^x	$a^x \ln(a)$	$a > 0$
$f(x)^{g(x)}$	$f(x)^{g(z)}\frac{\mathrm{d}g(x)}{\mathrm{d}x}\ln(f(x))+f(x)^{g(z)-1}g(x)\frac{\mathrm{d}f(x)}{\mathrm{d}x}$	None
x^x	$x^x(\ln(x)+1)$	$x \neq 0$
$H(x)$ (Heaviside)	$\delta(x-a)$	None

Table 6.10: **Most common derivatives**

6.3.1.3 Implicit Differentiation

Thus far, the functions we have been concerned with functions that have been defined explicitly. A function is defined explicitly if *the output is given directly in terms of the input*. For instance, in the function:

$$f(x)=4x^2 \tag{6.3.239}$$

the value of $f(x)$ is given explicitly or directly in terms of the input. Just by knowing the input we can immediately find the output. A second type of function that is also useful for us to consider is an "implicitly defined function". A function is defined implicitly if *the output cannot be found directly from the input*. For instance (stupid simple example):

$$\sqrt{f}=2x \tag{6.3.240}$$

is an implicitly defined function, because for each positive x value there is a corresponding f value, but we cannot find it directly from the function. We would need to square both sides, and then we would have the explicitly defined function:

$$f=4x^2 \tag{6.3.241}$$

It is also possible for us to have implicitly defined functions that we cannot rewrite as an explicitly defined function!!!

For instance we might have the function:

$$\sin(f(x))+f(x)=x \tag{6.3.242}$$

For a given x value, there *may* be a corresponding output value $f(x)$ which makes this a true statement. In this way a function $f(x)$ would be defined for all such x where there is a solution. For instance, we have $f(0)=0$, because setting $x=f(x)=0$ in the above equation is a true statement. Right now we don't have the proper tools to solve such an equation, but the important concept here is that we can have a function defined in such a way.

When we speak of functions, we mean that we have a rule which provides us with at most one output for a given input (there is no output for inputs at which the function is not defined). In a more general sense we might want to look at rules that provide us with multiple outputs for a given input. Such an example would be the equation:

$$x^2+y^2=1 \tag{6.3.243}$$

which is the equation for the unit circle (see section Analytical Geometry page 2768). It turns out that this object consists of two functions, namely:

$$y=\pm\sqrt{1-x^2} \tag{6.3.244}$$

The equation of this circle does not define a function (because the output is multi-valued!!), but it does define some type of curve in the x-y plane. In general, we should be able to describe an arbitrary curve as a combination of some number of functions. It is sensible (and useful) to consider the slope of certain points on the curve, which would simply correspond to the slope of the specific function that defines that part of the curve.

To solve the problem of finding the derivative of a function defined in a way such as $\sin(f(x))+f(x)=x$ or by a curve like a circle, we employ the chain rule once again. The way in which we will employ it is named "implicit differentiation". The process works as follows: we differentiate both sides of the equation with respect to x (or the independent variable), and then we solve for the derivative of the dependent variable. Anywhere we find the function f (or the dependent variable), we will use the chain rule to find the derivative. Let us begin with a few simple examples:

✍**Examples:**

E1. We want to find $\mathrm{d}y/\mathrm{d}x$ if $y^2=x$.

One method of solving this problem would be rewriting it in terms of an explicit function of y, and differentiating. Since we have $y=\pm\sqrt{x}$, we actually have two functions, and we would find:

$$\frac{\mathrm{d}y_1}{\mathrm{d}x}=\frac{1}{2\sqrt{x}} \quad \text{and} \quad \frac{\mathrm{d}y_2}{\mathrm{d}x}=-\frac{1}{2\sqrt{x}} \tag{6.3.245}$$

This works sufficiently well in this situation, but what about a function we cannot rewrite explicitly? We would need implicit differentiation. Let's apply implicit differentiation to this situation, as a means of exercise:

$$\begin{aligned} y^2&=x\\ \frac{\mathrm{d}}{\mathrm{d}x}y^2&=\frac{\mathrm{d}}{\mathrm{d}x}x\\ 2y\frac{\mathrm{d}y}{\mathrm{d}x}&=1\\ \frac{\mathrm{d}y}{\mathrm{d}x}&=\frac{1}{2y} \end{aligned} \tag{6.3.246}$$

Were we unable to rewrite y explicitly in terms of x, this is as far as we could go, but we know that $y=\pm\sqrt{x}$, and plugging in this result we find that:

$$\frac{\mathrm{d}y_1}{\mathrm{d}x}=\frac{1}{2\sqrt{x}} \quad \text{and} \quad \frac{\mathrm{d}y_2}{\mathrm{d}x}=-\frac{1}{2\sqrt{x}}$$

once again. In this way, we were able to calculate both derivatives at once.

E2. We want to find $\mathrm{d}f/\mathrm{d}x$ for $\sin(f)+f=x$.

Here we have no choice but to apply implicit differentiation:

$$\begin{aligned} \sin(f)+f&=x\\ \frac{\mathrm{d}}{\mathrm{d}x}(\sin(f)+f)&=\frac{\mathrm{d}x}{\mathrm{d}x}\\ \cos(f)\frac{\mathrm{d}f}{\mathrm{d}x}+\frac{\mathrm{d}f}{\mathrm{d}x}&=1\\ \frac{\mathrm{d}f}{\mathrm{d}x}(\cos(f)+1)&=1\\ \frac{\mathrm{d}f}{\mathrm{d}x}&=\frac{1}{\cos(f)+1} \end{aligned} \tag{6.3.247}$$

A famous case of application in pure mathematics of implicit differentiation (we will see later for physics) is the one at the origin of this technique: the "folium of Descartes[4]" defined by:

$$x^3+y^3-9xy=0 \tag{6.3.248}$$

The curve was first proposed by René Descartes in... 11638 (holocene calendar).

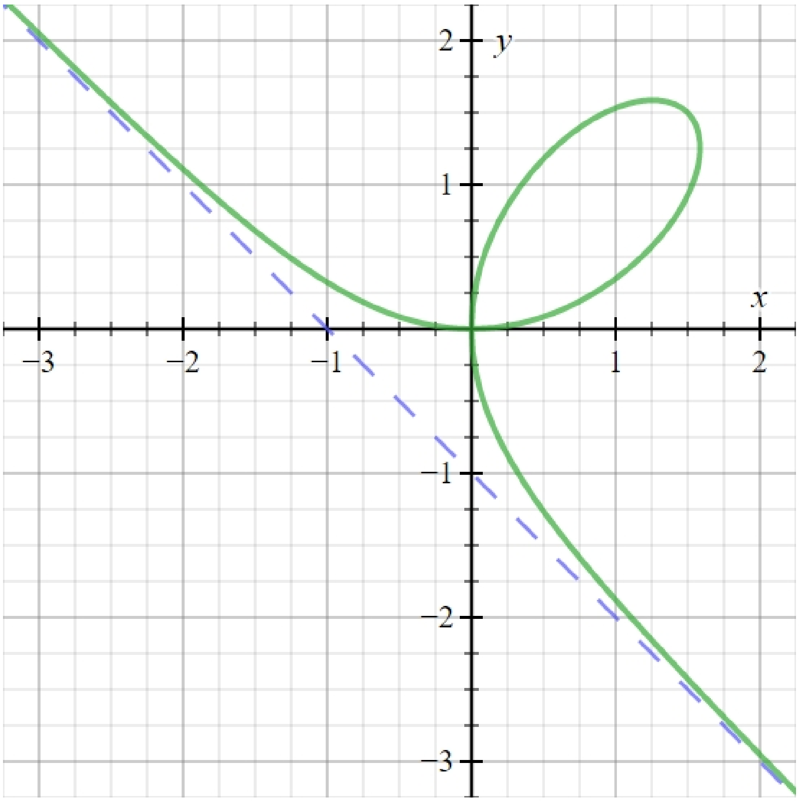


Figure 6.38: The folium of Descartes (green) with asymptote (blue) (source: Wikipedia)

Its claim to fame lies in an incident in the development of calculus. Descartes challenged Pierre de Fermat to find the tangent line to the curve at an arbitrary point since Fermat had recently discovered a method for finding tangent lines. Fermat solved the problem easily, something Descartes was unable to do. Since the invention of calculus, the slope of the tangent line can be found easily using implicit differentiation in any point as we will show it!

Consider now that we want to find the slope of the curve at the point $(2,4)$. Then we use implicit differentiation:

$$\begin{gathered}x^3+y^3-9xy=0\\3x^2+3y^2\frac{\mathrm{d}y}{\mathrm{d}x}-9y-9x\frac{\mathrm{d}y}{\mathrm{d}x}=0\\(3y^2-9y)\frac{\mathrm{d}y}{\mathrm{d}x}=9y-3x^2\\\frac{\mathrm{d}y}{\mathrm{d}x}=\frac{9y-3x^2}{3y^2-9y}=\frac{3y-x^2}{y^2-3y}\end{gathered} \tag{6.3.249}$$

---

[4] The name comes from the Latin word folium which means "leaf".

Evaluating the derivative at the point $(2,4)$ we find:

$$\left.\frac{\mathrm{d}y}{\mathrm{d}x}\right|_{(2,4)}=\left.\frac{3y-x^2}{y^2-3y}\right|_{(2,4)}=\frac{12-4}{16-6}=\frac{4}{5} \tag{6.3.250}$$

Now that we have the slope of the tangent line at the point of interest, we use the point-slope form:

$$\begin{gathered}y_t-y_0=m(x-x_0)\\ y_t-4=\frac{4}{5}(x-4)y_t=\frac{4}{5}(x-2)+4=\frac{4}{5}x+\frac{12}{5}\end{gathered} \tag{6.3.251}$$

Now as far as the line normal to the curve at this point is concerned, we need to find the line perpendicular to the tangent line. This line will cross through the same point, but the slope will be the negative reciprocal of the slope of the tangent line. It follows that:

$$y_n=-\frac{5}{4}(x-2)+4=-\frac{5}{4}x+\frac{13}{2} \tag{6.3.252}$$

Ok now let us focus on an example applied to physics (putting apart the famous case of looking for the tangent of an ellipse). We will prove in the section of Continuum Mechanics the Van der Waals equation (see page 3907):

$$\left(P+\frac{n^2a}{V^2}\right)(V-nb)=nRT \tag{6.3.253}$$

If T remains constant, consider that we want to find the rate of change of the volume with respect to the pressure, that is to say $\mathrm{d}V/\mathrm{d}P$! We can challenge here to calculate this rate to transform this equation into an explicitly defined function... So we know we have to use implicit differentiation. First:

$$\frac{\mathrm{d}}{\mathrm{d}P}\left(\left(P+\frac{n^2a}{V^2}\right)(V-nb)\right)=\frac{\mathrm{d}}{\mathrm{d}P}(nRT) \tag{6.3.254}$$

This gives immediately:

$$\left(1-\frac{n^2a}{V^3}\frac{\mathrm{d}V}{\mathrm{d}P}\right)(V-nb)+\left(P+\frac{n^2a}{V^2}\right)\frac{\mathrm{d}V}{\mathrm{d}P}=0 \tag{6.3.255}$$

Now we distribute:

$$V-nb-\frac{n^2a}{V^2}\frac{\mathrm{d}V}{\mathrm{d}P}+\frac{n^3ab}{V^3}\frac{\mathrm{d}V}{\mathrm{d}P}+P\frac{\mathrm{d}V}{\mathrm{d}P}+\frac{n^2a}{V^2}\frac{\mathrm{d}V}{\mathrm{d}P}=0 \tag{6.3.256}$$

After simplification and rearrangement we get:

$$\left(\frac{n^3ab}{V^3}+P\right)\frac{\mathrm{d}V}{\mathrm{d}P}=nb-V \tag{6.3.257}$$

Finally:

$$\frac{\mathrm{d}V}{\mathrm{d}P}=\frac{nb-V}{\dfrac{n^3ab}{V^3}+P} \tag{6.3.258}$$

The special case of the examples above with the Van der Waals equation and the folium of Descartes is in some text books introduced as following with a two variables case:

$$\frac{\mathrm{d}}{\mathrm{d}x}f(x,y)=\frac{\mathrm{d}}{\mathrm{d}x}(c^{te}) \tag{6.3.259}$$

Therefore:

$$\frac{\partial f}{\partial x}\frac{\mathrm{d}x}{\mathrm{d}x}+\frac{\partial f}{\partial y}\frac{\mathrm{d}y}{\mathrm{d}x}=0 \tag{6.3.260}$$

Reduce to:

$$\frac{\partial f}{\partial x}+\frac{\partial f}{\partial y}\frac{\mathrm{d}y}{\mathrm{d}x}=0 \tag{6.3.261}$$

Finally:

$$\boxed{\frac{\mathrm{d}y}{\mathrm{d}x}=-\frac{\dfrac{\partial f}{\partial x}}{\dfrac{\partial f}{\partial y}}} \tag{6.3.262}$$

That's it for now. We will stop here on this topic as we don't need more techniques or example to our study of physics and engineering as introduced in this textbook.

6.3.1.4 Smoothness

Smoothness has to do with how many derivatives of a function exist and are continuous. The term "smooth function" is often used technically to mean a function that has derivatives of all orders everywhere in its domain.

Definition (#6.3.197): A "differentiability class" is a classification of functions according to the properties of their derivatives. Higher order differentiability classes correspond to the existence of more derivatives.

Consider an open set on the real line $\mathbb{R}$ and a function f defined on that set with real or complex values. Let k be a non-negative integer. The function f is said to be of (differentiability) class $\mathcal{C}^k$ if the derivatives $f',f'',\ldots,f(k)$ exist and are continuous (the continuity is implied by differentiability for all the derivatives except for $f(k)$). The function f is said to be of class $\mathcal{C}^\infty$, or smooth, if it has derivatives of all orders. The function f is said to be of class $\mathcal{C}^\omega$, or simply "analytic", if f is smooth and if it equals its Taylor series expansion around any point in its domain (see section Sequences and Series page 1696). $\mathcal{C}^\omega$ is thus strictly contained in $\mathcal{C}^\infty$.

6.3.2 Integral Calculus

We will discuss here the basic principles of integral calculus in $\mathbb{R}^n$. Most advanced topics will come depending the time that are available to the redactors of this textbook but the reader can already refer to the Complex Analysis section (see page 2390) for integration techniques based on the Residue Theorem that is very powerful and useful especially for some integral in quantum physics.

> ❞ *Differentiation is a science, Integration is an art.* ❞

quote
6.3:1497.#53

For information this textbook in mainly dedicated to the Darboux integral, the Riemann integral and the Lebesgue integral. Only if we have the time and there is a practical necessity for this, we will also in the future introduce the Regulated Integral, the Riemann-Stieltjes integral and the Lebesgue-Stielties integral!

6.3.2.1 Definite Integral

The origin of Integral Calculus seems to come from Archimedes that was fascinated with calculating the areas of various shapes. He used a process that has come to be known as the *method of exhaustion*, which used smaller and smaller shapes, the areas of which could be calculated exactly, to fill an irregular region and thereby obtain closer and closer approximations to the total area. In this process, an area bounded by curves is filled with rectangles, triangles, and shapes with exact area formulas. These areas are then summed to approximate the area of the curved region. This subsection introduces the Definite Integrals.

The first idea of the concept of integral is to calculate the algebraic area (positive area if above the x-axis or negative below) between a curve and its support. See the figure below with a positive area and the notations for the developments that will follow:

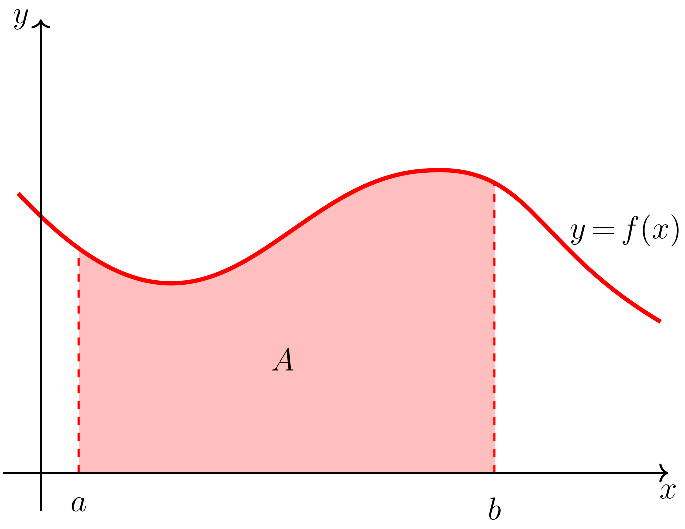

Figure 6.39: **Area A to be calculated in a bounded continuous positive function**

Or with different algebraic areas (the difference between the blue area and the yellow area is named the "net signed area"):

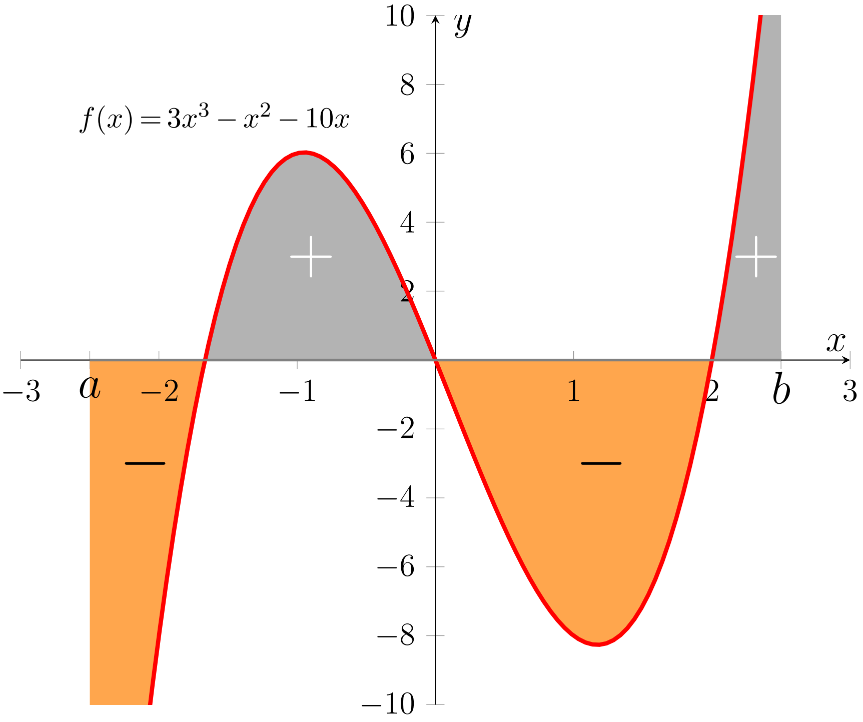

Figure 6.40: **Area A to be calculated in a bounded continuous positive and negative function**

An approximate value of the area under a curve can be achieved by a division into n vertical rectangular bands of the same width (or from different width). In particular (among a lot of other possibilities), we can achieve a framework of this area with the help of a sum of upper bound areas (majorant) A_M (also sometimes denoted S and named "upper Darboux sum") or a lower bound sum (minorant) A_m (also sometimes denoted s and named "lower Darboux sum") for a given cutting:

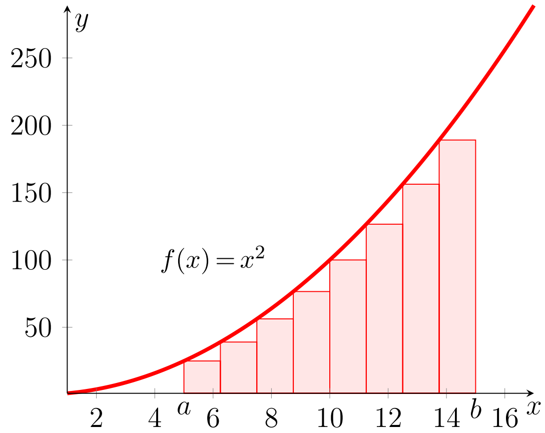

Figure 6.41: **Minorant sum of areas A_m**

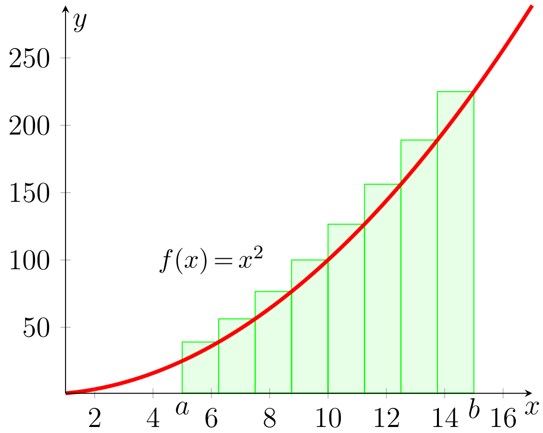

Figure 6.42: **Minorant sum of areas A_M**

Or if we superimposed the both we can see the difference between the minorant and majorant areas and guess that if the number of rectangles tends to infinity, both results converge (it's common representation in many textbooks):

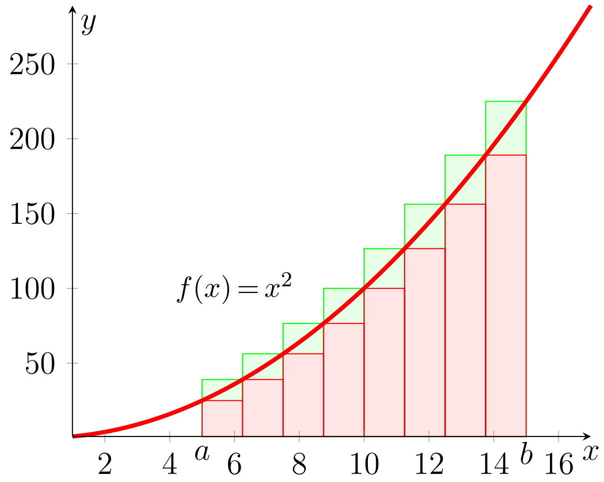

Figure 6.43: **Minorant and majorant sum of areas superimposed**

Suppose now, as mentioned just before, that the number n of bands tends to infinity. As the bands are of the same width, the width of each bands tends to 0 (objectively it is not necessary for the width of the cutting of the subintervals to be the same everywhere).

If the sums A_m and A_M have both a limit when the number n of bands tends to infinity, then the area A under the curve is between these two limits. We write this:

$$\lim_{n\rightarrow+\infty} A_m < A < \lim_{n\rightarrow+\infty} A_M \tag{6.3.263}$$

Obviously if these two limits are equal, their value is that of the area A under the curve.

Hence a first direct definition of the definite integral named also "Riemann integral".

Definition (#6.3.198): Given an interval $[a,b]$, divided into n equal parts, let f be a continuous function on the interval $[a,b]$, consider A_m, the algebraic minorant sum of areas and A_M the algebraic majorant sum. We name "definite integral" of f from a to b, denoted by:

$$\boxed{\int\limits_a^b f(x)\mathrm{d}x} \tag{6.3.264}$$

the number A such that:

$$A=\lim_{n\to+\infty} A_m=\lim_{n\to+\infty} A_M \tag{6.3.265}$$

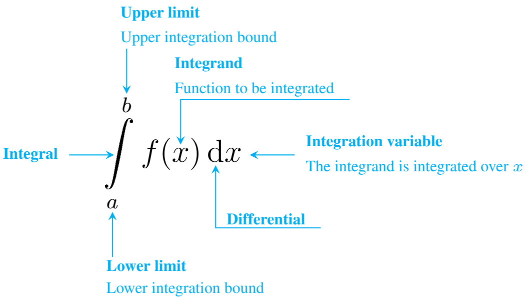
provided that this limit exists. If this limit exists, then we say that f is "integrable" on $[a,b]$ and the definite integral exists.

The symbol:

$$\int_a^b \tag{6.3.266}$$

is only the symbol of a discrete sum $\sum$ but applied to the case of infinitely small increments.

The numbers a and b of the integral (that can also be functions sometimes!) are named the "integration limits" or "integration bounds": a is the "lower bound", b is the "upper bound".



Upper limit
Upper integration bound
Integrand
Function to be integrated
Integral
$\int_a^b f(x)\,\mathrm{d}x$
Integration variable
The integrand is integrated over x
Differential
Lower limit
Lower integration bound

(6.3.267)

Intuitively, it is obvious that when $a=b$ we extend the definition as follows:

$$\int\limits_a^b f(x)\mathrm{d}x=0 \tag{6.3.268}$$

Finally, notice that it is quite possible that the result of the integral to be negative or even complex since it is an algebraic surface! That is to say the result can be in general in $\mathbb{C}$.

Remarks

R1. Other letters rather than x can be used in the evaluation of the definite integral. So if f is integrable on $[a,b]$, then $\int\limits_a^b f(x)\mathrm{d}x=\int\limits_a^b f(t)\mathrm{d}t=\int\limits_a^b f(s)\mathrm{d}s$, etc. This is why the variable x is sometimes named "dummy variable".

R2. As we will see below, it is essential not to confuse between a "definite integral" and a "indefinite integral". Thus, an indefinite integral, denoted $\int f(x)\mathrm{d}x$ is a function, or more precisely, a family of functions also named "primitives of f" (see below) while a definite integral, denoted $\int\limits_a^b f(x)\mathrm{d}x$ is considered as a constant.

Let us present a second approach for the definition of the integral, somewhat more rigorous than the previous one (following the request of several readers). We will use this time, by tradition the notation S surface instead of the area A.

Let f be a bounded function on $[a,b]$. We consider a subdivision σ of its support $[a,b]$ that we note:

$$\sigma=\{x_0=a<x_1<x_2\ldots<x_{n-1}<x_n=b\} \tag{6.3.269}$$

where the intervals are not necessarily of equal sizes.

We write for $i=1,2,3,\ldots,n$:

$$m_i=\inf_{x\in[x_{i-1},x_i]} f(x) \quad \text{and} \quad M_i=\sup_{x\in[x_{i-1},x_i]} f(x) \tag{6.3.270}$$

Definitions (#6.3.199):

D1. We name "lower Darboux sum" (also sometimes named "minorant sum" and denoted A_m) associated with f and σ the surface:

$$s_{[a,b]}(f,\sigma)=\sum_{i=1}^{n} m_i(x_i-x_{i-1}) \tag{6.3.271}$$

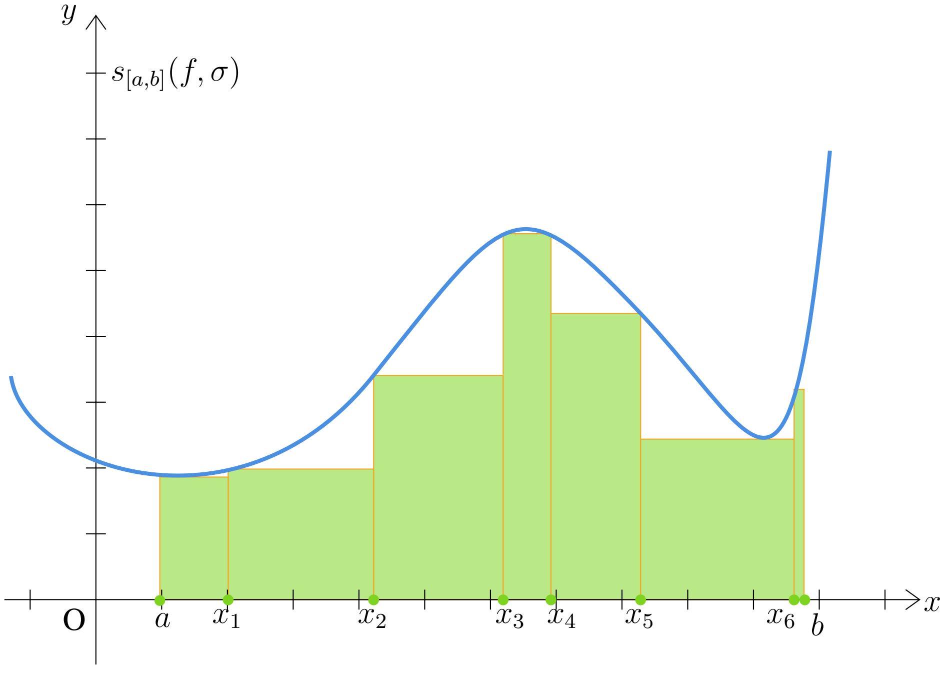


Figure 6.44: **Principle of calculating the lower Darboux sum**

D2. We name "upper Darboux sum" (also sometimes named "majorant sum" and denoted A_M) associated with f and σ the surface:

$$S_{[a,b]}(f,\sigma)=\sum_{i=1}^{n} M_i(x_i-x_{i-1}) \tag{6.3.272}$$

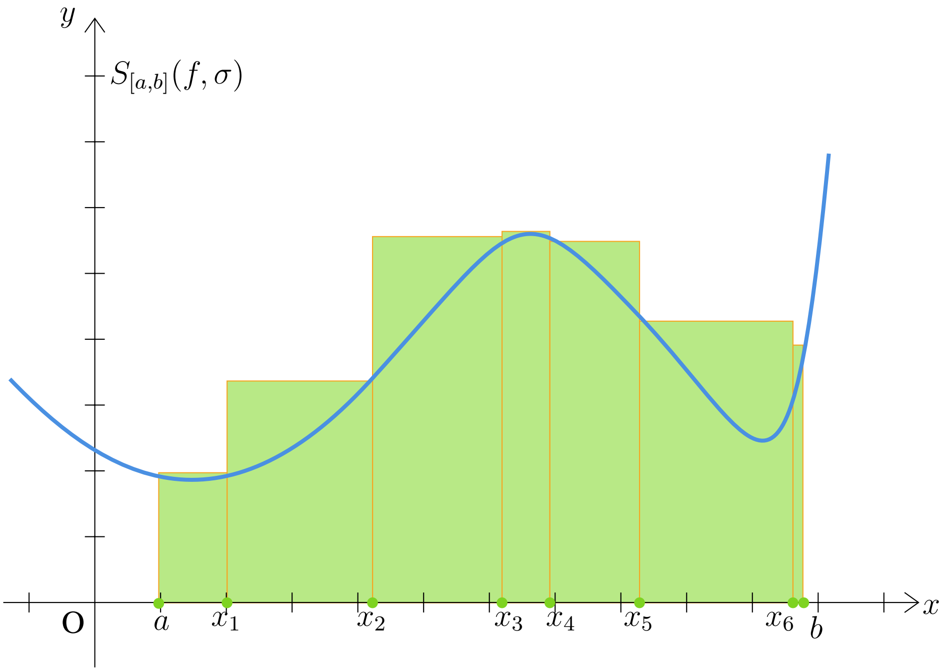

Figure 6.45: Principle of calculating the upper Darboux sum

A function f is said to be "Riemann-integrable on $[a,b]$" if and only if the above two surfaces coincide when the intervals become infinitely small.

$$\int\limits_a^b f(x)\mathrm{d}x \tag{6.3.273}$$

All Riemann-integrable functions on $[a,b]$ are denoted sometimes by $\mathcal{R}_{[a,b]}$.

We can make a quick proof and dirty proof of that equivalence (as it's not very interesting for an engineer because the result is quite intuitive).

Theorem 6.14. Remember that we have the following definition of the Darboux integrability: Let f be defined and bounded on $[a,b]$, then f is Darboux integrable if for all $\varepsilon>0$ there exists a partition P of $[a,b]$ such that $U(f,P)-L(f,P)<\varepsilon$ (where U and L are the upper and lower Riemann sums respectively).

A function is "Riemann integrable" if:

$$\sup_P\{L(f,P)\}=\underline{\int_a^b} f(x)=\overline{\int_a^b} f(x)=\inf_P\{U(f,P)\} \tag{6.3.274}$$

or equivalently:

$$\inf_P\{U(f,P)\}-\sup_P\{L(f,P)\}<\varepsilon \tag{6.3.275}$$

for any $\varepsilon>0$. In this case the supremum of the lower sums is the same as the infimum of the upper sums.

Proof 6.14.1. Let $\varepsilon>0$. There exists P such that $U(f,P)-L(f,P)<\varepsilon$. Then since:

$$L(f,P)\leq\sup_P\{L(f,P)\}\leq\inf_P\{U(f,P)\}\leq U(f,P) \tag{6.3.276}$$

clearly:

$$\inf_P\{U(f,P)\}-\sup_P\{L(f,P)\}<\varepsilon \tag{6.3.277}$$

holds.

■ Q.E.D.

Example:

Suppose we want to show that the function $f(x)=x$ is Darboux-integrable on the interval $[0,1]$ and determine its value. To do this we partition $[0,1]$ into n equally sized subintervals each of length $1/n$. We denote a partition of n equally sized subintervals as P_n.

Now since $f(x)=x$ is strictly increasing on $[0,1]$, the infimum on any particular subinterval is given by its starting point. Likewise the supremum on any particular subinterval is given by its end point. The starting point of the k-th subinterval in P_n is $(k-1)/n$ and the end point is k/n. Thus the lower Darboux sum on a partition P_n is given by:

$$\begin{aligned}L_{f,P_n}&=\sum_{k=1}^{n}f\left(x_{k-1}\right)\left(x_k-x_{k-1}\right)=\sum_{k=1}^{n}\frac{k-1}{n}\cdot\frac{1}{n}=\frac{1}{n^2}\sum_{k=1}^{n}[k-1]\\&=\frac{1}{n^2}\left[\frac{(n-1)n}{2}\right]\end{aligned} \tag{6.3.278}$$

similarly, the upper Darboux sum is given by:

$$\begin{aligned}U_{f,P_n}&=\sum_{k=1}^{n}f\left(x_{k}\right)\left(x_k-x_{k-1}\right)=\sum_{k=1}^{n}\frac{k}{n}\cdot\frac{1}{n}=\frac{1}{n^2}\sum_{k=1}^{n}k\\&=\frac{1}{n^2}\left[\frac{(n+1)n}{2}\right]\end{aligned} \tag{6.3.279}$$

Since:

$$U_{f,P_n}-L_{f,P_n}=\frac{1}{n} \tag{6.3.280}$$

Thus for given any $\varepsilon > 0$, we have that any partition P_n with $n > \frac{1}{\varepsilon}$ satisfies:

$$U_{f,P_n} - L_{f,P_n} < \varepsilon \tag{6.3.281}$$

which shows that f is Darboux integrable. To find the value of the integral note that:

$$\int\limits_0^1 f(x)dx = \lim_{n\to\infty} U_{f,P_n} = \lim_{n\to\infty} L_{f,P_n} = \frac{1}{2} \tag{6.3.282}$$

In other words:

$$\underline{\int_a^b} f(x) - \overline{\int_a^b} f(x) = U(f,P_n) - L(f,P_n) = \mathcal{O}\left(\frac{1}{n}\right) \tag{6.3.283}$$

And as $n \to +\infty$, we have:

$$\underline{\int_a^b} f(x) - \overline{\int_a^b} f(x) = 0 \tag{6.3.284}$$

Hence:

$$\underline{\int_a^b} f(x) = \overline{\int_a^b} f(x) \tag{6.3.285}$$

Therefore the function is also Riemann integrable!

Darboux sums are not very useful for the effective calculation of an integral, for example using a computer, because it is usually quite difficult to find the $\inf$ and $\sup$ on sub-intervals. Rather, we consider:

$$s_{[a,b]}(f) = \sum_{i=1}^{n} (x_i - x_{i-1}) f(x_{i-1}) \quad \text{or} \quad S_{[a,b]}(f) = \sum_{i=1}^{n} (x_i - x_{i-1}) f(x_i) \tag{6.3.286}$$

The "Riemann sum" is defined from the fact that we if denote a "partition" (or "regular partition" if they all have the same width) of the interval $[a,b]$ by:

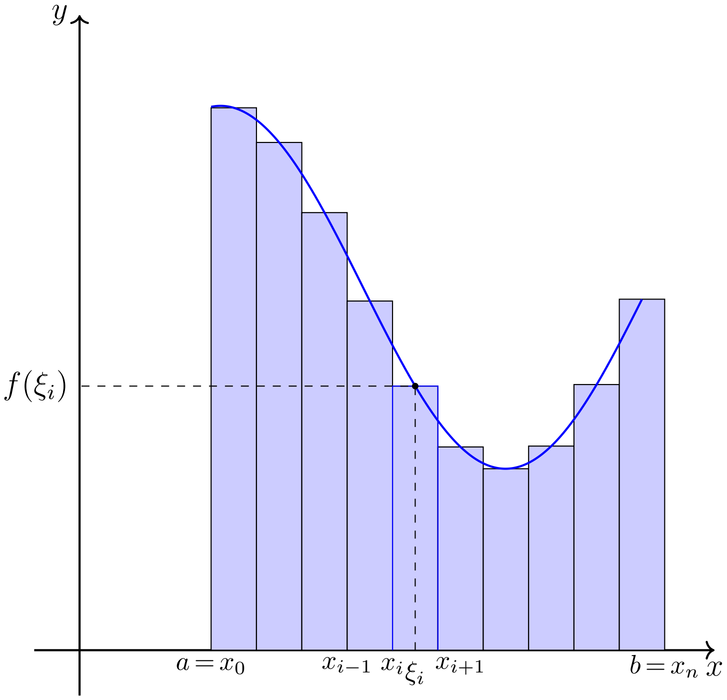
$$\Delta x_i = x_i - x_{i-1} \tag{6.3.287}$$

and that:

$$f(x_i) = f(\xi_i) \tag{6.3.288}$$

where $\xi_i \in [x_{i-1}, x_i]$, then:

$$\boxed{S \cong s_{[a,b]}(f) = S_{[a,b]}(f) = \sum_{i=1}^{n} f(\xi_i)\Delta x_i} \tag{6.3.289}$$



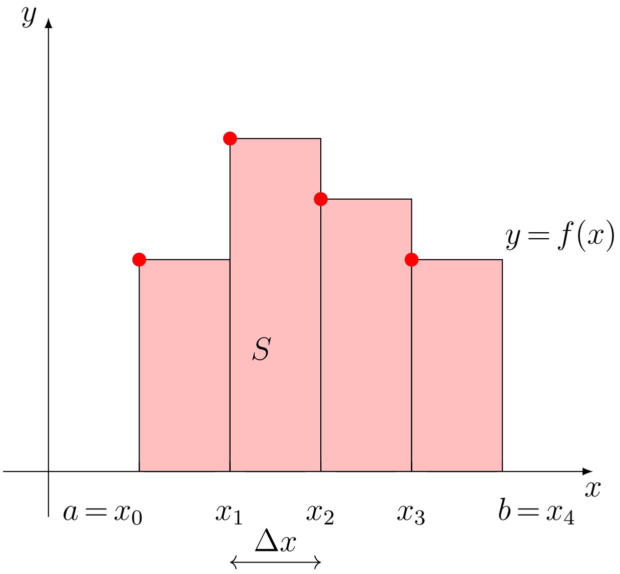
y
$f(\xi_i)$
$a = x_0$
x_{i-1}
x_i
ξ_i
x_{i+1}
$b = x_n$
x

Figure 6.46: **Riemann Sum**

But as we must choose an ξ_i, we often takes either the right or the left one, thus taking randomly the "method of left rectangles":

$$S \cong \sum_{i=1}^{n} f(x_{i-1})\Delta x_i \tag{6.3.290}$$

Which would give us the example below:



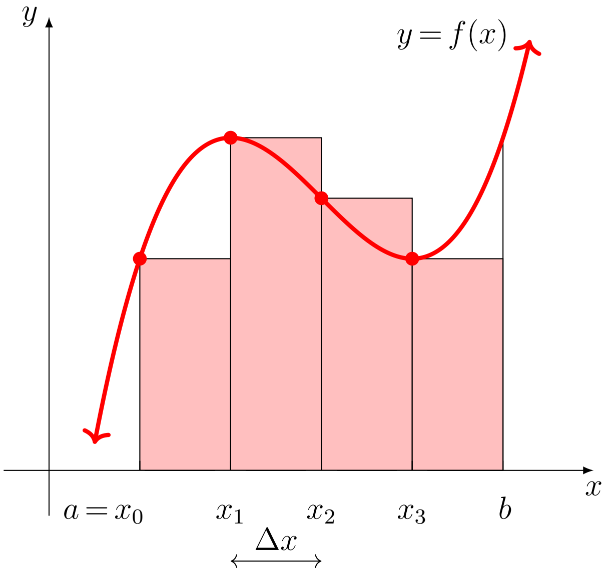
y
$y = f(x)$
S
x
$a = x_0$
x_1
x_2
x_3
$b = x_4$
Δx

Figure 6.47: **Principle of calculating methods using left rectangles**

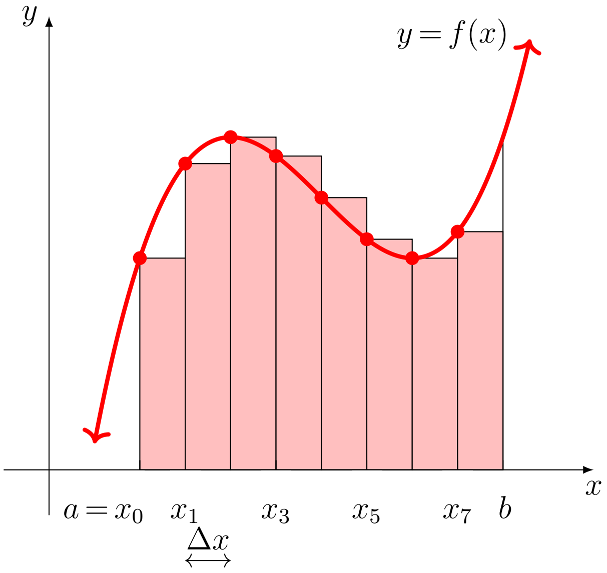
either:

$$\begin{aligned} S &= \sum_{i=1}^{4} f(x_{i-1})\Delta x_i = f(x_0)\Delta x_1 + f(x_1)\Delta x_2 + f(x_2)\Delta x_3 + f(x_3)\Delta x_4 \\ &= f(x_0)(x_1 - x_0) + f(x_1)(x_2 - x_1) + f(x_2)(x_3 - x_2) + f(x_3)(x_4 - x_3) \end{aligned} \tag{6.3.291}$$

But it is easy for a step function... but it is less so for a continuous function for which we will get only an approximate value of the actual surface! The idea is then to take intervals smaller and smaller:



y
$y = f(x)$
x
$a = x_0$
x_1
x_2
x_3
b
Δx



y
$y = f(x)$
x
$a = x_0$
x_1
x_3
x_5
x_7
b
Δx

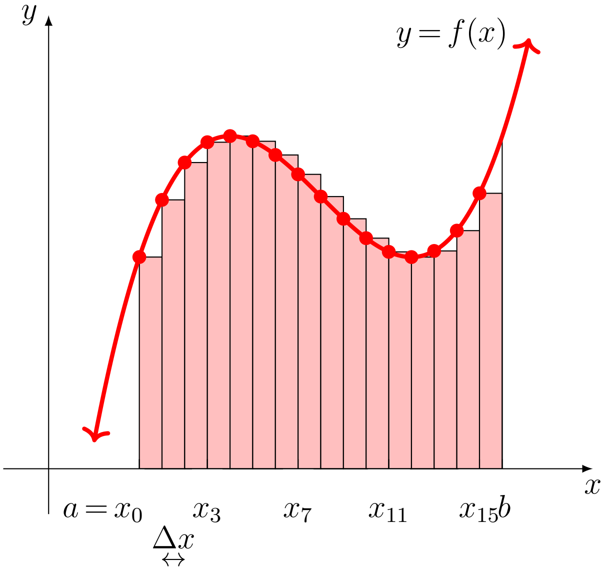


Figure 6.48: **Principle of the calculation of the Riemann integral with left rectangles method**

And then, at the limit, we get the desired quantity:

$$S \underset{\lim \Delta x_i \to 0}{=} \int\limits_a^b f(x)\mathrm{d}x \tag{6.3.292}$$

The fact to search this limit is named "calculate the integral," and more specifically for the chosen method: "calculate the Riemann integral".

✍**Example:**

We want to use the construction of the definite integral to evaluate:

$$\int\limits_0^2 x^2\mathrm{d}x \tag{6.3.293}$$

using a right-endpoint approximation to generate the Riemann sum.

For this purpose we first set up the Riemann sum. Based on the limits of integration, we have $a=0$ and $b=2$. For $i=0,1,2,\ldots,n$, let $P=\{x_i\}$ be a regular partition of $[0,2]$. Then:

$$x_i = x_0 + i\Delta x = 0 + i\left[\frac{2}{n}\right] = \frac{2i}{n} \tag{6.3.294}$$

Thus, the function value at the right endpoint of the interval is:

$$f(x_i) = x_i^2 = \left(\frac{2i}{n}\right)^2 = \frac{4i^2}{n^2} \tag{6.3.295}$$

Then the Riemann sum takes the form:

$$\sum_{i=1}^{n} f(x_i)\Delta x = \sum_{i=1}^{n}\left(\frac{4i^2}{n^2}\right)\frac{2}{n} = \sum_{i=1}^{n}\frac{8i^2}{n^3} = \frac{8}{n^3}\sum_{i=1}^{n} i^2 \tag{6.3.296}$$

Using the Gauss summation relation of $\sum_{i=1}^{n} i^2$ (see section Sequences and Series page 1667), we have:

$$\begin{aligned}\sum_{i=1}^{n} f(x_i)\Delta x &= \frac{8}{n^3}\sum_{i=1}^{n} i^2 = \frac{8}{n^3}\left[\frac{n(n+1)(2n+1)}{6}\right] = \frac{8}{n^3}\left[\frac{2n^3+3n^2+n}{6}\right]\\ &= \frac{16n^3+24n^2+n}{6n^3} = \frac{8}{3}+\frac{4}{n}+\frac{1}{6n^2}\end{aligned} \tag{6.3.297}$$

Now, to calculate the definite integral, we need to take the limit as $n \to +\infty$. We get:

$$\begin{aligned}\int_0^2 x^2 \mathrm{d}x &= \lim_{n\to+\infty}\sum_{i=1}^{n} f(x_i)\Delta x = \lim_{n\to+\infty}\left(\frac{8}{3}+\frac{4}{n}+\frac{1}{6n^2}\right)\\ &= \lim_{n\to+\infty}\left(\frac{8}{3}\right)+\lim_{n\to+\infty}\left(\frac{4}{n}\right)+\lim_{n\to+\infty}\left(\frac{1}{6n^2}\right) = \frac{8}{3}+0+0 = \frac{8}{3}\end{aligned} \tag{6.3.298}$$

Remark

The definition of the Darboux integral has the advantage of being easier to apply in computations or proofs than that of the "real" Riemann integral that doesn't take necessarily equal with interval and therefore defined by:

$$\int_a^b f(t)\mathrm{d}t := \lim_{\substack{p\to 0\\ \sum^*(p)}} \sum_{k=1}^{n} f(t_k)\times\Delta x_k \tag{6.3.299}$$

where $\sum^*(p)$ is the set of subdivisions of $[a,b]$ such that $\max|\Delta x_k| \leq p; t_k \in [x_k, x_{k+1}]$ (disclaimer: of course for Riemann this limit must exist in the $\varepsilon-\delta$ sense!). Consequently, introductory textbooks on calculus and real analysis often develop Riemann integration using the Darboux integral, rather than the true Riemann integral.

6.3.2.2 Indefinite Integral

We have seen before in our study of derivatives the following problem: given a function denoted by $F(x)$, find its derivative $f(x)$, that is to say the algebraic function:

$$F'(x) = f(x) \tag{6.3.300}$$

Definition (#6.3.200): We say that the function $F(x)$ is a "primitive" or "indefinite integral" of the function $f(x)$ on any segment $[a,b]$ if at any point in any segment we have $F'(x) = f(x)$.

Two more explicit and less technical alternative definitions are:

- An "indefinite integral" is a FUNCTION of x (or another variable), while a "definite integral" is a VALUE!

- The collection of all antiderivatives of $f(x)$ is named the "indefinite integral" of f with respect to x.

Another way to see the indefinite integral concept is to go through the "fundamental theorem of integral and differential calculus" also sometimes named "fundamental theorem of calculus" whose two properties are stated as follows:

1. If A (area) is the function defined by $A(X)=\int\limits_a^X f(t)\mathrm{d}t$ for each X in any $[a,b]$, then A is the primitive of f on $[a,b]$ which is zero in a (or in other words: $f(t)$ is the derivative of A).
2. If F is a primitive of f on any $[a,b]$, then:

$$\boxed{\int\limits_a^b f(t)\mathrm{d}t=F(b)-F(a)} \tag{6.3.301}$$

that can also be written obviously as following:

$$\int\limits_a^b F'(t)\mathrm{d}t=\int\limits_a^b \frac{\mathrm{d}F}{\mathrm{d}t}\mathrm{d}t=F(b)-F(a) \tag{6.3.302}$$

Some people then say that the sum of the changes outside of a function (the left side of the equality) is equal to the changes inside the function (the right side of the equality). That's typically a special 1-dimensional case statement of the Stokes (general manifold) theorem!

Let us prove the first property of this fundamental theorem:

Proof 6.14.2. Given the function:

$$A(X)=\int\limits_a^X f(t)\mathrm{d}t \tag{6.3.303}$$

If f is positive, and $h>0$ (the proof in the case where $h<0$ is similar) and as $X>0$, we know that we can think of $A(X)$ as the area under the curve of f from $t=a$ to $t=X$.

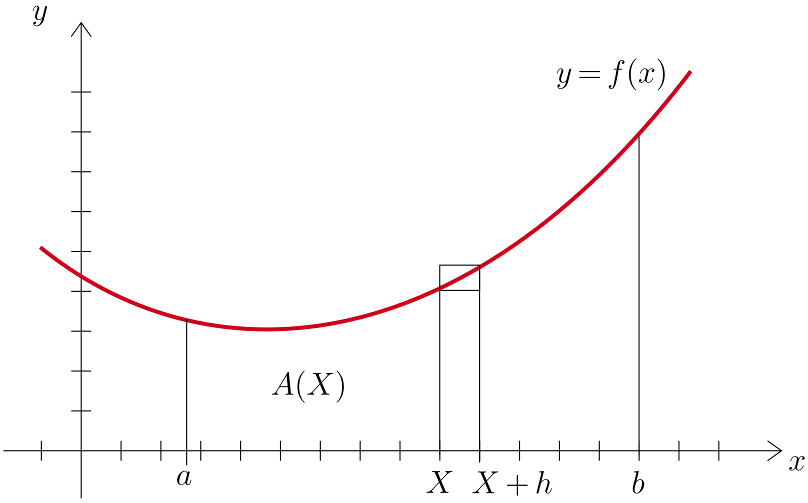

Figure 6.49: **Graphical representation of the area**

To show that A is a primitive of f, we will prove that $A' = f$. According to the definition of the derivative:

$$A'(X) = \lim_{h \to 0} \frac{A(X+h) - A(X)}{h} \tag{6.3.304}$$

Let us study this quotient: $A(x+h) - A(x)$ is represented by the area of the strip of width h, sandwiched between two rectangles of width h.

Given M the maximum of f on the interval $[X, X+h]$ and m the minimum interval of f over the same interval. The respective areas of the two rectangles are Mh and mh.

We then have the following double inequality:

$$mh \leq A(X+h) - A(X) \leq Mh \tag{6.3.305}$$

As h is positive, we can divide by h without changing the meaning of the inequalities:

$$m \leq \frac{A(X+h) - A(X)}{h} \leq M \tag{6.3.306}$$

When $h \to 0^+$ and if f is a continuous function, then M and m have for limit $f(X)$, and the ratio:

$$\frac{A(X+h) - A(X)}{h} \tag{6.3.307}$$

which is between m and M, has effectively for limit $f(X)$.

As $A'(X) = f(X)$ for all X, this shows that the derivative of the area function is f. And therefore A is an indefinite primitive of f. As $A(a) = 0$, A is effectively the primitive of f which vanishes on a.

Another very short and nice way to prove that is to write:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}x}F(x)&=\lim_{h\to 0}\frac{1}{h}\left[\int\limits_a^{x+h}f(t)\mathrm{d}t-\int\limits_a^{x}f(t)\mathrm{d}t\right]\\&=\lim_{h\to 0}\frac{1}{h}\int\limits_x^{x+h}f(t)\mathrm{d}t\\&=\lim_{h\to 0}\frac{1}{h}\left[f(x)h+\mathcal{O}\left(h^2\right)\right]\\&=f(x)\end{aligned}\tag{6.3.308}$$

■ Q.E.D.

Before starting the proof of the second properties of the fundamental theorem, let us give and prove the following theorem that will we be essential to us: If $F_1(x)$ and $F_2(x)$ are two primitives of $f(x)$ on any segment $[a,b]$, their difference is a constant (this result is very important in physics in terms of the study of what we name the "initial conditions").

Proof 6.14.3. We have after the definition of the concept of Primitive:

$$\begin{gathered}F_1'(x)=f(x)\\F_2'(x)=f(x)\end{gathered}\tag{6.3.309}$$

for $\forall x\in[a,b]$.

Let us write:

$$F_1(x)-F_2(x)=\varphi(x)\tag{6.3.310}$$

We can write:

$$F_1'(x)-F_2'(x)=\left[F_1(x)-F_2(x)\right]'=\varphi'(x)=f(x)-f(x)=0\tag{6.3.311}$$

So it comes from what we saw during our study of derivatives that:

$$\varphi(x)=c^{te}\tag{6.3.312}$$

Then we have:

$$F_1(x)-F_2(x)=c^{te}\tag{6.3.313}$$

■ Q.E.D.

It follows from this theorem that if we know any primitive $F(x)$ of the function $f(x)$ any other primitive of this function will be of the form:

$$F(x)+c^{te}\tag{6.3.314}$$

where c^{te} is named the "constant of integration".

So finally, we name "indefinite integral" of $f(x)$ and we denote by:

$$\int f(x)\mathrm{d}x \tag{6.3.315}$$

any expression of the form $F(x)+c^{te}$ where $F(x)$ is a primitive of $f(x)$. Thus, by writing convention:

$$\boxed{\int f(x)\mathrm{d}x=F(x)+c^{te}} \tag{6.3.316}$$

if and only if $F'(x)=f(x)$.

In this context, $f(x)$ is also named "integrand function" and $f(x)\mathrm{d}x$, the "function under the sum sign".

Remark

An "antiderivative" of a function f is one function F whose derivative is f. The indefinite integral of f is the set of ALL antiderivatives of f. Therefore indefinite integral and antiderivative is not the same as the first is the set of all the seconds! If f and F are as described just now, the indefinite integral of f has the form $\{F+c^{te}|c^{te}\in\mathbb{R}\}$ when an antiderivative is just one element of this set!! But not all teachers are according on the definition of antiderivatives...

Caution!!! Sometimes not every antiderivative is an area function. This is exactly what's happening with the constant function $f(x)=0$. No matter what a we pick, we will always have:

$$\int\limits_a^x 0\mathrm{d}t=0 \tag{6.3.317}$$

for every x. And it's not just the always zero function which does this!

Geometrically, we can consider the indefinite integral as a set (family) of curves as we move from one to another by performing a translation in the positive or negative direction of the axis.

Let us return to the proof of item (2) of the fundamental theorem of integral (and differential) calculus:

Proof 6.14.4. Let F be a primitive of f. Since two primitives differ by a constant, we have well:

$$A(X)=F(X)+c^{te} \tag{6.3.318}$$

that we can also write:

$$\int\limits_a^X f(t)\mathrm{d}t=F(X)+c^{te} \tag{6.3.319}$$

for all X in $[a,b]$. The particular case $X=a$ gives $\int\limits_a^a f(t)\mathrm{d}t$ and therefore $F(a)+c^{te}=0$ and we get obviously $c^{te}=-F(a)$. Substituting, we get:

$$\int\limits_a^X f(t)\mathrm{d}t=F(X)-F(a) \tag{6.3.320}$$

As this identity is valid for all X in the interval $[a,b]$ it is true especially for $X=b$. Therefore:

$$\boxed{\int\limits_a^b f(t)\mathrm{d}t=F(b)-F(a)} \tag{6.3.321}$$

■ Q.E.D.

This last result also shows something useful!: It is not necessary when we evaluate and integral to take into account the constant of the general primitive since it is cancelled by the difference of the two primitives!!

Remarks

R1. The above fundamental theorem that shows the link between primitive and integral led us to use the same symbol $\int$ to write a primitive (introduced by Leibniz in the late 117th century), which is a function, and an integral that it is a number.

R2. We also proved in the section of Analytical Mechanics using an integral how to calculate the full length of a curve in the plane if the function $f(x)$ is explicitly known.

Here are some trivial properties of integration that is good to remember because often used elsewhere in this textbook (if it do not seem obvious to you, contact us and we will give the detailed proof):

P1. The derivative of an indefinite integral is equal to the integrand:

$$\left(\int f(x)\mathrm{d}x\right)'=\left(F(x)+c^{te}\right)'=f(x) \tag{6.3.322}$$

P2. The differential of an indefinite integral is equal to the expression under the integral sign:

$$\mathrm{d}\left(\int f(x)\mathrm{d}x\right)=f(x) \tag{6.3.323}$$

P3. The indefinite integral of the differential of a given function is equal to the sum of this function and an arbitrary constant:

$$\int F(x)\mathrm{d}x=F(x) \tag{6.3.324}$$

P4. The indefinite integral of the sum (or subtraction) of two or more algebraic functions is equal to the algebraic sum of their integral (do not forget that we work with the set of all primitives and not a specific given one primitive!):

$$\int [f_1(x)+f_2(x)]\,\mathrm{d}x=\int f_1(x)\mathrm{d}x+\int f_2(x)\mathrm{d}x \tag{6.3.325}$$

Proof 6.14.5. To prove this, following the request of a reader, we will prove that the derivative of the left-hand side allows us to find the derivative of the right-hand side and vice versa (reciprocal) with the above properties.

According to P1 we have:

$$\left(\int [f_1(x)+f_2(x)]\,\mathrm{d}x\right)'=\left(\int f_1(x)\mathrm{d}x\right)'+\left(\int f_2(x)\mathrm{d}x\right)'=f_1(x)+f_2(x) \tag{6.3.326}$$

Let us check if it is the same with the right-hand side (we assume known the properties of derivatives that we proved earlier in this section):

$$\begin{aligned}\left(\int f_1(x)\mathrm{d}x+\int f_2(x)\mathrm{d}x\right)'&=\left(\int f_1(x)\mathrm{d}x\right)'+\left(\int f_2(x)\mathrm{d}x\right)'\\&=f_1(x)+f_2(x)\end{aligned} \tag{6.3.327}$$

■ Q.E.D.

P5. We can get out a constant factor from the integral sign, that is to say:

$$\int c^{te}f(x)\mathrm{d}x=c^{te}\int f(x)\mathrm{d}x \tag{6.3.328}$$

We justify this equality by deriving the two members (and according to the properties of derivatives):

$$\begin{aligned}\left(\int c^{te}f(x)\mathrm{d}x\right)'&=c^{te}f(x)\\\left(c^{te}\int f(x)\mathrm{d}x\right)'&=c^{te}\left(\int f(x)\mathrm{d}x\right)'=c^{te}f(x)\end{aligned} \tag{6.3.329}$$

P6. We can take out a constant factor in the argument of the integrated function (rather rarely used):

$$\int f(ax)\mathrm{d}x=\frac{1}{a}F(ax)+c^{te} \tag{6.3.330}$$

Indeed, by differentiating both members of equality we have following the properties of derivatives:

$$\left(\int f(ax)\mathrm{d}x\right)'=\left(\frac{1}{a}F(ax)+c^{te}\right)'=f(ax) \tag{6.3.331}$$

P7. The integration of a function whose argument is summed (or subtracted) is algebraically the primitive of the argument summed (respectively subtracted):

$$\int f(x+b)\mathrm{d}x = F(x+b)+c^{te} \tag{6.3.332}$$

This property can be showed identically to the previous one using also the derivatives properties.

P8. The combination of properties P6 and P7 allows us to write:

$$\int f(ax+b)\mathrm{d}x = \frac{1}{a}F(ax+b)+c^{te} \tag{6.3.333}$$

P9. Let f be a continuous function on $[a,b]$, we have for all c belonging to this interval:

$$\int\limits_a^b f(x)\mathrm{d}x = \int\limits_a^c f(x)\mathrm{d}x + \int\limits_c^b f(x)\mathrm{d}x \tag{6.3.334}$$

This theorem, sometimes named "Chasles relation" (by its vector equivalent) follows directly from the definition of the indefinite integral. F being a primitive of f on $[a,b]$ we have:

$$F(c)-F(a)+F(b)-F(c) = F(b)-F(a) \tag{6.3.335}$$

P10. This is a property often used in the section of Statistics (we do not find an easy way to express this property by everyday language so...):

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}y}\int\limits_{g(x)}^{h(y)} f(t)\mathrm{d}t &= \frac{\mathrm{d}}{\mathrm{d}y}\left(F(h(y))-F(g(x))\right)\\ &= f(h(y))\frac{\mathrm{d}h(y)}{\mathrm{d}y}+f(g(x))\frac{\mathrm{d}g(x)}{\mathrm{d}y}\\ &= f(h(y))h'(y)\end{aligned} \tag{6.3.336}$$

Let us see now two properties that will be helpful we sometimes to calculate difficult integrals:

P11. If a function is even (see section Functional Analysis page 2212), the integral on symmetrical bounds is equivalent to:

$$\begin{aligned}\int\limits_{-L}^{+L} f(x)\mathrm{d}x &= \int\limits_{-L}^{0} f(x)\mathrm{d}x + \int\limits_{0}^{+L} f(x)\mathrm{d}x = \int\limits_{-L}^{0} \underset{u=-x}{f(-x)\mathrm{d}x} + \int\limits_{0}^{+L} f(x)\mathrm{d}x\\ &= -\int\limits_{-L}^{0} f(u)\mathrm{d}u + \int\limits_{0}^{+L} f(x)\mathrm{d}x = \int\limits_{0}^{+L} f(u)\mathrm{d}u + \int\limits_{0}^{+L} f(x)\mathrm{d}x = 2\int\limits_{0}^{+L} f(x)\mathrm{d}x\end{aligned} \tag{6.3.337}$$

P12. If a function is odd (see section Functional Analysis page 2212), the integral on symmetrical bounds is equivalent to:

$$\begin{aligned}\int\limits_{-L}^{+L} f(x)\mathrm{d}x &= \int\limits_{-L}^{0} f(x)\mathrm{d}x + \int\limits_{0}^{+L} f(x)\mathrm{d}x = \int\limits_{-L}^{0} -f(-x)\mathrm{d}x + \int\limits_{0}^{+L} f(x)\mathrm{d}x \\ &= \underset{u=-x}{\int\limits_{0}^{+L} f(-x)\mathrm{d}y} + \int\limits_{0}^{+L} f(x)\mathrm{d}x = -\int\limits_{0}^{+L} f(u)\mathrm{d}u + \int\limits_{0}^{+L} f(x)\mathrm{d}x = 0\end{aligned} \tag{6.3.338}$$

P13. The integral of a periodic function is invariant under a shift of its integration. This is a property that we will use further below to finalize the proof of the integral representation of the zero order Bessel function of the first type.

If f is a periodic function of period T we know that for any value a:

$$\int\limits_{a}^{a+T} f(t)\mathrm{d}t = \int\limits_{0}^{T} f(t)\mathrm{d}t \tag{6.3.339}$$

So now consider:

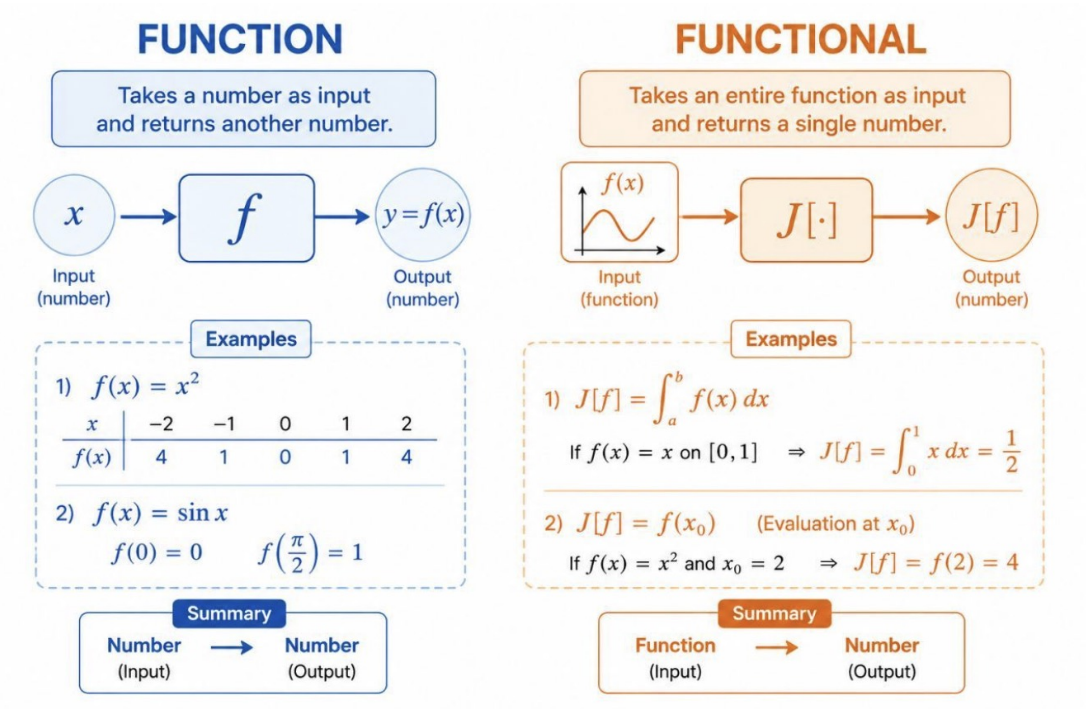
$$\int\limits_{a}^{a+T} f(t)\mathrm{d}t = \int\limits_{0}^{T} f(t)\mathrm{d}t + \int\limits_{T}^{a+T} f(t)\mathrm{d}t \tag{6.3.340}$$

We do the change of variable $y = t - T$, then we have for the last integral:

$$\int\limits_{a}^{a+T} f(t)\mathrm{d}t = \int\limits_{0}^{T} f(y+T)\mathrm{d}y = \int\limits_{0}^{a} f(y)\mathrm{d}y \tag{6.3.341}$$

Therefore:

$$\int\limits_{a}^{a+T} f(t)\mathrm{d}t = \int\limits_{0}^{T} f(t)\mathrm{d}t + \int\limits_{0}^{a} f(y)\mathrm{d}y = \int\limits_{0}^{T} f(t)\mathrm{d}t \tag{6.3.342}$$



FUNCTION

Takes a number as input and returns another number.

$x \rightarrow \boxed{f} \rightarrow y=f(x)$

Input (number) Output (number)

Examples

1) $f(x) = x^2$

x	-2	-1	0	1	2
$f(x)$	4	1	0	1	4

2) $f(x) = \sin x$

$f(0) = 0 \qquad f\left(\frac{\pi}{2}\right) = 1$

Summary

Number (Input) → Number (Output)

FUNCTIONAL

Takes an entire function as input and returns a single number.

$f(x) \rightarrow \boxed{J[\cdot]} \rightarrow J[f]$

Input (function) Output (number)

Examples

1) $J[f] = \int_a^b f(x)\,dx$

If $f(x) = x$ on $[0,1]$ $\Rightarrow J[f] = \int_0^1 x\,dx = \frac{1}{2}$

2) $J[f] = f(x_0)$ (Evaluation at x_0)

If $f(x) = x^2$ and $x_0 = 2$ $\Rightarrow J[f] = f(2) = 4$

Summary

Function (Input) → Number (Output)

6.3.2.3 Double Integral

The idea of double integrals is to measure the volume of the area bounded by the graph of a function of two variables over a domain D of the plane (below D is rectangular):

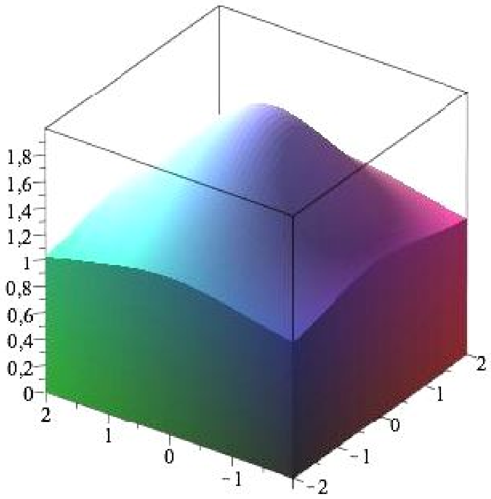


Figure 6.50: **Example of a continuous function of two variables over a squared domain**

It could be obvious to the reader that double integrals are extremely important in the field of Applied Mathematics!

Again, the idea is the same as the definite integral. If we adapt a simplistic approach, we decompose the continuous function like a staircase and the volume to calculate is then reduced to the sum of the volumes of parallelepipeds:

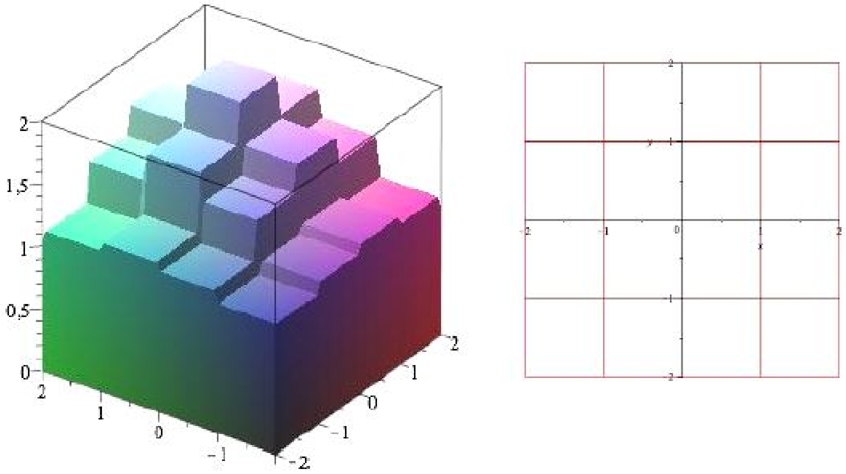

Figure 6.51: **Volume decomposition into big parallelepipeds**

Therefore we have the double sum:

$$V \cong \sum f(x_i,y_i)\Delta x_i \Delta y_i = \sum f(x_i,y_i)\Delta y_i \Delta x_i \qquad (6.3.343)$$

For a continuous function, we proceed by successive approximations: we calculate the Riemann sums for subdivisions always thinner and thinner of the domain D:

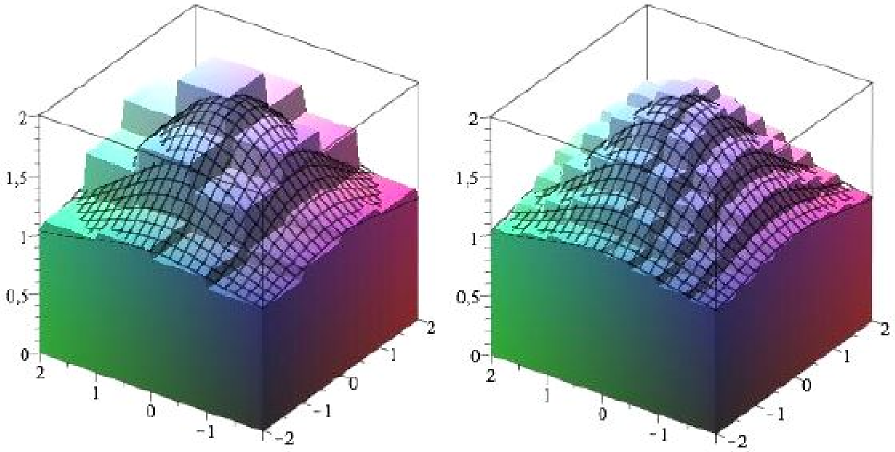

Figure 6.52: Decomposition of the volume in always thinner parallelepipeds

and therefore at the limit:

$$V=\iint_D f(x,y)\mathrm{d}x\mathrm{d}y=\iint_D f(x,y)\mathrm{d}y\mathrm{d}x \tag{6.3.344}$$

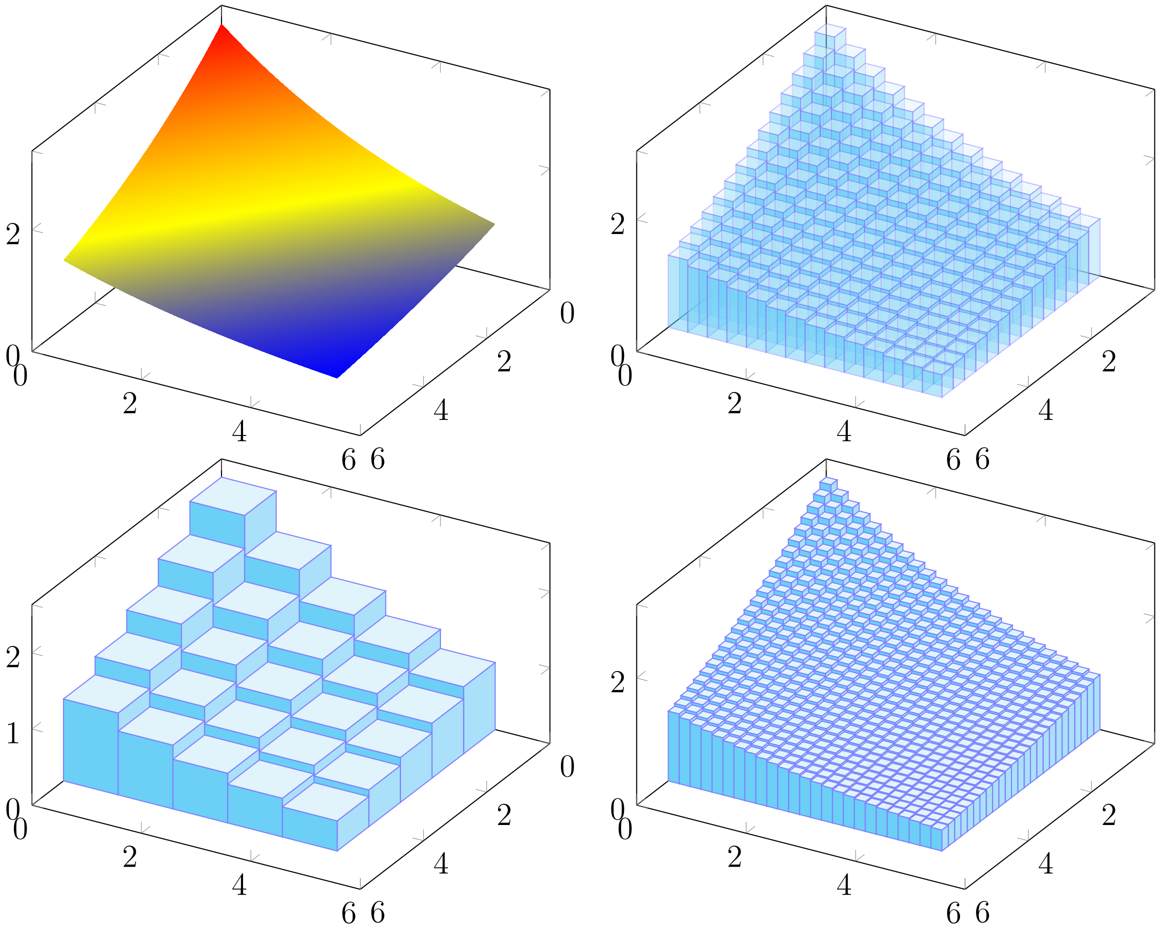

Figure 6.53: Illustration of a double integral on a square domain with TikZ

But..., when we want to integrate an area that is not rectangular, things get a priori more complicated ... Let's see a workaround.

For this purpose, we will build closed bounded domain D as follows:

$$(x,y)\in D\Leftrightarrow\begin{cases}x\in[a,b]\\ y\in[u(x),v(x)]\end{cases} \tag{6.3.345}$$

where the reader will have noticed that the support is the variable x by trough the two functions u and v. This then is what we name a "type I domain" (and therefore if it is y that parametrizes x then it is "type II domain").

This can be illustrated by the figure below:

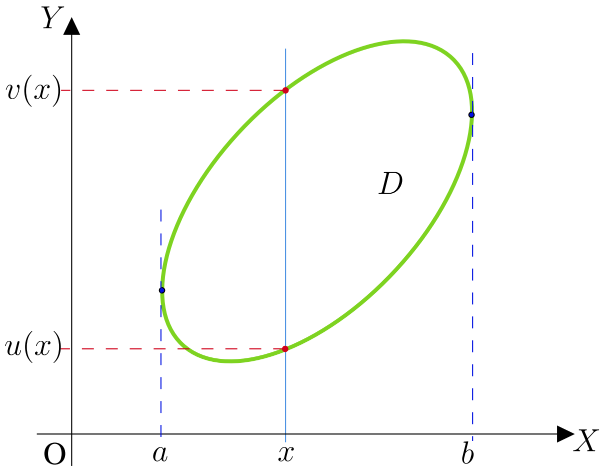

Figure 6.54: **Example of a type I domain**

where we notice that this simplistic approach (there are other possible approaches but that need the use of Measurement Theory) requires that the domain is simply convex[5] (that is to say they are no holes outside the domain D between $u(x)$ and $v(x)$) or decomposed into simply convex disjoint subdomains.

To resume, we can integrate as follows:

$$V=\iint_D f(x,y)\mathrm{d}x\mathrm{d}y=\int\limits_a^b\left(\int\limits_{u(x)}^{v(x)}f(x,y)\mathrm{d}y\right)\mathrm{d}x \tag{6.3.346}$$

So we transform the double integral in two nested simple integrals.

---

[5] As we have seen in the section of Geometric Shapes an area is convex if any couple of points on the bounds of the area with a crossing line has this latter no outside of the area

6.3.2.3.1 Fubini's theorem

We will see now an important theorem used repeatedly in different section of this textbook and which permits to reverse the order of integration.

Remembering that:

$$(x,y)\in D \Leftrightarrow \begin{cases} x\in[a,b] \\ y\in[u(x),v(x)] \end{cases} \tag{6.3.347}$$

we can also use:

$$(x,y)\in D \Leftrightarrow \begin{cases} y\in[c,d] \\ x\in[\alpha(y),\beta(y)] \end{cases} \tag{6.3.348}$$

So with this parametrization we can write:

$$V=\iint_D f(x,y)\mathrm{d}x\mathrm{d}y=\int\limits_a^b\left(\int\limits_{u(x)}^{v(x)} f(x,y)\mathrm{d}y\right)\mathrm{d}x=\int\limits_c^d\left(\int\limits_{\alpha(y)}^{\beta(y)} f(x,y)\mathrm{d}x\right)\mathrm{d}y \tag{6.3.349}$$

We can change the order of integration, the calculation is different, but the result is the same. But that's not what really interests us here!

Consider a function such as (we say that the function can be "variable separable"):

$$f(x,y)=\varphi(x)\psi(y) \tag{6.3.350}$$

Therefore:

$$V=\iint_D f(x,y)\mathrm{d}x\mathrm{d}y=\int\limits_a^b\left(\int\limits_{u(x)}^{v(x)} f(x,y)\mathrm{d}y\right)\mathrm{d}x=\int\limits_a^b\left(\int\limits_{u(x)}^{v(x)} \varphi(x)\psi(y)\mathrm{d}y\right)\mathrm{d}x \tag{6.3.351}$$

Suppose that the domain is a rectangle (we do this simplification otherwise the proof complicates considerably). Meaning:

$$(x,y)\in D \Leftrightarrow \begin{cases} x\in[a,b] \\ y\in[c,d] \end{cases} \tag{6.3.352}$$

Therefore the integral linearity property:

$$\begin{aligned} V&=\int\limits_a^b\left(\int\limits_{u(x)}^{v(x)} \varphi(x)\psi(y)\mathrm{d}y\right)\mathrm{d}x=\int\limits_a^b\left(\int\limits_c^d \varphi(x)\psi(y)\mathrm{d}y\right)\mathrm{d}x=\int\limits_a^b\left(\varphi(x)\int\limits_c^d \psi(y)\mathrm{d}y\right)\mathrm{d}x \\ &=\int\limits_a^b\varphi(x)\left(\int\limits_c^d \psi(y)\mathrm{d}y\right)\mathrm{d}x=\left(\int\limits_c^d \psi(y)\mathrm{d}y\right)\int\limits_a^b\varphi(x)\mathrm{d}x=\int\limits_a^b\varphi(x)\mathrm{d}x\int\limits_c^d \psi(y)\mathrm{d}y \end{aligned} \tag{6.3.353}$$

6.3.2.4 Integration by Substitution

When we can not easily determine the primitive of a given function, we can find sometimes, with a smart change of variables (sometimes very subtle...), bypass the difficulty. It does not work every time (because some functions are not formally integrable) but it is worth a try before taking out your computer.

Again, we give only the general form of the method. It is the role of teachers in schools to train, and train, and train students to understand and master these techniques. In addition, the sections in this textbook that treats of exact sciences (physics, computer science, astrophysics, chemistry, ...) replete with examples using this technique and thus serve implicitly as exercises.

Consider we want to calculate the integral (not bounded for the moment):

$$\int f(x)\mathrm{d}x \tag{6.3.354}$$

although we do not know directly how to calculate the primitive of this function $f(x)$ (at least we imagine being in that situation) we know (in one way or another) that exists (we do treat of improper integrals at this level).

The technique then consists in this integral to perform the following change of variable:

$$x=\varphi(t) \tag{6.3.355}$$

where $\varphi(t)$ is a continuous function and also its derivative, and having an inverse function. Then $\mathrm{d}x=\varphi'(t)\mathrm{d}t$, and let us prove now that in this case the equality:

$$\int f(x)\mathrm{d}x=\int f(\varphi(t))\varphi'(t)\mathrm{d}t \tag{6.3.356}$$

is satisfied.

Proof 6.14.6. We imply here that the variable t will be replaced after integration of the right member by its expression in function of x. To justify this equality in this sense, it suffices to show that the considered amounts where each is a defined only with a difference of a given arbitrary constant have the same derivative with respect to x. The derivative of the left member is:

$$\left(\int f(x)\mathrm{d}x\right)'=f(x) \tag{6.3.357}$$

We derive only the right member with respect to x considering that t is a function of x. We know that:

$$\frac{\mathrm{d}x}{\mathrm{d}t}=\varphi'(t) \tag{6.3.358}$$

We get therefore:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}x}\left(\int f(\varphi(t))\varphi'(t)\mathrm{d}t\right)&=\frac{d}{\mathrm{d}t}\left(\int f(\varphi(t))\varphi'(t)\mathrm{d}t\right)\frac{\mathrm{d}t}{\mathrm{d}x}\\&=f(\varphi(t))\varphi'(t)\frac{1}{\varphi'(t)}\\&=f(\varphi(t))\\&=f(x)\end{aligned} \tag{6.3.359}$$

■ Q.E.D.

Obviously, the function $x=\varphi(t)$ must be chosen so that we know how to calculate the indefinite integral on the right side of equality.

Remark

Sometimes it is preferable to choose the change of variable in the form $t=\varphi(x)$ instead of $x=\psi(t)$ because as this to a large tendency to simplify the length of the equation instead of making it longer.

It is obvious that this theorem will be more explicitly written:

$$\boxed{\int\limits_{\varphi(a)}^{\varphi(b)} f(x)\mathrm{d}x=\int\limits_{a}^{b} f(\varphi(t))\varphi'(t)\mathrm{d}t} \tag{6.3.360}$$

6.3.2.4.1 Jacobian

Consider a domain D of the plane u, v delimited by a curve L. Suppose that the x, y coordinates are functions of the new variables u, v (always in the context of a change of variables!) by the following relations:

$$\begin{gathered} x=\varphi(u,v) \quad y=\phi(u,v) \\ (x,y)\in D \underset{\varphi,\phi}{\longrightarrow} (\varphi,\phi)\in D' \end{gathered} \tag{6.3.361}$$

where the functions $\varphi(x,y)$ and $\phi(u,v)$ are unique, continuous and have continuous derivatives in a given domain D' which we will define later. It corresponds therefore following previous relations to any pair of values u, v only one couple of values x, y and vice versa.

It follows from what was said just before that at any point $P(x,y)$ of the plane Oxy corresponds univocally a point $P'(u,v)$ of the plane Ouv of coordinates u, v defined by the above relations. The numbers v and u will be named "curvilinear coordinates" of P and we will see concrete and schematics examples of these in the section of Vector Calculus.

If in the Oxy plane the set of points P describes a closed curve L defining a domain D, the corresponding set of points describes in Ouv a given domain D'. It corresponds to any point of D' a point of D. Thus, the relations of transformation establish a bi-univocal correspondence between the points of the domains D and D'.

Now consider in D' a straight line of equation $u=c^{te}$. In general, the relations of transformation make it corresponds in the plane Oxy a curved line (or vice versa). Therefore, let us cut the domain D' by the multiple straight lines of equations $u=c^{te}$ and $v=c^{te}$ into small rectangular areas (we will not take into account at the limit, the rectangles on the boundary of D'). The corresponding curves of the domain D then cut this latter it into quadrilateral (defined by curves therefore). Obviously, the reverse applies!

Consider in the plane Ouv the rectangle $\Delta s'$ limited by the straight lines:

$$\begin{gathered} u=c^{te}, u+\Delta u=c^{te} \\ v=c^{te}, v+\Delta v=v^{te} \end{gathered} \tag{6.3.362}$$

and the curvilinear quadrilateral corresponding Δs in the plane Oxy. We will designate areas of these partial domains also by $\Delta s'$ by Δs. We have obviously:

$$\Delta s' = \Delta u \Delta v \tag{6.3.363}$$

The areas Δs and $\Delta s'$ are different in general.

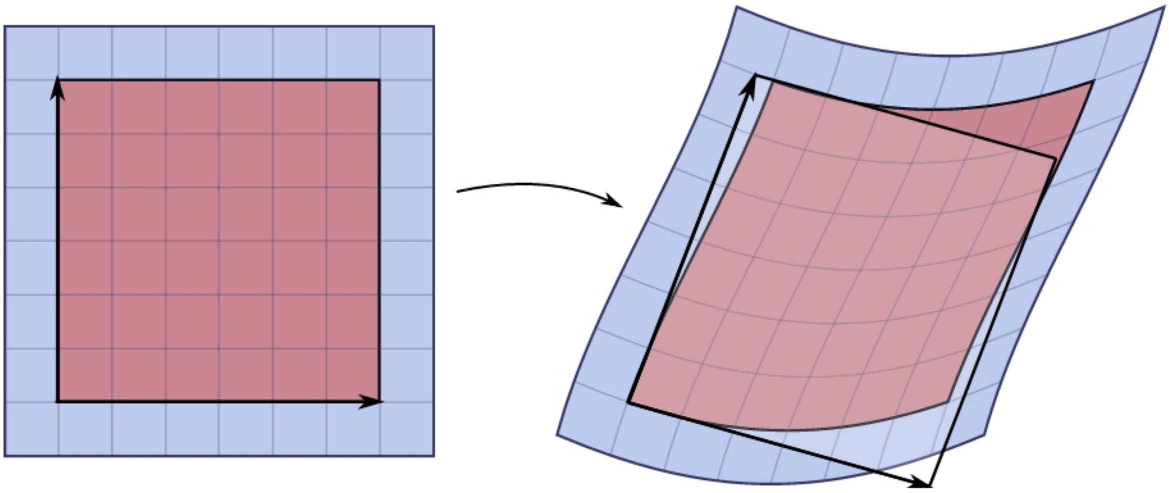

Figure 6.55: **A nonlinear map $f:\mathbb{R}^2 \mapsto \mathbb{R}^2$ sends a small square to a distorted parallelogram**

Suppose in D a continuous function $z=f(x,y)$. It corresponds to any value of this function of the domain D the same value $z=F(u,v)$ (what we want to check) in D', where:

$$F(u,v)=f(x,y)=f\left(\varphi(u,v),\phi(u,v)\right) \tag{6.3.364}$$

Consider the integrals sum of the function z in the domain D. We obviously have the following equality:

$$\sum f(x,y)\Delta s=\sum F(u,v)\Delta s \tag{6.3.365}$$

Let us calculate Δs, that is to say the area of the curvilinear quadrilateral P_1,P_2,P_3,P_4 in the plane Oxy:

We determine the coordinates of its vertices:

$$\begin{array}{lll}
P_1(x_1,y_1) & x_1=\varphi(u,v) & y_1=\phi(u,v)\\
P_2(x_2,y_2) & x_2=\varphi(u+\Delta u,v) & y_2=\phi(u+\Delta u,v)\\
P_3(x_3,y_3) & x_3=\varphi(u+\Delta u,v+\Delta v) & y_3=\phi(u+\Delta u,v+\Delta v)\\
P_4(x_4,y_4) & x_4=\varphi(u,v+\Delta v) & y_4=\phi(u,v+\Delta v)
\end{array}$$

We will assimilate in the calculation of the are of the quadrilateral P_1,P_2,P_3,P_4 the arcs $P_1P_2,P_2P_3,P_3P_4,P_4P_1$ to parallel line segments. We will also replace the increasing values of the functions by their differentials. This means that we ignore the infinitely small differentials of higher order than Δu and Δv. The previous relations then become:

$$\begin{array}{ll}
x_1=\varphi(u,v) & y_1=\phi(u,v)\\
x_2=\varphi(u,v)+\dfrac{\partial\varphi}{\partial u}\Delta u & y_2=\phi(u,v)+\dfrac{\partial\phi}{\partial u}\Delta u\\
x_3=\varphi(u,v)+\dfrac{\partial\varphi}{\partial u}\Delta u+\dfrac{\partial\varphi}{\partial v}\Delta v & y_3=\phi(u,v)+\dfrac{\partial\phi}{\partial u}\Delta u+\dfrac{\partial\phi}{\partial v}\Delta v\\
x_4=\varphi(u,v)+\dfrac{\partial\varphi}{\partial v}\Delta v & y_4=\phi(u,v)+\dfrac{\partial\phi}{\partial v}\Delta v
\end{array} \tag{6.3.366}$$

Under these assumptions, the curvilinear quadrilateral $P_1P_2P_3P_4$ can be likened to a parallelogram. His area is therefore approximately equal to twice the area of the triangle $P_1P_2P_3$, area that we can calculate by using the properties of the determinant (as we will prove it in the section on Linear Algebra, in $\mathbb{R}^2$ the determinant represents a parallelogram while in $\mathbb{R}^3$ it represents the volume of a parallelepiped):

$$\begin{aligned}\Delta s &\cong |\det(\vec{v}_1,\vec{v}_2)| = |\det(M)|\\ &= \left|\det\begin{bmatrix} a_{11} & a_{12}\\ a_{21} & a_{22}\end{bmatrix}\right| = |a_{11}a_{22}-a_{21}a_{12}|\end{aligned} \tag{6.3.367}$$

Such as (this is here that the best choice has to be done so that the final expression is the simplest and most aesthetic, for this purpose we proceed by trials and finally we make the choice below):

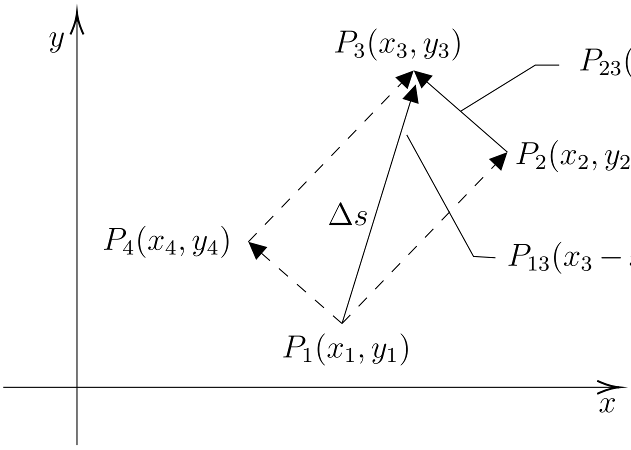

Figure 6.56: **Graphical representation of the determinant**

Thus we have:

$$\begin{aligned}\Delta s &\cong |\det(\vec{v}_1,\vec{v}_2)| = |D(\vec{P}_{13},\vec{P}_{23})|\\ &= \left|\det\begin{bmatrix}(x_3-x_1) & (x_3-x_2)\\ (y_3-y_1) & (y_3-y_2)\end{bmatrix}\right|\\ &= |(x_3-x_1)(y_3-y_2)-(x_3-x_2)(y_3-y_1)|\\ &= \left|\left(\frac{\partial\varphi}{\partial u}\Delta u+\frac{\partial\varphi}{\partial v}\Delta v\right)\frac{\partial\phi}{\partial v}\Delta v-\left(\frac{\partial\phi}{\partial u}\Delta u+\frac{\partial\phi}{\partial v}\Delta v\right)\frac{\partial\varphi}{\partial v}\Delta v\right|\\ &= \left|\frac{\partial\varphi}{\partial u}\frac{\partial\phi}{\partial v}\Delta u\Delta v-\frac{\partial\varphi}{\partial v}\frac{\partial\phi}{\partial u}\Delta u\Delta v\right|\\ &= \left|\frac{\partial\varphi}{\partial u}\frac{\partial\phi}{\partial v}\Delta u\Delta v-\frac{\partial\varphi}{\partial v}\frac{\partial\phi}{\partial u}\Delta u\Delta v\right| = \left|\frac{\partial\varphi}{\partial u}\frac{\partial\phi}{\partial v}-\frac{\partial\varphi}{\partial v}\frac{\partial\phi}{\partial u}\right|\Delta u\Delta v\\ &= |\det(J)|\Delta u\Delta v\\ &= \left|\det\begin{bmatrix}\dfrac{\partial\varphi}{\partial u} & \dfrac{\partial\varphi}{\partial v}\\ \dfrac{\partial\phi}{\partial u} & \dfrac{\partial\phi}{\partial v}\end{bmatrix}\right|\Delta s'\end{aligned} \tag{6.3.368}$$

Therefore the following relation (containing what is usually named the "functional determinant"):

$$\Delta s\cong\left|\det\begin{bmatrix}\dfrac{\partial\varphi}{\partial u} & \dfrac{\partial\varphi}{\partial v}\\ \dfrac{\partial\phi}{\partial u} & \dfrac{\partial\phi}{\partial v}\end{bmatrix}\right|\Delta s' \tag{6.3.369}$$

with:

$$J=\begin{bmatrix}\dfrac{\partial\varphi}{\partial u} & \dfrac{\partial\varphi}{\partial v}\\ \dfrac{\partial\phi}{\partial u} & \dfrac{\partial\phi}{\partial v}\end{bmatrix} \tag{6.3.370}$$

that is the "Jacobian matrix" (its determinant is simply named the "Jacobian" (for short)) of the coordinate transformation $\mathbb{R}^2\rightarrow\mathbb{R}^3$. By applying exactly the same reasoning to $\mathbb{R}^3$, then the Jacobian is written (by changing some notations because otherwise it becomes unreadable):

$$J=\begin{bmatrix}\dfrac{\partial P}{\partial u} & \dfrac{\partial P}{\partial v} & \dfrac{\partial P}{\partial w}\\ \dfrac{\partial Q}{\partial u} & \dfrac{\partial Q}{\partial v} & \dfrac{\partial Q}{\partial w}\\ \dfrac{\partial R}{\partial u} & \dfrac{\partial R}{\partial v} & \dfrac{\partial R}{\partial w}\end{bmatrix} \tag{6.3.371}$$

In short, what it is useful exactly? Well let us come back to our relation:

$$\Delta s\cong|\det(J)|\Delta s' \tag{6.3.372}$$

which is finally only an approximation because in the calculations of the area Δs we neglected the infinitely small differential of higher order. However, more the dimensions of the elementary domains Δs and $\Delta s'$ are small, and more we are approaching the true equality. The equality finally taking place when we go to the limit (finally also in math we make approximations... eh!), the surfaces of the elementary domains tending to zero:

$$|\det(J)|=\lim_{\Delta s\rightarrow 0}\frac{\Delta s}{\Delta s'} \tag{6.3.373}$$

We apply now the equality obtained to calculate the double integral (we can do the same with the triple of course). So we can finally write (this is the only way of putting the thing that makes sense):

$$\begin{gathered}\sum f(x,y)\Delta s=\sum F(u,v)\Delta s\\ \Downarrow\\ \sum f(x,y)\Delta s\cong\sum F(u,v)|\det(J)|\Delta s'\end{gathered} \tag{6.3.374}$$

Passing to the limit, we get the strict equality:

$$\boxed{\iint_D f(x,y)\mathrm{d}x\mathrm{d}y=\iint_{D'} F(u,v)|\det(J)|\mathrm{d}u\mathrm{d}v} \tag{6.3.375}$$

This is the coordinate transformation relation in a double integral! It allows us to reduce the calculation of a double integral in the domain D to domain D', which can simplify the problem. Similarly, for a triple integral, we write:

$$\boxed{\iiint_D f(x,y,z)\mathrm{d}x\mathrm{d}y\mathrm{d}z=\iiint_{D'} F(u,v,w)|\det(J)|\mathrm{d}u\mathrm{d}v\mathrm{d}w} \tag{6.3.376}$$

✍**Examples:**

Let us now determine the Jacobian for the most common coordinate systems (we send the reader back again to Vector Calculus section for more information about these systems):

E1. Polar coordinates $x=r\cos(\phi),y=r\sin(\phi)$:

$$\left|\det\begin{bmatrix}\dfrac{\partial x}{\partial r} & \dfrac{\partial x}{\partial \phi}\\ \dfrac{\partial y}{\partial r} & \dfrac{\partial y}{\partial \phi}\end{bmatrix}\right|=\left|\det\begin{bmatrix}\cos(\phi) & -r\sin(\phi)\\ \sin(\phi) & r\cos(\phi)\end{bmatrix}\right|=|r| \tag{6.3.377}$$

Since r^2 is always positive, we simply write:

$$|\det(J)|=r \tag{6.3.378}$$

E2. In cylindrical coordinates $x=r\cos(\phi),y=r\sin(\phi),z=z$ (see section Linear Algebra page 1961 for the calculation of such a determinant):

$$\begin{aligned}\left|\det\begin{bmatrix}\dfrac{\partial x}{\partial r} & \dfrac{\partial x}{\partial \phi} & \dfrac{\partial x}{\partial z}\\ \dfrac{\partial y}{\partial r} & \dfrac{\partial y}{\partial \phi} & \dfrac{\partial y}{\partial z}\\ \dfrac{\partial z}{\partial r} & \dfrac{\partial z}{\partial \phi} & \dfrac{\partial z}{\partial z}\end{bmatrix}\right| &= \left|\det\begin{bmatrix}\cos(\phi) & -r\sin(\phi) & 0\\ \sin(\phi) & r\cos(\phi) & 0\\ 0 & 0 & 1\end{bmatrix}\right|\\ &=\left|\begin{bmatrix}\cos(\phi)r\cos(\phi)\cdot 1-\cos(\phi)\cdot 0\cdot 0\\ +r\sin(\phi)\sin(\phi)\cdot 1-r\sin(\phi)\cdot 0\cdot 0\\ +0\cdot\sin(\phi)\cdot 0-1\cdot r\cos(\phi)\cdot 0\end{bmatrix}\right|\\ &=|r|\end{aligned} \tag{6.3.379}$$

Since r is always positive, we simply write:

$$|\det(J)|=r \tag{6.3.380}$$

E3. In spherical coordinates $x=r\sin(\theta)\cos(\phi),y=r\sin(\theta)\sin(\phi),z=r\cos(\theta)$ (see section Linear Algebra page 1961 for the calculation of such a determinant):

$$\begin{aligned}\left|\det\begin{bmatrix}\dfrac{\partial x}{\partial r} & \dfrac{\partial x}{\partial \phi} & \dfrac{\partial x}{\partial \theta}\\ \dfrac{\partial y}{\partial r} & \dfrac{\partial y}{\partial \phi} & \dfrac{\partial y}{\partial \theta}\\ \dfrac{\partial z}{\partial r} & \dfrac{\partial z}{\partial \phi} & \dfrac{\partial z}{\partial \theta}\end{bmatrix}\right| &= \left|\det\begin{bmatrix}\sin(\theta)\cos(\phi) & -r\sin(\theta)\sin(\phi) & r\cos(\theta)\cos(\phi)\\ \sin(\theta)\sin(\phi) & r\sin(\theta)\cos(\phi) & r\cos(\theta)\sin(\phi)\\ \cos(\theta) & 0 & -r\sin(\theta)\end{bmatrix}\right|\\ &=\left|\begin{matrix}-\sin(\theta)\cos(\phi)r\sin(\theta)\cos(\phi)r\sin(\theta)-\sin(\theta)\cos(\phi)r\cos(\theta)\sin(\phi)\cdot 0\\ -r\sin(\theta)\sin(\phi)\sin(\theta)\sin(\phi)r\sin(\theta)-r\sin(\theta)\sin(\phi)r\cos(\theta)\sin(\phi)\cos(\theta)\\ +r\cos(\theta)\cos(\phi)\sin(\theta)\sin(\phi)\cdot 0+r\cos(\theta)\cos(\phi)r\sin(\theta)\cos(\phi)r\sin(\theta)\end{matrix}\right|\\ &=\left|\begin{matrix}-(\sin^3(\theta)\cos^2(\phi)r^2+\sin^3(\theta)\sin^2(\phi)r^2)\\ -(r^2\sin(\theta)\sin^2(\phi)\cos^2(\theta)+r^2\cos^2(\theta)\cos^2(\phi)\sin(\theta))\end{matrix}\right|\\ &=|-\sin^3(\theta)r^2-r^2\sin(\theta)\cos^2(\theta)|\\ &=|-r^2\sin(\theta)(\sin^2(\theta)+\cos^2(\theta))|\\ &=|-r^2\sin(\theta)|\end{aligned} \tag{6.3.381}$$

Since r is always positive, we simply write:

$$|\det(J)| = r^2 \sin(\theta) \quad \text{with} \quad \sin(\theta) \geq 0 \tag{6.3.382}$$

The definition of differentiability in multivariable calculus is a bit technical. There are subtleties to watch out for, as one has to remember the existence of the derivative is a more stringent condition than the existence of partial derivatives. But, in the end, if our function is nice enough so that it is differentiable, then the derivative itself isn't too complicated. It's a fairly straightforward generalization of the single variable derivative.

In single variable calculus, you learned that the derivative of a function $f:\mathbb{R}\rightarrow\mathbb{R}$ at a single point is just a real number, the rate of increase of the function (i.e., slope of the graph) at that point. We could think of that number as a 1×1 matrix, so if we like, we could denote the derivative of $f(x)$ at $x=a$ as:

$$\mathrm{D}f(a) = \left[\dfrac{\mathrm{d}f}{\mathrm{d}x}(a)\right] \tag{6.3.383}$$

For a scalar-valued function of multiple variables, such as $f(x,y)$ or $f(x,y,z)$, we can think of the partial derivatives as the rates of increase of the function in the coordinate directions. If the function is differentiable, then the derivative is simply a row matrix containing all of these partial derivatives, which we name the "matrix of partial derivatives" (that corresponds to the Jacobian matrix). For $f:\mathbb{R}^n\rightarrow\mathbb{R}$, viewed as a $f(\vec{x})$, where $\vec{x}=(x_1,x_2,\ldots,x_n)$, the $1\times n$ matrix of partial derivatives at $\vec{x}=\vec{a}$ is:

$$\mathrm{D}f(\mathbf{a}) = \left[\dfrac{\partial f}{\partial x_1}(\vec{a}), \dfrac{\partial f}{\partial x_2}(\vec{a}), \ldots, \dfrac{\partial f}{\partial x_n}(\vec{a})\right] \tag{6.3.384}$$

The last generalization is to vector-valued functions, $f:\mathbb{R}^n\rightarrow\mathbb{R}^m$. Here, $f(\vec{x})$ is a function of the vector $\vec{x}=(x_1,x_2,\ldots,x_n)$ whose output is a vector of m components. We could write f in terms of its components as:

$$f(\vec{x}) = (f_1(\vec{x}), f_2(\vec{x}), \ldots, f_m(\vec{x})) = \begin{bmatrix} f_1(\vec{x}) \\ f_2(\vec{x}) \\ \vdots \\ f_m(\vec{x}) \end{bmatrix} \tag{6.3.385}$$

(Recall that when we view vectors as matrices, we view them as column matrices, so the components are stacked up on top of each other.)

To form the matrix of partial derivatives, we think of $f(\vec{x})$ as column matrix, where each component is a scalar-valued function. The matrix of partial derivatives of each component $f_i(\vec{x})$ would be a $1\times n$ row matrix, as above. We just stack these row matrices on top of each other to form a larger matrix. We get that the full $m\times n$ matrix of partial derivatives at $\vec{x}=\vec{a}$ is:

$$\mathrm{D}f(\vec{a}) = \begin{bmatrix} \frac{\partial f_1}{\partial x_1}(\vec{a}) & \frac{\partial f_1}{\partial x_2}(\vec{a}) & \ldots & \frac{\partial f_1}{\partial x_n}(\vec{a}) \\ \frac{\partial f_2}{\partial x_1}(\vec{a}) & \frac{\partial f_2}{\partial x_2}(\vec{a}) & \ldots & \frac{\partial f_2}{\partial x_n}(\vec{a}) \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial f_m}{\partial x_1}(\vec{a}) & \frac{\partial f_m}{\partial x_2}(\vec{a}) & \ldots & \frac{\partial f_m}{\partial x_n}(\vec{a}) \end{bmatrix} \tag{6.3.386}$$

Though we should probably refer to the derivative of f as the linear transformation that is associated with the matrix $\mathrm{D}f(\vec{a})$, it's fine at this level to refer to the "matrix of partial derivatives" $Df(\vec{a})$ as "the derivative" of f at the point $\vec{a}$ (assuming that f is differentiable at $\vec{a}$, of course).

✍**Example:**

Let $f(x,y)=x^2+y^2$. We want to find $\mathrm{D}f(1,2)$ and the equation for the tangent plane (using the multivariate Taylor development as seen at page 1714) at $(x,y)=(1,2)$.

We have first:

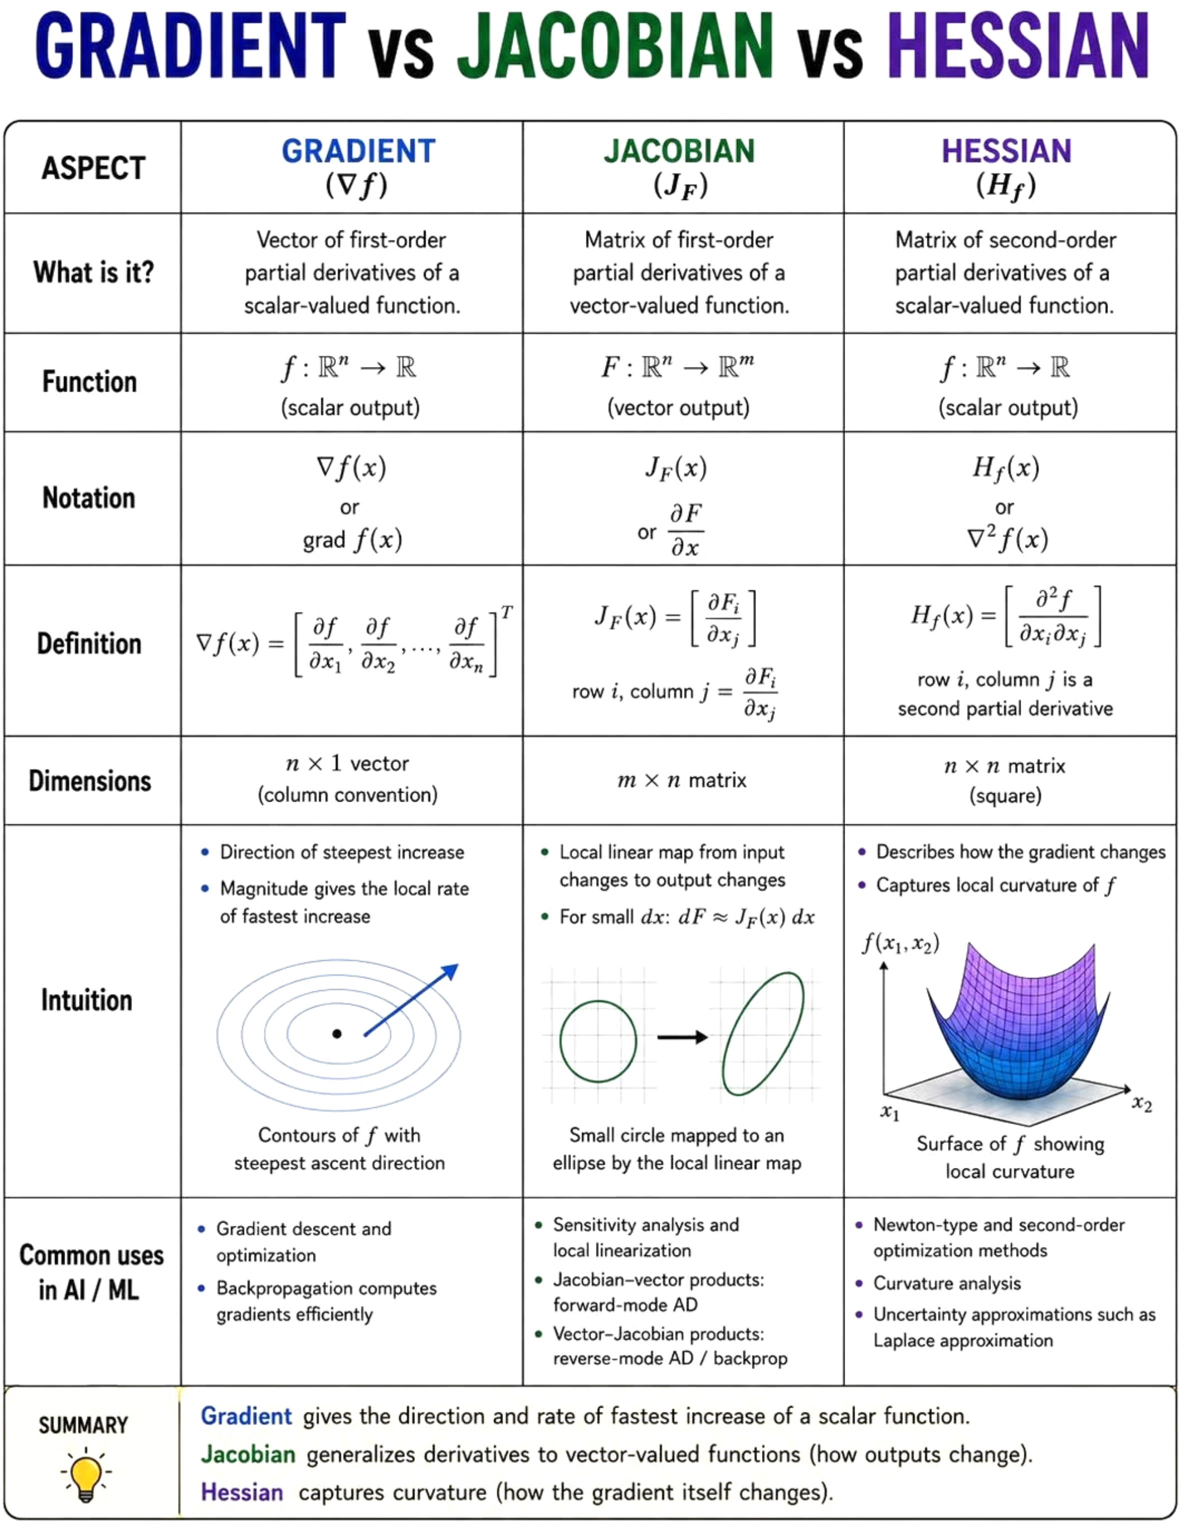
$$\begin{aligned}
&\frac{\partial f}{\partial x}(x,y)=2x\\
&\frac{\partial f}{\partial x}(1,2)=2\\
&\frac{\partial f}{\partial y}(x,y)=2y\\
&\frac{\partial f}{\partial y}(1,2)=4
\end{aligned}\tag{6.3.387}$$

So $\mathrm{D}f(1,2)=[2 \quad 4]$.

Since both partial derivatives $\frac{\partial f}{\partial x}(x,y)$ and $\frac{\partial f}{\partial y}(x,y)$ are continuous functions, we know that $f(x,y)$ is differentiable. Therefore, $\mathrm{D}f(1,2)$ is the derivative of f, and the function has a tangent plane there.

To calculate the equation of the tangent plane, the only additional calculation is the value of f at $(x,y)=(1,2)$, which is $f(1,2)=1^2+2^2=5$. The equation for the tangent plane is therefore (still using Taylor multivariate approximation):

$$\begin{aligned}
z &\cong f(1,2)+\frac{\partial f}{\partial x}(1,2)(x-1)+\frac{\partial f}{\partial y}(1,2)(y-2)\\
&=5+2(x-1)+4(y-2)
\end{aligned}\tag{6.3.388}$$



GRADIENT vs JACOBIAN vs HESSIAN

ASPECT	**GRADIENT** (∇f)	**JACOBIAN** (J_F)	**HESSIAN** (H_f)
What is it?	Vector of first-order partial derivatives of a scalar-valued function.	Matrix of first-order partial derivatives of a vector-valued function.	Matrix of second-order partial derivatives of a scalar-valued function.
Function	$f : \mathbb{R}^n \to \mathbb{R}$ (scalar output)	$F : \mathbb{R}^n \to \mathbb{R}^m$ (vector output)	$f : \mathbb{R}^n \to \mathbb{R}$ (scalar output)
Notation	$\nabla f(x)$ or grad $f(x)$	$J_F(x)$ or $\frac{\partial F}{\partial x}$	$H_f(x)$ or $\nabla^2 f(x)$
Definition	$\nabla f(x) = \left[\frac{\partial f}{\partial x_1}, \frac{\partial f}{\partial x_2}, \ldots, \frac{\partial f}{\partial x_n} \right]^T$	$J_F(x) = \left[\frac{\partial F_i}{\partial x_j} \right]$ row i, column $j = \frac{\partial F_i}{\partial x_j}$	$H_f(x) = \left[\frac{\partial^2 f}{\partial x_i \partial x_j} \right]$ row i, column j is a second partial derivative
Dimensions	$n \times 1$ vector (column convention)	$m \times n$ matrix	$n \times n$ matrix (square)
Intuition	- Direction of steepest increase - Magnitude gives the local rate of fastest increase Contours of f with steepest ascent direction	- Local linear map from input changes to output changes - For small dx: $dF \approx J_F(x)\, dx$ Small circle mapped to an ellipse by the local linear map	- Describes how the gradient changes - Captures local curvature of f Surface of f showing local curvature
Common uses in AI / ML	- Gradient descent and optimization - Backpropagation computes gradients efficiently	- Sensitivity analysis and local linearization - Jacobian–vector products: forward-mode AD - Vector–Jacobian products: reverse-mode AD / backprop	- Newton-type and second-order optimization methods - Curvature analysis - Uncertainty approximations such as Laplace approximation

SUMMARY

Gradient gives the direction and rate of fastest increase of a scalar function.
Jacobian generalizes derivatives to vector-valued functions (how outputs change).
Hessian captures curvature (how the gradient itself changes).

6.3.2.5 Integration by Parts

When we seek to make integrations, it is very common that we have to use a tool (or calculation method) named "integration by parts". There are different degrees of use of this tool and we'll start with the most simple and that is the most used in all chapters and sections in this textbook.

First we start from the derivative of the product of two functions proved above:

$$(f(t)g(t))' = f'(t)g(t) + f(t)g'(t) \tag{6.3.389}$$

so we have:

$$f(t)g'(t) = (f(t)g(t))' - f'(t)g(t) \tag{6.3.390}$$

and we get:

$$\int\limits_a^b f(t)g'(t)\mathrm{d}t = \int\limits_a^b \left[(f(t)g(t))' - f'(t)g(t)\right]\mathrm{d}t = \int\limits_a^b (f(t)g(t))'\mathrm{d}t - \int\limits_a^b f'(t)g(t)\mathrm{d}t \tag{6.3.391}$$

after a final simplification we finally get the famous very important equality:

$$\boxed{\int\limits_a^b f(t)g'(t)\mathrm{d}t = f(t)g(t)\Big|_a^b - \int\limits_a^b f'(t)g(t)\mathrm{d}t} \tag{6.3.392}$$

But sometimes we will need the generalization of that relation. We can show that if f and g are two applications (functions) of class $\mathcal{C}^n$ (n times differentiable) on $[a,b]$ in $\mathbb{C}$, then:

$$\int\limits_a^b f(t)g^{(n)}(t)\mathrm{d}t = \left[\sum_{k=0}^{n-1}(-1)^k f^{(k)}\cdot g^{(n-1-k)}\right]_a^b + (-1)^n \int\limits_a^b f^{(n)}(t)g(t)\mathrm{d}t \tag{6.3.393}$$

Proof 6.14.7. Let us proceed by induction on n (beware it is not necessarily easy to understand as often with demonstrations by induction!).

Knowing that the relation is true for $n=1$, we assume it true for n (as given in the above relation!) and we prove it for $n+1$ (so we must laid on the previous relation but with $n+1$ instead of n):

$$\begin{aligned}\int\limits_a^b f(t)\cdot g^{(n+1)}(t)\mathrm{d}t &= f(t)g^{(n)}(t)\Big|_a^b - \int\limits_a^b f'(t)g^{(n)}(t)\mathrm{d}t = f(t)g^{(n)}(t)\Big|_a^b - \left[\sum_{k=0}^{n-1}(-1)^k f^{(k+1)}g^{(n-1-k)}\right]_a^b \\ &\quad + (-1)^{n+1}\int\limits_a^b f^{(n+1)}(t)g(t)\mathrm{d}t \\ &= f(t)g^{(n)}(t)\Big|_a^b - \left[\sum_{k=0}^{n}(-1)^k f^{(k)}g^{(n-k)}\right]_a^b + (-1)^{n+1}\int\limits_a^b f^{(n+1)}(t)g(t)\mathrm{d}t \\ &= \left[\sum_{k=0}^{n}(-1)^k f^{(k)}g^{(n-k)}\right]_a^b + (-1)^{n+1}\int\limits_a^b f^{(n+1)}(t)g(t)\mathrm{d}t\end{aligned} \tag{6.3.394}$$

Remark

The trick (proposed by a reader) in this proof is to see that $-(-1)^n$ gives a minus sign when n is even and plus sign when n is odd and also that $+(-1)^{n+1}$ gives a minus sing when n is even and plus sign when n is odd.

For $n=1$ we fall back on the well known and very often used equality in this textbook:

$$\int\limits_a^b f(t)g'(t)\mathrm{d}t = f(t)g(t)\Big|_a^b - \int\limits_a^b f'(t)g(t)\mathrm{d}t \tag{6.3.395}$$

■ Q.E.D.

6.3.2.6 Usual Primitives

There are in math and physics many primitives or functions defined on integrals we see quite frequently (but not exclusively). Furthermore, all primitive proved below will be used in the various chapters on Mechanics, Engineering, Atomistic, Social Mathematics, etc of this textbook. So, as in any formula booklet, we propose you the most sixty knows primitives but with... the proofs!

> Caution! Because the fundamental theorem of calculus proved earlier above (page 1509) says that the integral of a function is the same as its antiderivative, we will not derive below the integrals of some functions for which the antiderivative can already be found in our list of usual derivatives that can be found at page 1475. Especially since the direct calculation of the integral of some simple functions (like the integral of $1/x$) is unnecessarily laborious (even if it is sometimes considered funny by some readers...).

So as just mentioned will omit the primitives that can be immediately deduced from the usual derivatives we have proved earlier. This means for example that we assume known the following very important primitives (certainly the most used in all pages of this textbook):

$$\begin{aligned}
&\int \frac{1}{x}\mathrm{d}x = \ln(x) + c^{te}\\
&\int \sin(x)\mathrm{d}x = -\cos(x) + c^{te}\\
&\int \cos(x)\mathrm{d}x = \sin(x) + c^{te}\\
&\int e^x\mathrm{d}x = e^x + c^{te}\\
&\ldots
\end{aligned} \tag{6.3.396}$$

Otherwise here is the list of the most common primitives (the reader will meet anyway many others - developed in the details - as he reads this textbook):

1. Primitive of $f(x) = \tan(x)$:

   By definition we have:

   $$\int \tan(x)\mathrm{d}x = \int \frac{\sin(x)}{\cos(x)}\mathrm{d}x \tag{6.3.397}$$

   We use the change of variable $u = \cos(x)$, $\mathrm{d}u = -\sin(x)\mathrm{d}x$ and therefore:

   $$\int \frac{\sin(x)}{\cos(x)}\mathrm{d}x = -\int \frac{1}{u}\mathrm{d}u = -\ln|u| = -\ln|\cos(x)| \tag{6.3.398}$$

   Therefore:

   $$F(x) = -\ln|\cos(x)| \tag{6.3.399}$$

2. Primitive of $f(x)=\cot(x)$:

   By definition we have:

$$\int \cot(x)\mathrm{d}x=\int \frac{\cos(x)}{\sin(x)}\mathrm{d}x \tag{6.3.400}$$

   We use the change of variable $u=\sin(x)$, $\mathrm{d}u=\cos(x)\mathrm{d}x$ and therefore:

$$\int \frac{\cos(x)}{\sin(x)}\mathrm{d}x=\int \frac{1}{u}\mathrm{d}u=\ln|u|=\ln|\sin(x)| \tag{6.3.401}$$

   Therefore:

$$F(x)=\ln|\sin(x)| \tag{6.3.402}$$

3. Primitive of $f(x)=\arcsin(x)$:

   We integrate by parts:

$$\int 1\cdot\arcsin(x)\mathrm{d}x=x\arcsin(x)-\int \frac{x}{\sqrt{1-x^2}}\mathrm{d}x \tag{6.3.403}$$

   If we put $u=1-x^2$, giving us $\mathrm{d}u=-2x\mathrm{d}x$, we get:

$$\int \frac{x}{\sqrt{1-x^2}}\mathrm{d}x=-\int \frac{1}{2\sqrt{u}}\mathrm{d}u=-\sqrt{u}=-\sqrt{1-x^2} \tag{6.3.404}$$

   Therefore:

$$F(x)=x\arcsin(x)+\sqrt{1-x^2} \tag{6.3.405}$$

4. Primitive of $f(x)=\arccos(x)$:

   We integrate by parts again:

$$\int 1\cdot\arccos(x)\mathrm{d}x=x\arccos(x)+\int \frac{x}{\sqrt{1-x^2}}\mathrm{d}x \tag{6.3.406}$$

   If we put $u=1-x^2$, giving us $\mathrm{d}u=-2x\mathrm{d}x$, we get:

$$\int \frac{x}{\sqrt{1-x^2}}\mathrm{d}x=-\int \frac{1}{2\sqrt{u}}\mathrm{d}u=-\sqrt{u}=-\sqrt{1-x^2} \tag{6.3.407}$$

   Therefore:

$$F(x)=x\arccos(x)-\sqrt{1-x^2} \tag{6.3.408}$$

5. Primitive of $f(x)=\arctan(x)$:

   We integrate by parts again:

$$\int 1\cdot\arctan(x)\mathrm{d}x=x\arctan(x)-\int \frac{x}{\sqrt{1+x^2}}\mathrm{d}x \tag{6.3.409}$$

   If we put $u=1+x^2$, giving us $\mathrm{d}u=2x\mathrm{d}x$, we get:

$$\int \frac{x}{\sqrt{1+x^2}}\mathrm{d}x=\int \frac{1}{2u}\mathrm{d}u=\frac{1}{2}\ln|u|=\frac{1}{2}\ln(1+x^2) \tag{6.3.410}$$

   Therefore:

$$F(x)=x\arctan(x)-\frac{1}{2}\ln(1+x^2) \tag{6.3.411}$$

6. Primitive of $f(x)=\text{arccot}(x)$:

   Once again... we integrate by part:

$$\int 1\cdot\text{arccot}(x)\mathrm{d}x=x\mathrm{d}(x)+\int\frac{x}{\sqrt{1+x^2}}\mathrm{d}x \tag{6.3.412}$$

   If we put $u=1+x^2$, giving us $\mathrm{d}u=2x\mathrm{d}x$, we get:

$$\int\frac{x}{\sqrt{1+x^2}}\mathrm{d}x=\int\frac{1}{2u}\mathrm{d}u=\frac{1}{2}\ln(|u|)=\frac{1}{2}\ln(1+x^2) \tag{6.3.413}$$

   Therefore:

$$F(x)=x\text{arccot}(x)+\frac{1}{2}\ln(1+x^2) \tag{6.3.414}$$

7. Primitive of $f(x)=xe^{ax}$ with $a\in\mathbb{R}\{0\}$:

   An integration by part gives:

$$\int xe^{ax}\mathrm{d}x=\frac{x}{a}e^{ax}-\frac{1}{a}\int e^{ax}\mathrm{d}x=\frac{x}{a}e^{ax}-\frac{1}{a^2}e^{ax}=e^{ax}\left(\frac{1}{a}x-\frac{1}{a^2}\right) \tag{6.3.415}$$

   Therefore:

$$F(x)=e^{ax}\left(\frac{1}{a}x-\frac{1}{a^2}\right) \tag{6.3.416}$$

   The generalization is in our point of view immediate and we get the following reduction formula:

$$\int x^ne^{ax}\mathrm{d}x=\frac{x^ne^{ax}}{a}-\frac{n}{a}\int x^{n-1}a^{ax}\mathrm{d}x \tag{6.3.417}$$

Remark

Another very important primitive with the exponential in physics is that we had proved in our study of the law of Gauss-Laplace law (Normal Law) in the section of Statistics (determination of the expected mean).

8. Primitive of $f(x)=\ln(x)$:

   We write:

$$\int\ln(x)\mathrm{d}x=\int 1\cdot\ln(x)\mathrm{d}x \tag{6.3.418}$$

   Integrating by parts we found:

$$\int 1\cdot\ln(x)\mathrm{d}x=x\ln(x)-\int x\frac{1}{x}\mathrm{d}x=x\ln(x)-x=x(\ln(x)-1) \tag{6.3.419}$$

   Finally:

$$F(x)=x(\ln(x)-1) \tag{6.3.420}$$

9. Primitive of $f(x)=x\ln(ax)$ with $a\in\mathbb{R}\{0\}$:

   An integration by part give us:

$$\int x\ln(ax)\mathrm{d}x=\frac{1}{2}x^2\ln(ax)-\frac{1}{2}\int x^2\frac{1}{x}\mathrm{d}x=\frac{1}{2}x^2\ln(ax)-\frac{1}{4}x^2 \tag{6.3.421}$$

   Therefore:

$$F(x)=\frac{1}{2}x^2\ln(ax)-\frac{1}{4}x^2 \tag{6.3.422}$$

10. Primitive of $f(x)=a^x$ for $a>0,a\neq 1$:

    To begin we write:

$$f(x)=a^x\Leftrightarrow f'(x)=a^x\ln(a) \tag{6.3.423}$$

    Therefore we get:

$$\frac{f'(x)}{\ln(a)}=a^x\Rightarrow\int\frac{f'(x)}{\ln(a)}\mathrm{d}x=\int a^x\mathrm{d}x \tag{6.3.424}$$

    and:

$$\frac{1}{\ln(a)}\int f'(x)\mathrm{d}x=\frac{f(x)}{\ln(a)}\quad\text{and}\quad\int a^x\mathrm{d}x=\int f(x)\mathrm{d}x=F(x) \tag{6.3.425}$$

    Finally:

$$F(x)=\frac{f(x)}{\ln(a)}=\frac{a^x}{\ln(a)} \tag{6.3.426}$$

11. Primitive of $f(x)=\log_a(x)$:

    For $a>0,a\neq 1$ knowing that (see the properties of logarithms in the section of Functional Analysis):

$$\log_a(x)=\frac{\ln(x)}{\ln(a)}=\frac{1}{\ln(a)}\ln(x) \tag{6.3.427}$$

    we get using the primitive of $\ln(x)$:

$$F(x)=\frac{x}{\ln(a)}\big(\ln(x)-1\big) \tag{6.3.428}$$

12. Primitive of $f(x)=\tanh(x)$:

    We have:

$$\int\tanh(x)\mathrm{d}x=\int\frac{\sinh(x)}{\cosh(x)}\mathrm{d}x \tag{6.3.429}$$

    we use the change of variables $u=\cosh(x),\mathrm{d}u=\sinh(x)\mathrm{d}x$ and we get:

$$\int\frac{\sinh(x)}{\cosh(x)}\mathrm{d}x=\int\frac{1}{u}\mathrm{d}u=\ln(|u|)=\ln|\cosh(x)| \tag{6.3.430}$$

    Finally:

$$F(x)=\ln\big(|\cosh(x)|\big) \tag{6.3.431}$$

13. Primitive of $f(x)=\coth(x)$:

    We know we have:

    $$\int \coth(x)\mathrm{d}x=\int \frac{\cosh(x)}{\sinh(x)}\mathrm{d}x \tag{6.3.432}$$

    we use the change of variables $u=\sinh(x)$, $\mathrm{d}u=\cosh(x)\mathrm{d}x$ and we get:

    $$\int \frac{\cosh(x)}{\sinh(x)}\mathrm{d}x=\int \frac{1}{u}\mathrm{d}u=\ln|u|=\ln|\sinh(x)| \tag{6.3.433}$$

    Finally:

    $$F(x)=\ln\left(|\sinh(x)|\right) \tag{6.3.434}$$

14. Primitive of $f(x)=\text{arcsinh}(x)$:

    We integrate by parts:

    $$\int 1\cdot\text{arcsinh}(x)\mathrm{d}x=x\text{arcsinh}(x)-\int \frac{x}{\sqrt{1+x^2}}\mathrm{d}x \tag{6.3.435}$$

    If we put $u=1+x^2$, $\mathrm{d}u=2x\mathrm{d}x$ we get:

    $$\int \frac{x}{\sqrt{1+x^2}}\mathrm{d}x=\int \frac{1}{2\sqrt{u}}\mathrm{d}u=\sqrt{u}=\sqrt{1+x^2} \tag{6.3.436}$$

    Finally:

    $$F(x)=x\text{arcsinh}(x)-\sqrt{1+x^2} \tag{6.3.437}$$

15. Primitive of $f(x)=\text{arccosh}(x)$:

    If we integrate by parts as before:

    $$\int 1\cdot\text{arccosh}(x)\mathrm{d}x=x\cdot\text{arccosh}(x)-\int \frac{x}{\sqrt{x^2-1}}\mathrm{d}x \tag{6.3.438}$$

    If we put $u=x^2-1$, $\mathrm{d}u=2x\mathrm{d}x$ we get:

    $$\int \frac{x}{\sqrt{x^2-1}}\mathrm{d}x=\int \frac{1}{2\sqrt{u}}\mathrm{d}u=\sqrt{u}=\sqrt{x^2-1} \tag{6.3.439}$$

    Finally:

    $$F(x)=x\text{arccosh}(x)-\sqrt{x^2-1} \tag{6.3.440}$$

16. Primitive of $f(x)=\text{arctanh}(x)$:

    We integrate by parts:

    $$\int 1\cdot\text{arctanh}(x)\mathrm{d}x=x\text{arctanh}(x)-\int \frac{x}{1-x^2}\mathrm{d}x \tag{6.3.441}$$

    If we put $u=1-x^2$, $\mathrm{d}u=-2x\mathrm{d}x$ we get:

    $$\int \frac{x}{1-x^2}\mathrm{d}x=-\int \frac{1}{2u}\mathrm{d}u=-\frac{1}{2}\ln(|u|)=-\frac{1}{2}\ln\left(|1-x^2|\right) \tag{6.3.442}$$

    Finally:

    $$F(x)=x\text{arctanh}(x)+\frac{1}{2}\ln|1-x^2| \tag{6.3.443}$$

17. Primitive of $f(x)=\text{arccoth}(x)$:

    We integrate by parts:

$$\int 1\cdot\text{arccoth}(x)\mathrm{d}x=\text{arccoth}(x)-\int\frac{x}{1-x^2}\mathrm{d}x \tag{6.3.444}$$

    If we put $u=1-x^2, \mathrm{d}u=-2x\mathrm{d}x$ we get:

$$\int\frac{x}{1-x^2}\mathrm{d}x=-\int\frac{1}{2u}\mathrm{d}u=-\frac{1}{2}\ln(|u|)=-\frac{1}{2}\ln\left(|1-x^2|\right) \tag{6.3.445}$$

    Finally:

$$F(x)=x\cdot\text{arccoth}(x)+\frac{1}{2}\ln\left(|1-x^2|\right) \tag{6.3.446}$$

18. Primitive of $f(x)=\sin^n(x)$ with $n\geq 2$:

    Let us put $I_n=\int\sin^n(x)\mathrm{d}x$. An integration by parts give:

$$I_n=\int\sin(x)\cdot\sin^{n-1}(x)\mathrm{d}x=-\cos(x)\cdot\sin^{n-1}(x)+(n+1)\int\cos^2(x)\cdot\sin^{n-2}(x)\mathrm{d}x \tag{6.3.447}$$

    substituting $\cos^2(x)$ by $1-\sin^2 x$ in the last primitive, we get:

$$I_n=-\cos(x)\cdot\sin^{n-1}(x)+(n-1)(I_{n-2}-I_n) \tag{6.3.448}$$

    and therefore:

$$F(x)=I_n=\frac{1}{n}\left(-\cos(x)\cdot\sin^{n-1}(x)+(n-1)I_{n-2}\right) \tag{6.3.449}$$

    All primitives of the same form (recurrence relation) are named "reduction formulas".

19. Primitive of $f(x)=\cos^n(x)$ with $n\geq 2$:

    In this case we have the recursive formula:

$$\begin{aligned}F(x)&=\int\cos^n(x)\mathrm{d}x=\frac{1}{n}\left(\sin(x)\cdot\cos^{n-1}(x)+(n-1)\int\cos^{n-2}(x)\mathrm{d}x\right)\\&=\frac{1}{n}\left(\sin(x)\cdot\cos^{n-1}(x)+(n-1)I_{n-2}\right)\end{aligned} \tag{6.3.450}$$

    that is proved exactly in the same way as the previous recursive relation (the reader can request the details if required).

20. Primitive of $f(x)=\tan^2(x)$:

    Knowing that $\tan'(x)=1+\tan^2(x)$ we have:

$$\int\tan^2(x)\mathrm{d}x=\int\left(\tan'(x)-1\right)\mathrm{d}x=\tan(x)-x \tag{6.3.451}$$

    Therefore:

$$F(x)=\tan(x)-x \tag{6.3.452}$$

21. Primitive of $f(x)=\cot^2(x)$:

    Knowing that $\cot'(x)=-1-\cot^2(x)$ we have:

$$\int \cot^2(x)\mathrm{d}x=\int \big(-\cot'(x)-1\big)\mathrm{d}x=-\cot(x)-x \tag{6.3.453}$$

    Therefore:

$$F(x)=\int \cot^2(x)\mathrm{d}x=-\cot(x)-x \tag{6.3.454}$$

22. Primitive of $f(x)=\sin^{-2}(x)$:

    Using remarkable trigonometric identities (see section Trigonometry page 2519), we have:

$$\int \frac{1}{\sin^2(x)}\mathrm{d}x=\int \frac{\sin^2(x)+\cos^2(x)}{\sin^2(x)}\mathrm{d}x=\int \big(1+\cot^2(x)\big)\mathrm{d}x=-\cot(x) \tag{6.3.455}$$

    Thanks to the primitive of $\cot^2(x)$. Therefore:

$$F(x)=\int \frac{1}{\sin^2(x)}\mathrm{d}x=-\cot(x) \tag{6.3.456}$$

23. Primitive of $f(x)=\cos^{-2}(x)$:

    Using once again remarkable trigonometric identities (see section Trigonometry page 2519), we have:

$$\int \frac{1}{\cos^2(x)}\mathrm{d}x=\int \frac{\sin^2(x)+\cos^2(x)}{\cos^2(x)}\mathrm{d}x=\int \big(1+\tan^2(x)\big)\mathrm{d}x=\tan(x) \tag{6.3.457}$$

    Thanks to the primitive of $\tan^2(x)$. Therefore:

$$F(x)=\int \frac{1}{\cos^2(x)}\mathrm{d}x=\tan(x) \tag{6.3.458}$$

24. Primitive of $f(x)=\sin^{-1}(x)$:

    We use the substitution $x=2\arctan(t), t=\tan(x/2)$. Knowing that (see section Trigonometry page 2519):

$$\sin(x)=\frac{2\tan\left(\dfrac{x}{2}\right)}{1+\tan^2\left(\dfrac{x}{2}\right)} \tag{6.3.459}$$

    we then get:

$$\sin(x)=\frac{2t}{1+t^2} \quad \text{and} \quad \mathrm{d}x=\frac{2}{1+t^2}\mathrm{d}t \tag{6.3.460}$$

    Therefore:

$$\int \frac{1}{\sin(x)}\mathrm{d}x=\int \frac{1}{t}\mathrm{d}t=\ln(|t|)=\ln\left(\left|\tan\frac{x}{2}\right|\right) \tag{6.3.461}$$

    Finally:

$$F(x)=\int \frac{1}{\sin(x)}\mathrm{d}x=\ln\left(\left|\tan\frac{x}{2}\right|\right) \tag{6.3.462}$$

25. Primitive of $f(x)=\cos^{-1}(x)$:

    Knowing that $\cos(x)=\sin(x+\pi/2)$ (see section Trigonometry page 2514) we have:

$$\int\frac{1}{\cos(x)}\mathrm{d}x=\int\frac{1}{\sin\left(x+\frac{\pi}{2}\right)}\mathrm{d}x \tag{6.3.463}$$

    We do the change of variable $x+\pi/2=u$, $\mathrm{d}u=\mathrm{d}x$:

$$\begin{aligned}\int\frac{1}{\cos(x)}\mathrm{d}x&=\int\frac{1}{\sin\left(x+\frac{\pi}{2}\right)}\mathrm{d}x=\int\frac{1}{\sin(u)}\mathrm{d}u\\&=\ln\left(\left|\tan\left(\frac{u}{2}\right)\right|\right)=\ln\left(\left|\tan\left(\frac{x}{2}+\frac{\pi}{4}\right)\right|\right)\end{aligned} \tag{6.3.464}$$

    thanks to the knowledge of the primitive of $\sin^{-1}(x)$. Finally:

$$F(x)=\int\frac{1}{\cos(x)}\mathrm{d}x=\ln\left(\left|\tan\left(\frac{x}{2}+\frac{\pi}{4}\right)\right|\right) \tag{6.3.465}$$

26. Primitive of $f(x)=\dfrac{1}{1+\cos(x)}$:

    We do the substitution $x=2\arctan(t), t=\tan(x/2)$, knowing that (see section Trigonometry page 2519):

$$\cos(x)=\frac{1-\tan^2\left(\frac{x}{2}\right)}{1+\tan^2\left(\frac{x}{2}\right)} \tag{6.3.466}$$

    we get:

$$\cos(x)=\frac{1-t^2}{1+t^2}\quad\text{and}\quad\mathrm{d}x=\frac{2}{1+t^2}\mathrm{d}t \tag{6.3.467}$$

    Therefore:

$$\int\frac{1}{1+\cos(x)}\mathrm{d}x=\int 1\mathrm{d}t=t=\tan\left(\frac{x}{2}\right) \tag{6.3.468}$$

    Finally:

$$F(x)=\int\frac{1}{1+\cos(x)}\mathrm{d}x=\tan\left(\frac{x}{2}\right) \tag{6.3.469}$$

27. Primitive of $f(x)=\dfrac{1}{1-\cos(x)}$:

    We do again the substitution $x=2\arctan(t), t=\tan(x/2)$. Then we find:

$$\int\frac{1}{1-\cos(x)}\mathrm{d}x=\int\frac{1}{t^2}\mathrm{d}t=-\frac{1}{t}=-\cot\left(\frac{x}{2}\right) \tag{6.3.470}$$

    So that finally:

$$F(x)=\int\frac{1}{1-\cos(x)}\mathrm{d}x=-\cot\left(\frac{x}{2}\right) \tag{6.3.471}$$

28. Primitive of $f(x)=\dfrac{1}{1+\sin(x)}$:

    Knowing that:

    $$\sin(x)=\cos\left(x-\frac{\pi}{2}\right) \tag{6.3.472}$$

    we can write:

    $$\int\frac{1}{1+\sin(x)}\mathrm{d}x=\int\frac{1}{1+\cos\left(x-\frac{\pi}{2}\right)}\mathrm{d}x \tag{6.3.473}$$

    By making the change of variables:

    $$u=x-\frac{\pi}{2}\quad\text{with}\quad\mathrm{d}u=\mathrm{d}x \tag{6.3.474}$$

    we get:

    $$\int\frac{1}{1+\sin(x)}\mathrm{d}x=\int\frac{1}{1+\cos(u)}\mathrm{d}u=\tan\left(\frac{u}{2}\right)=\tan\left(\frac{x}{2}-\frac{\pi}{4}\right) \tag{6.3.475}$$

    Finally:

    $$F(x)=\int\frac{1}{1+\sin(x)}\mathrm{d}x=\tan\left(\frac{x}{2}-\frac{\pi}{4}\right) \tag{6.3.476}$$

29. Primitive of $f(x)=\dfrac{1}{1-\sin(x)}$:

    By the same reasoning as above using the cosine we get:

    $$F(x)=\int\frac{1}{1-\sin(x)}\mathrm{d}x=-\cot\left(\frac{x}{2}-\frac{\pi}{4}\right) \tag{6.3.477}$$

30. Primitive of $f(x)=\sinh^n(x)$ with $n\geq 2$:

    Let us put:

    $$I_n=\int\sinh^n(x)\mathrm{d}x \tag{6.3.478}$$

    An integration by parts gives (we proved during our study of usual derivatives that the primitive of the hyperbolic sine was the hyperbolic cosine):

    $$\begin{aligned}I_n=\int\sinh(x)\sinh^{n-1}(x)\mathrm{d}x&=\cosh(x)\sinh(x)^{n-1}(x)\\&\quad-(n-1)\int\cosh^2(x)\sinh^{n-2}(x)\mathrm{d}x\end{aligned} \tag{6.3.479}$$

    by substituting $\cosh^2(x)$ and $1+\sinh^2(X)$ in the last integral, we get:

    $$I_n=\cosh(x)\sinh(x)^{n-1}(x)-(n-1)(I_{n-2}+I_n) \tag{6.3.480}$$

    and therefore:

    $$F(x)=I_n=\int\sinh^n(x)=\frac{1}{n}\left(\cosh(x)\sinh(x)^{n-1}(x)-(n-1)I_{n-2}\right) \tag{6.3.481}$$

    Therefore we get easily the special case:

    $$F(x)=\int\sinh^2(x)=\frac{1}{2}\left(\cosh(x)\sinh(x)(x)-x\right) \tag{6.3.482}$$

31. Primitive of $f(x)=\cosh^n(x)$ with $n\geq 2$:

    In this case we also have the recurrence relation:

$$I_n=\int\cosh(x)^n x\mathrm{d}x=\frac{1}{n}\big(\sinh(x)\cosh(x)^{n-1}(x)+(n-1)I_{n-2}\big)\tag{6.3.483}$$

    that is proved in the same way as above. So we also get easily the special case:

$$\int\cosh^2(x)\mathrm{d}x=\frac{1}{2}(\cosh(x)\sinh(x)+x)\tag{6.3.484}$$

32. Primitive of $f(x)=\tanh^2(x)$:

    Knowing that (proved during our study of usual derivatives):

$$\tanh'(x)=1-\tanh^2(x)\tag{6.3.485}$$

    we have:

$$\int\tanh^2(x)\mathrm{d}x=\int\big(1-\tanh'(x)\big)\mathrm{d}x=x-\tanh(x)\tag{6.3.486}$$

    Therefore:

$$F(x)=\int\tanh^2(x)\mathrm{d}x=x-\tanh(x)\tag{6.3.487}$$

33. Primitive of $f(x)=\coth^2(x)$:

    Knowing that (proved during our study of usual derivatives):

$$\coth'(x)=1-\coth^2(x)\tag{6.3.488}$$

    we have:

$$\int\coth^2(x)\mathrm{d}x=\int\big(1-\coth'(x)\big)\mathrm{d}x=x-\coth(x)\tag{6.3.489}$$

    Therefore:

$$F(x)=\int\coth^2(x)\mathrm{d}x=x-\coth(x)\tag{6.3.490}$$

34. Primitive of $f(x)=\dfrac{1}{\sinh^2(x)}$:

    We have using the primitive of $f(x)=\coth^2(x)$:

$$\int\sinh^2(x)\mathrm{d}x=\int\frac{\cosh^2(x)-\sinh^2(x)}{\sinh^2(x)}\mathrm{d}x=\int(\coth^2(x)-1)\mathrm{d}x=-\coth(x)\tag{6.3.491}$$

    Therefore:

$$F(x)=\int\sinh^2(x)\mathrm{d}x=\coth(x)\tag{6.3.492}$$

35. Primitive of $f(x)=\dfrac{1}{\cosh^2(x)}$:

    We have using the primitive of $f(x)=\tanh^2(x)$:

$$\int \cosh^2(x)\mathrm{d}x=\int \frac{\cosh^2(x)-\sinh^2(x)}{\cosh^2(x)}\mathrm{d}x=\int (1-\tanh^2(x))\mathrm{d}x=\tanh(x) \tag{6.3.493}$$

    Therefore:

$$F(x)=\int \cosh^2(x)\mathrm{d}x=\tanh(x) \tag{6.3.494}$$

36. Primitive of $f(x)=\dfrac{1}{\sinh(x)}$:

    We do the substitution:

$$t=e^x \quad \text{with} \quad \mathrm{d}x=\frac{\mathrm{d}t}{t} \tag{6.3.495}$$

    We get using the derivative of arctanh(x):

$$\begin{aligned}\int \frac{1}{\sinh(x)}\mathrm{d}x&=\int \frac{2}{e^x-e^{-x}}\mathrm{d}x=\int \frac{2}{t\left(t-\dfrac{1}{t}\right)}\mathrm{d}t=\int \frac{2}{t^2-1}\mathrm{d}t\\&=-2\text{arctanh}(t)=-2\text{arctanh}(e^x)\end{aligned} \tag{6.3.496}$$

    and finally:

$$F(x)=\int \frac{1}{\sinh(x)}\mathrm{d}x=-2\text{arctanh}(e^x) \tag{6.3.497}$$

37. Primitive of $f(x)=\dfrac{1}{\cosh(x)}$:

    We do the substitution:

$$t=e^x \quad \text{with} \quad \mathrm{d}x=\frac{\mathrm{d}t}{t} \tag{6.3.498}$$

    We get using the derivative of $\arctan(x)$:

$$\begin{aligned}\int \frac{1}{\cosh(x)}\mathrm{d}x&=\int \frac{2}{e^x+e^{-x}}\mathrm{d}x=\int \frac{2}{t\left(t+\dfrac{1}{t}\right)}\mathrm{d}t\\&=\int \frac{2}{t^2+1}\mathrm{d}t=2\arctan(t)=2\arctan(e^x)\end{aligned} \tag{6.3.499}$$

    and finally:

$$F(x)=\int \frac{1}{\cosh(x)}\mathrm{d}x=2\arctan(e^x) \tag{6.3.500}$$

38. Primitive of $f(x)=\dfrac{1}{1+\cosh(x)}$:

We do the substitution:

$$t=e^x \text{ with } \mathrm{d}x=\frac{\mathrm{d}t}{t} \tag{6.3.501}$$

We get:

$$\begin{aligned}\int\frac{1}{1+\cosh(x)}\mathrm{d}x&=\int\frac{2}{2+e^x+e^{-x}}\mathrm{d}x=\int\frac{2}{t\left(2+t+\dfrac{1}{t}\right)}\mathrm{d}t\\&=\int\frac{2}{(t+1)^2}\mathrm{d}t=-\frac{2}{1+t}+c^{te}=-\frac{2}{1+e^x}+c^{te}\end{aligned} \tag{6.3.502}$$

Finally we get:

$$F(x)=\int\frac{1}{1+\cosh(x)}\mathrm{d}x=-\frac{2}{1+e^x}+1=\frac{e^x-1}{e^x+1}=\tanh\left(\frac{x}{2}\right) \tag{6.3.503}$$

39. Primitive of $f(x)=\dfrac{1}{1-\cosh(x)}$:

We do the substitution:

$$t=e^x \text{ with } \mathrm{d}x=\frac{\mathrm{d}t}{t} \tag{6.3.504}$$

We get:

$$\begin{aligned}\int\frac{1}{1-\cosh(x)}\mathrm{d}x&=\int\frac{2}{2-e^x-e^{-x}}\mathrm{d}x=\int\frac{2}{t\left(2-t-\dfrac{1}{t}\right)}\mathrm{d}t=\int\frac{2}{(t-1)^2}\mathrm{d}t\\&=\frac{2}{t-1}+c^{te}=\frac{2}{e^x-1}+c^{te}\end{aligned} \tag{6.3.505}$$

Finally:

$$F(x)=\int\frac{1}{1-\cosh(x)}\mathrm{d}x=\frac{2}{e^x-1}+1=\frac{e^x+1}{e^x-1}=\coth\left(\frac{x}{2}\right) \tag{6.3.506}$$

40. Primitive of $f(x)=\dfrac{1}{1+\sinh(x)}$:

We do the substitution:

$$t=e^x \text{ with } \mathrm{d}x=\frac{\mathrm{d}t}{t} \tag{6.3.507}$$

We get:

$$\int\frac{1}{1+\sinh(x)}\mathrm{d}x=\int\frac{2}{2+e^x-e^{-x}}\mathrm{d}x=\int\frac{2}{2t+t^2-1}\mathrm{d}t \tag{6.3.508}$$

But:

$$\begin{aligned}\frac{2}{2t+t^2-1}&=\frac{2}{(t+1-\sqrt{2})(t+1+\sqrt{2})}\\&=\frac{1}{\sqrt{2}}\left(\frac{1}{(t+1-\sqrt{2})}-\frac{1}{(t+1+\sqrt{2})}\right)\end{aligned}\tag{6.3.509}$$

Therefore:

$$\begin{aligned}\int\frac{2}{2t+t^2-1}\mathrm{d}t&=\frac{1}{\sqrt{2}}\left(\int\frac{1}{(t+1-\sqrt{2})}\mathrm{d}t-\int\frac{1}{(t+1+\sqrt{2})}\mathrm{d}t\right)\\&=\frac{1}{\sqrt{2}}\left[\ln\left(\left|t+1-\sqrt{2}\right|\right)-\ln\left(\left|t+1+\sqrt{2}\right|\right)\right]\\&=\frac{1}{\sqrt{2}}\ln\left(\frac{\left|t+1-\sqrt{2}\right|}{\left|t+1+\sqrt{2}\right|}\right)=\frac{1}{\sqrt{2}}\ln\left(\frac{\left|e^x+1-\sqrt{2}\right|}{\left|e^x+1+\sqrt{2}\right|}\right)\end{aligned}\tag{6.3.510}$$

Therefore:

$$F(x)=\int\frac{1}{1+\sinh(x)}\mathrm{d}x=\frac{1}{\sqrt{2}}\ln\left(\frac{\left|e^x+1-\sqrt{2}\right|}{\left|e^x+1+\sqrt{2}\right|}\right)\tag{6.3.511}$$

41. Primitive of $f(x)=\dfrac{1}{1-\sinh(x)}$:

We still do the same substitution:

$$t=e^x\ \text{ with }\ \mathrm{d}x=\frac{\mathrm{d}t}{t}\tag{6.3.512}$$

We get:

$$\int\frac{1}{1-\sinh(x)}\mathrm{d}x=\int\frac{2}{2-e^x+e^{-x}}\mathrm{d}x=-\int\frac{2}{-2t+t^2-1}\mathrm{d}t\tag{6.3.513}$$

But:

$$\begin{aligned}\frac{2}{-2t+t^2-1}&=\frac{2}{(t-1-\sqrt{2})(t-1+\sqrt{2})}\\&=\frac{1}{\sqrt{2}}\left(\frac{1}{(t-1-\sqrt{2})}-\frac{1}{(t-1+\sqrt{2})}\right)\end{aligned}\tag{6.3.514}$$

Therefore:

$$\begin{aligned}-\int\frac{2}{-2t+t^2-1}\mathrm{d}t&=-\frac{1}{\sqrt{2}}\left(\int\frac{1}{(t-1-\sqrt{2})}\mathrm{d}t+\int\frac{1}{(t-1+\sqrt{2})}\mathrm{d}t\right)\\&=\frac{1}{\sqrt{2}}\left[\ln\left(\left|t-1+\sqrt{2}\right|\right)-\ln\left(\left|t-1-\sqrt{2}\right|\right)\right]\\&=\frac{1}{\sqrt{2}}\ln\left(\frac{\left|t-1+\sqrt{2}\right|}{\left|t-1-\sqrt{2}\right|}\right)\frac{1}{\sqrt{2}}\ln\left(\frac{\left|e^x-1+\sqrt{2}\right|}{\left|e^x-1-\sqrt{2}\right|}\right)\end{aligned}\tag{6.3.515}$$

Finally:

$$F(x)=\int\frac{1}{1-\sinh(x)}\mathrm{d}x=\frac{1}{\sqrt{2}}\ln\left(\frac{\left|e^x-1+\sqrt{2}\right|}{\left|e^x-1-\sqrt{2}\right|}\right)\tag{6.3.516}$$

42. Primitive of $f(x)=e^{ax}\sin(bx)$ with $a,b\in\mathbb{R}, a^2+b^2\neq 0$:

    A first integration by parts gives:

$$\int e^{ax}\sin(bx)\mathrm{d}x=\frac{1}{a}e^{ax}\sin(bx)-\frac{b}{a}\int e^{ax}\cos(bx)\mathrm{d}x \tag{6.3.517}$$

    A second integration by parts gives:

$$\int e^{ax}\sin(bx)\mathrm{d}x=\frac{1}{a}e^{ax}\sin(bx)+\frac{b}{a}\left(\frac{1}{a}e^{ax}\cos(bx)-\frac{b}{a}\int e^{ax}\sin(bx)\mathrm{d}x\right) \tag{6.3.518}$$

    So we have the equality:

$$\int e^{ax}\sin(bx)\mathrm{d}x=\frac{1}{a}e^{ax}\sin(bx)-\frac{b}{a^2}e^{ax}\cos(bx)-\frac{b^2}{a^2}\int e^{ax}\sin(bx)\mathrm{d}x \tag{6.3.519}$$

    Therefore redistributing the previous relation:

$$F(x)=\int e^{ax}\sin(bx)\mathrm{d}x=\int e^{ax}\sin(bx)\mathrm{d}x=\frac{e^{ax}}{a^2+b^2}\big(a\sin(bx)-b\cos(bx)\big) \tag{6.3.520}$$

43. Primitive of $f(x)=e^{ax}\cos(bx)$ with $a,b\in\mathbb{R}, a^2+b^2\neq 0$:

    A similar reasoning than before shows that (we can detail on demand as always!):

$$F(x)=\int e^{ax}\cos(bx)\mathrm{d}x=\frac{e^{ax}}{a^2+b^2}\big(a\cos(bx)+b\sin(bx)\big) \tag{6.3.521}$$

44. Primitive of $f(x)=x\sin(ax)$ with $a\in\mathbb{R}^*$:

    And integration by parts gives us:

$$\begin{aligned}F(x)=\int x\sin(ax)\mathrm{d}x&=-\frac{1}{a}x\cos(ax)+\frac{1}{a}\int\cos(ax)\mathrm{d}x\\&=-\frac{1}{a}x\cos(ax)+\frac{1}{a^2}\sin(ax)\end{aligned} \tag{6.3.522}$$

45. Primitive of $f(x)=x\cos(ax)$ with $a\in\mathbb{R}^*$:

    And integration by parts gives us:

$$\begin{aligned}F(x)=\int x\cos(ax)\mathrm{d}x&=\frac{1}{a}x\sin(ax)-\frac{1}{a}\int\sin(ax)\mathrm{d}x\\&=\frac{1}{a}x\sin(ax)+\frac{1}{a^2}\cos(ax)\end{aligned} \tag{6.3.523}$$

46. Primitive of $f(x)=\dfrac{1}{(x-a)(x-b)}$ with $a\neq b$:

    We have the following relation (in integral calculus we name such decomposition a "partial fraction decomposition"):

$$\frac{1}{(x-a)(x-b)}=\frac{1}{a-b}\left(\frac{1}{(x-a)}-\frac{1}{(x-b)}\right) \tag{6.3.524}$$

Therefore:

$$\begin{aligned}\int\frac{1}{(x-a)(x-b)}\mathrm{d}x&=\frac{1}{a-b}\int\left(\frac{1}{(x-a)}-\frac{1}{(x-b)}\right)\mathrm{d}x\\&=\frac{1}{a-b}\left(\int\frac{1}{(x-a)}\mathrm{d}x-\int\frac{1}{(x-b)}\mathrm{d}x\right)\\&=\frac{1}{a-b}(\ln|x-a|-\ln|x-b|)\\&=\frac{1}{a-b}\ln\left(\left|\frac{x-a}{x-b}\right|\right)\end{aligned}\tag{6.3.525}$$

Finally:

$$F(x)=\int\frac{1}{(x-a)(x-b)}\mathrm{d}x=\frac{1}{a-b}\ln\left(\left|\frac{x-a}{x-b}\right|\right)\tag{6.3.526}$$

47. Primitive of $f(x)=\dfrac{1}{a^2-x^2}$ with $a\neq 0$:

We have using the previous result:

$$\begin{aligned}\int\frac{1}{a^2-x^2}\mathrm{d}x=\int\frac{1}{(a+x)(a-x)}\mathrm{d}x&=-\int\frac{1}{(x+a)(x-a)}\mathrm{d}x\\=-\frac{1}{2a}\ln\left(\left|\frac{x-a}{x+a}\right|=\frac{1}{2a}\ln\left|\frac{x+a}{x-a}\right|\right)\end{aligned}\tag{6.3.527}$$

Therefore:

$$F(x)=\int\frac{1}{a^2-x^2}\mathrm{d}x=\frac{1}{2a}\ln\left(\left|\frac{x+a}{x-a}\right|\right)\tag{6.3.528}$$

48. Primitive of $f(x)=\dfrac{1}{a^2+x^2}$ with $a\neq 0$:

Doing a change of variable:

$$x=au\qquad\text{with}\qquad\mathrm{d}x=a\mathrm{d}u\tag{6.3.529}$$

We get using the derivative of $\arctan(x)$:

$$\begin{aligned}F(x)=\int\frac{1}{a^2+x^2}\mathrm{d}x&=\frac{1}{a}\int\frac{1}{1+u^2}\mathrm{d}u\\&=\frac{1}{a}\arctan(u)=\frac{1}{a}\arctan\left(\frac{x}{a}\right)\end{aligned}\tag{6.3.530}$$

49. Given:

$$I_{n+1}=\int\frac{1}{(1-x^2)^{n+1}}\mathrm{d}x\tag{6.3.531}$$

with $n\in\mathbb{N}$. We get:

$$\begin{aligned}I_{n+1}&=\int\frac{1}{(1-x^2)^{n+1}}\mathrm{d}x=\int\left(\frac{1-x^2}{(1-x^2)^{n+1}}+\frac{x^2}{(1-x^2)^{n+1}}\right)\mathrm{d}x\\&=\int\frac{1}{(1-x^2)^{n}}\mathrm{d}x+\int\frac{x^2}{(1-x^2)^{n+1}}\mathrm{d}x=I_n+\int\frac{x^2}{(1-x^2)^{n+1}}\mathrm{d}x\end{aligned}\tag{6.3.532}$$

But this last primitive can be solved by parts:

$$\begin{aligned}\int\frac{x^2}{(1-x^2)^{n+1}}\mathrm{d}x&=\int\frac{x}{(1-x^2)^{n+1}}x\mathrm{d}x\\&=\frac{1}{2n(1-x^2)^n}x-\int\frac{1}{2n(1-x^2)^n}\mathrm{d}x=\frac{1}{2n(1-x^2)^n}x-\frac{1}{2n}I_n\end{aligned} \tag{6.3.533}$$

Therefore:

$$I_{n+1}=I_n+\frac{1}{2n(1-x^2)^n}x-\frac{1}{2n}I_n=\frac{1}{2n(1-x^2)^n}x-\frac{(2n-1)}{2n}I_n \tag{6.3.534}$$

What we find most frequently in the literature under the form:

$$\boxed{2nI_{n+1}=\frac{x}{(1-x^2)^n}+(2n-1)I_n} \tag{6.3.535}$$

Identically to the next development, we have for (the sign change):

$$I_{n+1}=\int\frac{1}{(1+x^2)^{n+1}}\mathrm{d}x \tag{6.3.536}$$

the following relation:

$$\boxed{2nI_{n+1}=\frac{x}{(1+x^2)^n}+(2n-1)I_n} \tag{6.3.537}$$

You can find an application of these two primitives in the Newtonian cosmological model of the Universe in the section of Astrophysics and also in the section of General Relativity in the study of the Shapiro effect!

50. Primitive of $f(x)=\dfrac{1}{(1-x^2)^2}$:

    We have using the primitives of $\dfrac{1}{(1-x^2)^n}$ (proved before) and of $\dfrac{1}{1-x^2}$ (also proved above):

    $$F(x)=\int\frac{1}{(1-x^2)^2}\mathrm{d}x=\frac{1}{2}\left[\frac{x}{1-x^2}+\frac{1}{2}\ln\left(\left|\frac{x+1}{x-1}\right|\right)\right] \tag{6.3.538}$$

51. Primitive of $f(x)=\dfrac{1}{(1+x^2)^2}$:

    We have using the primitives of $\dfrac{1}{(1+x^2)^n}$ (proved before) and of $\dfrac{1}{1+x^2}$ (also proved above):

    $$F(x)=\int\frac{1}{(1+x^2)^2}\mathrm{d}x=\frac{1}{2}\left(\frac{x}{1+x^2}+\arctan(x)\right) \tag{6.3.539}$$

    You can find an application of this primitive in the section of General Relativity for the proper falling time into a non-rotating Black Hole.

52. Primitive of $f(x)=\sqrt{x^2-a^2}$ with $a\in\mathbb{R}^*$ (case relative to the area under a hyperbola):

We can assume without loss of generality $a>0$. Note that the domain of definition of f is $]-\infty,-a]\cup[a,+\infty[$.

We will determine now a primitive of f only on the interval $[a,+\infty[$ (because that is it we will need in some sections of this textbook).

Let us make the change of variable:

$$x=a\cdot\cosh(t) \tag{6.3.540}$$

So with:

$$t=\text{arccosh}\left(\frac{1}{a}x\right),\quad \mathrm{d}x=a\sinh(t)\mathrm{d}t \tag{6.3.541}$$

where we consider the function $\cosh:\mathbb{R}^+\to[1,+\infty[$ with for reciprocal the function $\text{arccosh}:[1,+\infty[\to\mathbb{R}^+$ given by (see section Trigonometry page 2534):

$$\text{arccosh}(y)=\ln\left(y+\sqrt{y^2-1}\right) \tag{6.3.542}$$

We get then using then primitive of $\sinh^2(x)$:

$$\begin{aligned}\int\sqrt{x^2-a^2}\mathrm{d}x=a^2\int\sinh^2(x)\mathrm{d}t&=\frac{a^2}{2}(\cosh(t)\sinh(t)-t)\\&=\frac{a^2}{2}\cdot\left(\frac{1}{a}x\sinh\left(\text{arccosh}\left(\frac{1}{a}x\right)\right)-\text{arccosh}\left(\frac{1}{a}x\right)\right)\end{aligned} \tag{6.3.543}$$

but (see section Trigonometry page 2532) as:

$$\sinh^2(u)=\cosh^2(u)-1 \tag{6.3.544}$$

Therefore:

$$\sinh\left(\text{arccosh}\left(\frac{1}{a}x\right)\right)=\sqrt{\cosh^2\left(\text{arccosh}\left(\frac{1}{a}x\right)\right)-1}=\sqrt{\frac{1}{a^2}x^2-1} \tag{6.3.545}$$

and using another identity proved in the section Trigonometry:

$$\text{arccosh}(x)=\ln\left(x+\sqrt{x^2+1}\right) \tag{6.3.546}$$

we have therefore:

$$\begin{aligned}\int\sqrt{x^2-a^2}\mathrm{d}x&=\frac{a^2}{2}\left(\frac{x}{a}\sqrt{\frac{x^2}{a^2}-1}-\ln\left(\frac{x}{a}+\sqrt{\frac{x^2}{a^2}-1}\right)\right)\\&=\frac{a^2}{2}\left(\frac{x}{a^2}\sqrt{x^2-a^2}-\ln\left(\frac{x}{a}+\frac{1}{a}\sqrt{x^2-a^2}\right)\right)\\&=\frac{a^2}{2}\left(\frac{x}{a^2}\sqrt{x^2-a^2}-\ln\left(x+\sqrt{x^2-a^2}\right)+\ln(a)\right)\end{aligned} \tag{6.3.547}$$

as the primitive are given to a given constant, we can write:

$$F(x)=\int\sqrt{x^2-a^2}\mathrm{d}x=\frac{x}{2}\sqrt{x^2-a^2}-\frac{a^2}{2}\ln\left(x+\sqrt{x^2-a^2}\right) \tag{6.3.548}$$

for $x\geq a$. F is then a primitive of $\sqrt{x^2-a^2}$ on the interval $[a,+\infty[$.

53. Primitive of $f(x)=\sqrt{a^2-x^2}$ with $a\in\mathbb{R}^*$:

    We can assume without loss of generality $a>0$. Note that the domain of definition of f is $[-a,a]$.

    We make the substitution:

$$x=a\sin(t) \qquad \text{with} \qquad \mathrm{d}x=a\cos(t)\mathrm{d}t \tag{6.3.549}$$

    we get:

$$\begin{aligned}\int\sqrt{a^2-x^2}\mathrm{d}x&=a^2\int\sqrt{1-\sin^2(t)}\cos(t)\mathrm{d}t=a^2\int\cos^2(t)\mathrm{d}t\\&=\frac{a^2}{2}\left(t+\sin(t)\cos(t)\right)=\frac{a^2}{2}\left[\arcsin\left(\frac{x}{a}\right)+\frac{x}{a}\cos\left(\arcsin\left(\frac{x}{a}\right)\right)\right]\end{aligned} \tag{6.3.550}$$

    where we used the primitive $\cos^n(x)$ with $n=2$ proved above. Now we have:

$$\cos(\arcsin(y))=\sqrt{1-\sin^2(\arcsin y)}=\sqrt{1-y^2} \tag{6.3.551}$$

    Then:

$$\begin{aligned}\int\sqrt{a^2-x^2}\mathrm{d}x&=\frac{a^2}{2}\left[\arcsin\left(\frac{x}{a}\right)+\frac{x}{a}\cos\left(\arcsin\left(\frac{x}{a}\right)\right)\right]\\&=\frac{a^2}{2}\left[\arcsin\left(\frac{x}{a}\right)+\frac{x}{a}\sqrt{1-\frac{x^2}{a^2}}\right]\\&=\frac{a^2}{2}\arcsin\left(\frac{x}{a}\right)+\frac{x}{2}\sqrt{a^2-x^2}\end{aligned} \tag{6.3.552}$$

    and:

$$F(x)=\int\sqrt{a^2-x^2}\mathrm{d}x=\frac{a^2}{2}\arcsin\left(\frac{x}{a}\right)+\frac{x}{2}\sqrt{a^2-x^2} \tag{6.3.553}$$

54. Primitive of $f(x)=\sqrt{x^2+a^2}$ with $a\in\mathbb{R}^*$:

    We can assume without loss of generality $a>0$.

    Let us make the change of variable:

$$x=a\sinh(t) \tag{6.3.554}$$

    with:

$$t=\operatorname{arcsinh}\left(\frac{1}{a}x\right),\quad \mathrm{d}x=a\cosh(t)\mathrm{d}t \tag{6.3.555}$$

    We get:

$$\int\sqrt{x^2+a^2}\mathrm{d}x=a^2\int\cosh^2(t)\mathrm{d}t=\frac{a^2}{2}\left(t+\sinh(t)\cosh(t)\right) \tag{6.3.556}$$

Therefore:

$$\int \sqrt{x^2+a^2}\mathrm{d}x=\frac{a^2}{2}(t+\sinh(t)\cosh(t))=\frac{a^2}{2}\left(\text{arcsinh}\left(\frac{x}{a}\right)+\frac{x}{a}\cosh\left(\text{arcsinh}\left(\frac{x}{a}\right)\right)\right) \tag{6.3.557}$$

But as we saw in the section on Trigonometry page 2532:

$$\text{arcsinh}\left(\frac{x}{a}\right)=\ln\left(\frac{x}{a}+\frac{1}{a}\sqrt{x^2+a^2}\right)=\ln(x+\sqrt{x^2+a^2})-\ln(a) \tag{6.3.558}$$

and:

$$\cosh\left(\text{arcsinh}\left(\frac{x}{a}\right)\right)=\sqrt{1+\sinh^2(\text{arcsinh}\left(\frac{x}{a}\right))}=\sqrt{1+\frac{x^2}{a^2}}=\frac{1}{a}\sqrt{a^2+x^2} \tag{6.3.559}$$

Finally we have:

$$F(x)=\int \sqrt{x^2+a^2}\mathrm{d}x=\frac{a^2}{2}\ln\left(x+\sqrt{x^2+a^2}\right)+\frac{x}{2}\sqrt{a^2+x^2} \tag{6.3.560}$$

where $ln(a)$ has been omitted because the primitives are given to a given constant.

55. Primitive of $f(x)=\dfrac{1}{\sqrt{a^2-x^2}}$ with $a\in\mathbb{R}^*$:

    We can assume without loss of generality $a>0$.

    We do the substitution:

$$x=a\sin(t)\qquad\text{with}\qquad \mathrm{d}x=a\cos(t)\mathrm{d}t \tag{6.3.561}$$

We get:

$$\begin{aligned}F(x)&=\int\frac{1}{\sqrt{a^2-x^2}}\mathrm{d}x=\int\frac{1}{\sqrt{a^2-a^2\sin^2(t)}}a\cos(t)\mathrm{d}t\\&=\int\frac{1}{a\sqrt{1-\sin^2(t)}}a\cos(t)\mathrm{d}t=\int\frac{1}{a\cos(t)}a\cos(t)\mathrm{d}t=\int 1\mathrm{d}t=t\\&=\arcsin\left(\frac{x}{a}\right)\end{aligned} \tag{6.3.562}$$

56. Primitive of $f(x)=\dfrac{1}{\sqrt{a^2+x^2}}$ with $a\in\mathbb{R}^*$:

    We can assume without loss of generality $a>0$.

    We do the substitution:

$$x=a\sinh(t)\qquad\text{with}\qquad t=\text{arcsinh}\left(\frac{1}{a}x\right),\quad \mathrm{d}x=a\cosh(t)\mathrm{d}t \tag{6.3.563}$$

We get in the same manner as the previous usual integrals:

$$\int\frac{1}{\sqrt{(x^2+a^2)}}\mathrm{d}x=\int 1\mathrm{d}x=t=\text{arcsinh}\left(\frac{x}{a}\right) \tag{6.3.564}$$

and knowing that (see section Trigonometry page 2534):

$$\text{arcsinh}(y)=\ln\left(y+\sqrt{y^2+1}\right) \tag{6.3.565}$$

We then get finally the following important primitive:

$$\boxed{F(x)=\int\frac{1}{\sqrt{x^2+a^2}}\mathrm{d}x=\ln(x+\sqrt{x^2+a^2})} \tag{6.3.566}$$

Proceeding in the same way, but using the hyperbolic cosine instead of hyperbolic sine, we get obviously (we can detail on demand as always):

$$\boxed{F(x)=\int\frac{1}{\sqrt{x^2-a^2}}\mathrm{d}x=\ln(x+\sqrt{x^2-a^2})} \tag{6.3.567}$$

We will reuse these last two relation in important practical cases of the section of Analytical Mechanics, Civil Engineering (where the constant a is equal 1, $\ln(a)$ will be equal to 0) and General Relativity (where a will be non-zero and therefore it will not be possible to omit the constant $\ln(a)$).

57. Primitive of $f(x)=\sqrt{\dfrac{1}{x}-1}$:

So the problem is:

$$\int\sqrt{\frac{1}{x}-1}\mathrm{d}x \tag{6.3.568}$$

Substitute:

$$u=\sqrt{\frac{1}{x}-1}\longrightarrow\mathrm{d}u=-\frac{1}{2\sqrt{\frac{1}{x}-1}x^2}\mathrm{d}x=-2\int\frac{u^2}{\left(u^2+1\right)^2}\,\mathrm{d}u \tag{6.3.569}$$

Now solving:

$$\int\frac{u^2}{\left(u^2+1\right)^2}\mathrm{d}u \tag{6.3.570}$$

Write u^2 as u^2+1-1 and split:

$$\int\frac{u^2}{\left(u^2+1\right)^2}\mathrm{d}u=\int\left(\frac{u^2+1}{\left(u^2+1\right)^2}-\frac{1}{\left(u^2+1\right)^2}\right)\mathrm{d}u=\int\left(\frac{1}{u^2+1}-\frac{1}{\left(u^2+1\right)^2}\right)\mathrm{d}u \tag{6.3.571}$$

We apply linearity:

$$\int\frac{u^2}{\left(u^2+1\right)^2}\mathrm{d}u=\int\frac{1}{u^2+1}\,\mathrm{d}u-\int\frac{1}{\left(u^2+1\right)^2}\mathrm{d}u \tag{6.3.572}$$

We know from earlier above that the first term is:

$$\int\frac{1}{u^2+1}\mathrm{d}u=\arctan(u) \tag{6.3.573}$$

Now solving:

$$\int \frac{1}{\left(u^2+1\right)^2}\mathrm{d}u \tag{6.3.574}$$

We also have proved this integral earlier above. Then:

$$\int \frac{1}{\left(u^2+1\right)^2}\mathrm{d}u == \frac{\arctan(u)}{2}+\frac{u}{2\left(u^2+1\right)} \tag{6.3.575}$$

Plug in solved integrals:

$$\int \frac{1}{u^2+1}\mathrm{d}u - \int \frac{1}{\left(u^2+1\right)^2}\mathrm{d}u = \frac{\arctan(u)}{2}-\frac{u}{2\left(u^2+1\right)} \tag{6.3.576}$$

Plug in solved integrals:

$$-2\int \frac{u^2}{\left(u^2+1\right)^2}\mathrm{d}u = \frac{u}{u^2+1}-\arctan(u) \tag{6.3.577}$$

We undo the substitution:

$$u=\sqrt{\frac{1}{x}-1} \tag{6.3.578}$$

This gives:

$$\sqrt{\frac{1}{x}-1}x-\arctan\left(\sqrt{\frac{1}{x}-1}\right) \tag{6.3.579}$$

Hence the problem is solved:

$$\int \sqrt{\frac{1}{x}-1}\mathrm{d}x = \sqrt{\frac{1}{x}-1}x-\arctan\left(\sqrt{\frac{1}{x}-1}\right)+c^{te} \tag{6.3.580}$$

58. In mathematics, there are several integrals known as the "Dirichlet integral". One of those is the improper integral of the sinc function over the positive real line:

$$\int\limits_0^{+\infty}\frac{\sin(\omega)}{\omega}\mathrm{d}\omega=\int\limits_0^{+\infty}\operatorname{sinc}(\omega)\mathrm{d}\omega \tag{6.3.581}$$

By Fubini's Theorem (see page 1521):

$$\int\limits_0^{+\infty}\left(\int\limits_0^{+\infty}e^{-xy}\sin(x)\mathrm{d}y\right)\mathrm{d}x=\int\limits_0^{+\infty}\left(\int\limits_0^{+\infty}e^{-xy}\sin(x)\mathrm{d}x\right)\mathrm{d}y \tag{6.3.582}$$

Then using the primitive of e^{ax}:

$$\int\limits_0^{+\infty}e^{-xy}\sin(x)\mathrm{d}y=-e^{-xy}\frac{\sin(x)}{x}\bigg|_0^{+\infty}=\frac{\sin(x)}{x} \tag{6.3.583}$$

and using the primitive of $e^{ax}\sin(bx)$:

$$\int_0^{+\infty} e^{-xy}\sin(x)\mathrm{d}x=\left.\frac{-e^{-xy}(y\sin(x)+\cos(x))}{y^2+1}\right|_0^{+\infty}=\frac{1}{y^2+1} \tag{6.3.584}$$

Hence:

$$\int_0^{+\infty}\frac{\sin(x)}{x}\mathrm{d}x=\int_0^{+\infty}\frac{1}{y^2+1}\mathrm{d}y \tag{6.3.585}$$

Using the primitive of $\frac{1}{x^2+a^2}$ seen earlier:

$$\int_0^{+\infty}\frac{\sin(x)}{x}\mathrm{d}x=\int_0^{+\infty}\frac{1}{y^2+1}\mathrm{d}y=\arctan(y)\Big|_0^{+\infty} \tag{6.3.586}$$

As:

$$\lim_{y\to+\infty}\arctan(y)=\frac{\pi}{2} \tag{6.3.587}$$

Then:

$$\int_0^{+\infty}\frac{\sin(x)}{x}\mathrm{d}x=\arctan(y)\Big|_0^{+\infty}=\frac{\pi}{2} \tag{6.3.588}$$

59. Let us consider an integral of the following form that we can use to improve the Stirling formula (see section Numerical Methods page 6301) and also that we need absolutely for the study of the circular Fresnel aperture diffraction (see section Wave Optics page 4470):

$$I=\int_a^b e^{-\lambda g(y)}h(y)\mathrm{d}y \tag{6.3.589}$$

where:

- λ is large;
- $g(y)$ is a smooth function which has a local minimum at y^* in the interior of the interval $[a,b]$;
- $h(y)$ is smooth.

The integral can be the characteristic generating function of the distribution of $g(Y)$ when Y has density h (see section Statistics page 926), it could be a posterior expectation of $h(Y)$, or just a "simple" integral.

When λ is large, the contribution to this integral is essentially entirely by construction originating from a neighbourhood around y^*.

We formalize this by Taylor expansion of the function g around y^*:

$$g(y)=g(y^*)+g'(y^*)(y-y^*)+\frac{1}{2}g''(y^*)(y-y^*)^2+\ldots \tag{6.3.590}$$

Since y^* is a local minimum, we have:

$$g'(y^*)=0 \qquad g''(y^*)>0 \tag{6.3.591}$$

and therefore:

$$g(y)=g(y^*)+\frac{1}{2}g''(y^*)(y-y^*)^2+\ldots \tag{6.3.592}$$

Therefore:

$$\begin{aligned}I&=\int\limits_a^b e^{-\lambda g(y)}h(y)\mathrm{d}y\\ &\cong\int\limits_a^b e^{-\lambda\left(g(y^*)+\frac{1}{2}g''(y^*)(y-y^*)^2\right)}h(y)\mathrm{d}y\\ &=e^{-\lambda g(y^*)}\int\limits_{-\infty}^{+\infty}e^{-\lambda g''(y^*)(y-y^*)^2/2}h(y)\mathrm{d}y\end{aligned} \tag{6.3.593}$$

The fact that above the bounds have change from $[a,b]$ to $]-\infty,+\infty[$ is that we assume that the area of interest is around y^* and that because λ is soooo large that veeeery quickly a bit away from y^* we can consider the curve as negligible!

If we approximate $h(y)$ linearly around y^*, that is to say:

$$h'(y^*)=\frac{h(y)-h(y^*)}{y-y^*} \tag{6.3.594}$$

such that:

$$h(y)=h'(y^*)(y-y^*)+h(y^*) \tag{6.3.595}$$

Therefore:

$$\begin{aligned}I&\cong e^{-\lambda g(y^*)}\int\limits_{-\infty}^{+\infty}e^{-\lambda g''(y^*)(y-y^*)^2/2}h(y)\mathrm{d}y\\ &=e^{-\lambda g(y^*)}\int\limits_{-\infty}^{+\infty}e^{-\lambda g''(y^*)(y-y^*)^2/2}\left(h'(y^*)(y-y^*)+h(y^*)\right)\mathrm{d}y\\ &=e^{-\lambda g(y^*)}h(y^*)\int\limits_{-\infty}^{+\infty}e^{-\lambda g''(y^*)(y-y^*)^2/2}\mathrm{d}y+e^{-\lambda g(y^*)}h'(y^*)\int\limits_{-\infty}^{+\infty}(y-y^*)e^{-\lambda g''(y^*)(y-y^*)^2/2}\mathrm{d}y\end{aligned} \tag{6.3.596}$$

The reader must not forget that here $\lambda g''(y^*)$ is a constant and that if we put:

$$\lambda g''(y^*)=\frac{1}{\sigma^2} \tag{6.3.597}$$

Then for the first integral above we see that we fall back on the integral of something very similar to the Gauss distribution (with mean y^* and standard deviation $\lambda g''(y^*)$) and then it comes almost immediately (see section Statistics page 695):

$$\int\limits_{-\infty}^{+\infty} e^{-\lambda g''(y^*)(y-y^*)^2/2}\mathrm{d}y=\sqrt{\frac{2\pi}{\lambda g''(y^*)}} \tag{6.3.598}$$

For the second integral:

$$\int\limits_{-\infty}^{+\infty} (y-y^*)e^{-\lambda g''(y^*)(y-y^*)^2/2}\mathrm{d}y \tag{6.3.599}$$

the change of variable $y-y^*=x$ give us:

$$\int\limits_{-\infty}^{+\infty} xe^{-\lambda g''(y^*)x^2/2}\mathrm{d}x \tag{6.3.600}$$

It is immediate that primitive is of the form:

$$c^{te}e^{-\lambda g''(y^*)x^2/2} \tag{6.3.601}$$

Therefore by symmetry the second integral is zero! We have finally:

$$\boxed{I\cong e^{-\lambda g(y^*)}h'(y^*)\sqrt{\frac{2\pi}{\lambda g''(y^*)}}} \tag{6.3.602}$$

This calculation is named "Laplace's Method of Integration" or simply "Laplace Integration".

Remark

People interesting in further reading on common and beautiful integrals can take a look to the very good book of P.J. Nahin: *Inside Interesting Integrals* [408].

To summarize here is a table with the most important primitives (some will be proved later in this textbook):

Function $f(x)$	**Primitive** $F(x)$
0	c^{te}
c^{te}	$c^{te}x$
$\frac{1}{x}$	$\ln(x)+c^{te}$
$\sin(x)$	$-\cos(x)+c^{te}$
$\cos(x)$	$\sin(x)+c^{te}$
e^x	e^x+c^{te}
$\tan(x)$	$-\ln\lvert\cos(x)\rvert+c^{te}$

Function $f(x)$	**Primitive** $F(x)$
$\cot(x)$	$\ln\lvert\sin(x)\rvert + c^{te}$
$\arcsin(x)$	$x\arcsin(x) + \sqrt{1-x^2} + c^{te}$
$\arctan(x)$	$x\arctan(x) - \frac{1}{2}\ln\left(1+x^2\right) + c^{te}$
$\text{arccot}(x)$	$x\,\text{arccot}(x) + \frac{1}{2}\ln\left(1+x^2\right) + c^{te}$
xe^{ax}	$e^{ax}\left(\frac{1}{a}x - \frac{1}{a^2}\right) + c^{te}$
$\ln(x)$	$x(\ln(x)-1) + c^{te}$
$x\ln(ax)$	$\frac{1}{2}x^2\ln(ax) - \frac{1}{4}x^2 + c^{te}$
a^x	$\dfrac{a^x}{\ln(a)} + c^{te}$
$\log_a(x)$	$\dfrac{x}{\ln(a)}(\ln(x)-1) + c^{te}$
$\tanh(x)$	$\ln(\lvert\cosh(x)\rvert) + c^{te}$
$\coth(x)$	$\ln(\lvert\sinh(x)\rvert) + c^{te}$
$\text{arcsinh}(x)$	$x\,\text{arcsinh}(x) - \sqrt{1+x^2} + c^{te}$
$\text{arccosh}(x)$	$x\,\text{arccosh}(x) - \sqrt{x^2-1} + c^{te}$
$\text{arctanh}(x)$	$x\,\text{arctanh}(x) + \frac{1}{2}\ln\lvert 1-x^2\rvert + c^{te}$
$\text{arccoth}(x)$	$x\cdot\text{arccoth}(x) + \frac{1}{2}\ln\left(\lvert 1-x^2\rvert\right) + c^{te}$
$\sin^n(x)$	$\dfrac{1}{n}\left(-\cos(x)\cdot\sin^{n-1}(x) + (n-1)I_{n-2}\right) + c^{te}$
$\cos^n(x)$	$\dfrac{1}{n}\left(\sin(x)\cdot\cos^{n-1}(x) + (n-1)I_{n-2}\right) + c^{te}$
$\tan^2(x)$	$\tan(x) - x + c^{te}$
$\cot^2(x)$	$-\cot(x) - x + c^{te}$
$\sin^{-2}(x)$	$-\cot(x) + c^{te}$
$\cos^{-2}(x)$	$\tan(x) + c^{te}$
$\sin^{-1}(x)$	$\ln\left(\left\lvert\tan\dfrac{x}{2}\right\rvert\right) + c^{te}$
$\cos^{-1}(x)$	$\ln\left(\left\lvert\tan\left(\dfrac{x}{2}+\dfrac{\pi}{4}\right)\right\rvert\right) + c^{te}$
$\dfrac{1}{1+\cos(x)}$	$\ln\left(\left\lvert\tan\left(\dfrac{x}{2}+\dfrac{\pi}{4}\right)\right\rvert\right) + c^{te}$
$\dfrac{1}{1-\cos(x)}$	$-\cot\left(\dfrac{x}{2}\right) + c^{te}$
$\dfrac{1}{1+\sin(x)}$	$\tan\left(\dfrac{x}{2}-\dfrac{\pi}{4}\right) + c^{te}$
$\dfrac{1}{1-\sin(x)}$	$-\cot\left(\dfrac{x}{2}-\dfrac{\pi}{4}\right) + c^{te}$
$\sinh^n(x)$	$\cosh(x)\sinh(x)^{n-1}(x) - (n-1)\left(I_{n-2}+I_n\right) + c^{te}$
$\cosh^n(x)$	$\dfrac{1}{n}\left(\sinh(x)\cosh(x)^{n-1}(x) + (n-1)I_{n-2}\right) + c^{te}$
$\tanh^2(x)$	$x - \tanh(x) + c^{te}$
$\coth^2(x)$	$x - \coth(x) + c^{te}$
$\sinh^{-2}(x)$	$\coth(x) + c^{te}$
$\cosh^{-2}(x)$	$\tanh(x) + c^{te}$
$\sinh^{-1}(x)$	$-2\,\text{arctanh}\left(e^2\right) + c^{te}$
$\cosh^{-1}(x)$	$2\arctan\left(e^x\right) + c^{te}$
$\dfrac{1}{1+\cosh(x)}$	$\tanh\left(\dfrac{x}{2}\right) + c^{te}$

Function $f(x)$	**Primitive** $F(x)$
$\dfrac{1}{1-\cosh(x)}$	$\coth\left(\dfrac{x}{2}\right)+c^{te}$
$\dfrac{1}{1+\sinh(x)}$	$\dfrac{1}{\sqrt{2}}\ln\left(\dfrac{\lvert e^x+1-\sqrt{2}\rvert}{\lvert e^x+1+\sqrt{2}\rvert}\right)+c^{te}$
$\dfrac{1}{1-\sinh(x)}$	$\dfrac{1}{\sqrt{2}}\ln\left(\dfrac{\lvert e^x-1+\sqrt{2}\rvert}{\lvert e^x-1-\sqrt{2}\rvert}\right)+c^{te}$
$e^{ax}\sin(bx)$	$\dfrac{e^{ax}}{a^2+b^2}(a\sin(bx)-b\cos(bx))+c^{te}$
$e^{ax}\cos(bx)$	$\dfrac{e^{ax}}{a^2+b^2}(a\cos(bx)+b\sin(bx))+c^{te}$
$x\sin(ax)$	$-\dfrac{1}{a}x\cos(ax)+\dfrac{1}{a^2}\sin(ax)+c^{te}$
$x\cos(ax)$	$\dfrac{1}{a}x\sin(ax)+\dfrac{1}{a^2}\cos(ax)+c^{te}$
$\dfrac{1}{(x-a)(x-b)}$	$\dfrac{1}{a-b}\ln\left(\left\lvert\dfrac{x-a}{x-b}\right\rvert\right)+c^{te}$
$\dfrac{1}{a^2-x^2}$	$\dfrac{1}{2a}\ln\left(\left\lvert\dfrac{x+a}{x-a}\right\rvert\right)+c^{te}$
$\dfrac{1}{a^2+x^2}$	$\dfrac{1}{a}\arctan\left(\dfrac{x}{a}\right)+c^{te}$
$\dfrac{1}{(1-x^2)^2}$	$\dfrac{1}{2}\left[\dfrac{x}{1-x^2}+\dfrac{1}{2}\ln\left(\left\lvert\dfrac{x+1}{x-1}\right\rvert\right)\right]+c^{te}$
$\dfrac{1}{(1+x^2)^2}$	$\dfrac{1}{2}\left(\dfrac{x}{1+x^2}+\arctan(x)\right)+c^{te}$
$\sqrt{x^2-a^2}$	$\dfrac{x}{2}\sqrt{x^2-a^2}-\dfrac{a^2}{2}\ln\left(x+\sqrt{x^2-a^2}\right)+c^{te}$
$\sqrt{a^2-x^2}$	$\dfrac{a^2}{2}\arcsin\left(\dfrac{x}{a}\right)+\dfrac{x}{2}\sqrt{a^2-x^2}+c^{te}$
$\sqrt{x^2+a^2}$	$\dfrac{a^2}{2}\ln\left(x+\sqrt{x^2+a^2}\right)+\dfrac{x}{2}\sqrt{a^2+x^2}+c^{te}$
$\left(\sqrt{a^2-x^2}\right)^{-1}$	$\arcsin\left(\dfrac{x}{a}\right)+c^{te}$
$\dfrac{1}{\sqrt{a^2+x^2}}$	$\ln\left(x+\sqrt{x^2-a^2}\right)+c^{te}$
$\sqrt{\dfrac{1}{x}-1}$	$\sqrt{\tfrac{1}{x}-1}x-\arctan\left(\sqrt{\tfrac{1}{x}-1}\right)+c^{te}$
$\delta(x-a)$	$\int\limits_{-\infty}^{\infty}\delta(x-a)\mathrm{d}x=1$
$\delta(x)$	$\int\limits_{-\infty}^{x}\delta(x)\mathrm{d}x=H(x)$ (Heaviside)

Table 6.11: **Most common primitives**

6.3.2.7 Leibniz integral rule

In Calculus, "Leibniz's integral rule", named after Gottfried Leibniz, states that for an integral of the form:

$$I=\int\limits_{a(x)}^{b(x)} f(x,t)\mathrm{d}t \tag{6.3.603}$$

where $-\infty<a(x),b(x)<+\infty$, the derivative of this integral is expressible as:

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}x}\left(\int\limits_{a(x)}^{b(x)} f(x,t)\mathrm{d}t\right)=f\left(x,b(x)\right)\frac{\mathrm{d}}{\mathrm{d}x}b(x)-f\left(x,a(x)\right)\frac{\mathrm{d}}{\mathrm{d}x}a(x)+\int\limits_{a(x)}^{b(x)}\frac{\partial}{\partial x}f(x,t)\mathrm{d}t} \tag{6.3.604}$$

This relation can be of use when evaluating certain definite integrals. When used in this context, the Leibniz rule for differentiating under the integral sign is also known as "Feynman's trick".

Notice that if $a(x)$ and $b(x)$ are constants rather than functions of x, we have a special case of Leibniz's rule:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(\int\limits_{a}^{b} f(x,t)\mathrm{d}t\right)=\int\limits_{a}^{b}\frac{\partial}{\partial x}f(x,t)\mathrm{d}t \tag{6.3.605}$$

Besides, if $a(x)=a$ and $b(x)=x$, which is a common situation as well (for example, in the proof of Cauchy's repeated integration formula), we have:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(\int_{a}^{x} f(x,t)\mathrm{d}t\right)=f\left(x,x\right)+\int_{a}^{x}\frac{\partial}{\partial x}f(x,t)\mathrm{d}t \tag{6.3.606}$$

Proof 6.14.8. First let us write:

$$I(\alpha)=\int\limits_{a(\alpha)}^{b(\alpha)} f(x,\alpha)\mathrm{d}x \tag{6.3.607}$$

We start from the very definition of the derivative:

$$\frac{\mathrm{d}I}{\mathrm{d}\alpha}=\lim_{\Delta\alpha\to 0}\frac{I(\alpha+\Delta\alpha)-I(\alpha)}{\Delta\alpha} \tag{6.3.608}$$

Now, since the integration limits depend (in general) on α, then a $\Delta\alpha$ will cause a Δa and a Δb

and so we have to write:

$$\begin{aligned}
I(\alpha+\Delta\alpha)-I(\alpha) &= \int\limits_{a+\Delta a}^{b+\Delta b} f(x,\alpha+\Delta\alpha)\mathrm{d}x-\int\limits_{a}^{b} f(x,\alpha)\mathrm{d}x\\
&= \left(\int\limits_{a+\Delta a}^{a}+\int\limits_{a}^{b}+\int\limits_{b}^{\mathrm{b}+\Delta b}\right) f(x,\alpha+\Delta\alpha)\mathrm{d}x-\int\limits_{a}^{b} f(x,\alpha)\mathrm{d}x\\
&= \int\limits_{a}^{b}\{f(x,\alpha+\Delta\alpha)-f(x,\alpha)\}\mathrm{d}x+\int\limits_{b}^{b+\Delta b} f(x,\alpha+\Delta\alpha)\mathrm{d}x\\
&\quad -\int\limits_{a}^{a+\Delta a} f(x,\alpha+\Delta\alpha)\mathrm{d}x
\end{aligned} \tag{6.3.609}$$

As $\Delta\alpha\rightarrow 0$ we have $\Delta a\rightarrow 0$ and $\Delta b\rightarrow 0$, too, and so:

$$\begin{aligned}
&\lim_{\Delta\alpha\to 0}\{I(\alpha+\Delta\alpha)-I(\alpha)\}\\
&\quad=\lim_{\Delta\alpha\to 0}\int\limits_{a}^{b}\{f(x,\alpha+\Delta\alpha)-f(x,\alpha)\}\mathrm{d}x+f(b,\alpha)\Delta b-f(a,\alpha)\Delta a
\end{aligned} \tag{6.3.610}$$

where the last two terms follow because as $\Delta a\rightarrow 0$ and $\Delta b\rightarrow 0$ the value of x over the entire integration interval remains practically unchanged at $x=a$ or at $x=b$ respectively. Thus:

$$\begin{aligned}
\frac{\mathrm{d}I}{\mathrm{d}\alpha}&=\lim_{\Delta\alpha\to 0}\frac{I(\alpha+\Delta\alpha)-I(\alpha)}{\Delta\alpha}=\lim_{\Delta\alpha\to 0}\frac{1}{\Delta\alpha}\int_a^b\{f(x,\alpha+\Delta\alpha)-f(x,\alpha)\}\mathrm{d}x\\
&\quad+\lim_{\Delta\alpha\to 0}f(b,\alpha)\frac{\Delta b}{\Delta\alpha}-\lim_{\Delta\alpha\to 0}f(a,\alpha)\frac{\Delta a}{\Delta\alpha}
\end{aligned} \tag{6.3.611}$$

or, taking the $1/\Delta\alpha$ inside the integral (the Riemann integral itself is defined as a limit, so what we are doing is reversing the order of two limiting operations, something a pure mathematician would want to justify but, as usual in this textbook, we won't worry about it!):

$$\frac{\mathrm{d}I}{\mathrm{d}\alpha}=\int\limits_{a}^{b}\frac{\partial f}{\partial\alpha}\mathrm{d}x+f(b,\alpha)\frac{\mathrm{d}b}{\mathrm{d}\alpha}-f(a,\alpha)\frac{\mathrm{d}a}{\mathrm{d}\alpha} \tag{6.3.612}$$

■ Q.E.D.

Differentiation under the integral sign is mentioned in the late physicist Richard Feynman's best-selling memoir *Surely You're Joking, Mr. Feynman!*in the chapter *A Different Box of Tools*. He describes learning it, while in high school, from an old text, *Advanced Calculus* (11926 according to holocene calendar), by Frederick S. Woods (who was a professor of mathematics in the Massachusetts Institute of Technology). The technique was not often taught when Feynman later received his formal education in Calculus, but using this technique, Feynman was able to solve otherwise difficult integration problems upon his arrival at graduate school at Princeton University:

«One thing I never did learn was contour integration. I had learned to do integrals by various methods shown in a book that my high school physics teacher Mr. Bader had given me. One day he told me to stay after class. "Feynman," he said, "you talk too much and you make too much noise. I know why. You're bored. So I'm going to give you a book. You go up there in the back, in the corner, and study this textbook, and when you know everything that's in this textbook, you can talk again." So every physics class, I paid no attention to what was going on with Pascal's Law, or whatever they were doing. I was up in the back with this textbook: "Advanced Calculus", by Woods. Bader knew I had studied "Calculus for the Practical Man" a little bit, so he gave me the real works. It was for a junior or senior course in college. It had Fourier series, Bessel functions, determinants, elliptic functions, all kinds of wonderful stuff that I didn't know anything about. That book also showed how to differentiate parameters under the integral sign, it's a certain operation. It turns out that's not taught very much in the universities; they don't emphasize it. But I caught on how to use that method, and I used that one damn tool again and again. So because I was self-taught using that book, I had peculiar methods of doing integrals. The result was, when guys at MIT or Princeton had trouble doing a certain integral, it was because they couldn't do it with the standard methods they had learned in school. If it was contour integration, they would have found it; if it was a simple series expansion, they would have found it. Then I come along and try differentiating under the integral sign, and often it worked. So I got a great reputation for doing integrals, only because my box of tools was different from everybody else's, and they had tried all their tools on it before giving the problem to me.»

✍**Example:**

Let us compute the following integral with variables limits:

$$I(\alpha)=\int\limits_{a(x)}^{b(x)} f(x,t)\mathrm{d}t=\int\limits_{0}^{\pi/2}\frac{\ln(1+\cos(\alpha)\cos(x))}{\cos(x)}\mathrm{d}x \qquad 0<\alpha<\pi \tag{6.3.613}$$

As both $a(x)$ and $b(x)$ are constants rather than functions of x, we will use the special case of Leibniz's integral rule:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(\int\limits_{a}^{b} f(x,t)\mathrm{d}t\right)=\int\limits_{a}^{b}\frac{\partial}{\partial x}f(x,t)\mathrm{d}t \tag{6.3.614}$$

Therefore differentiating under the integral with respect to α , we have (at the end we use one of the previous usual primitive and trigonometric relations):

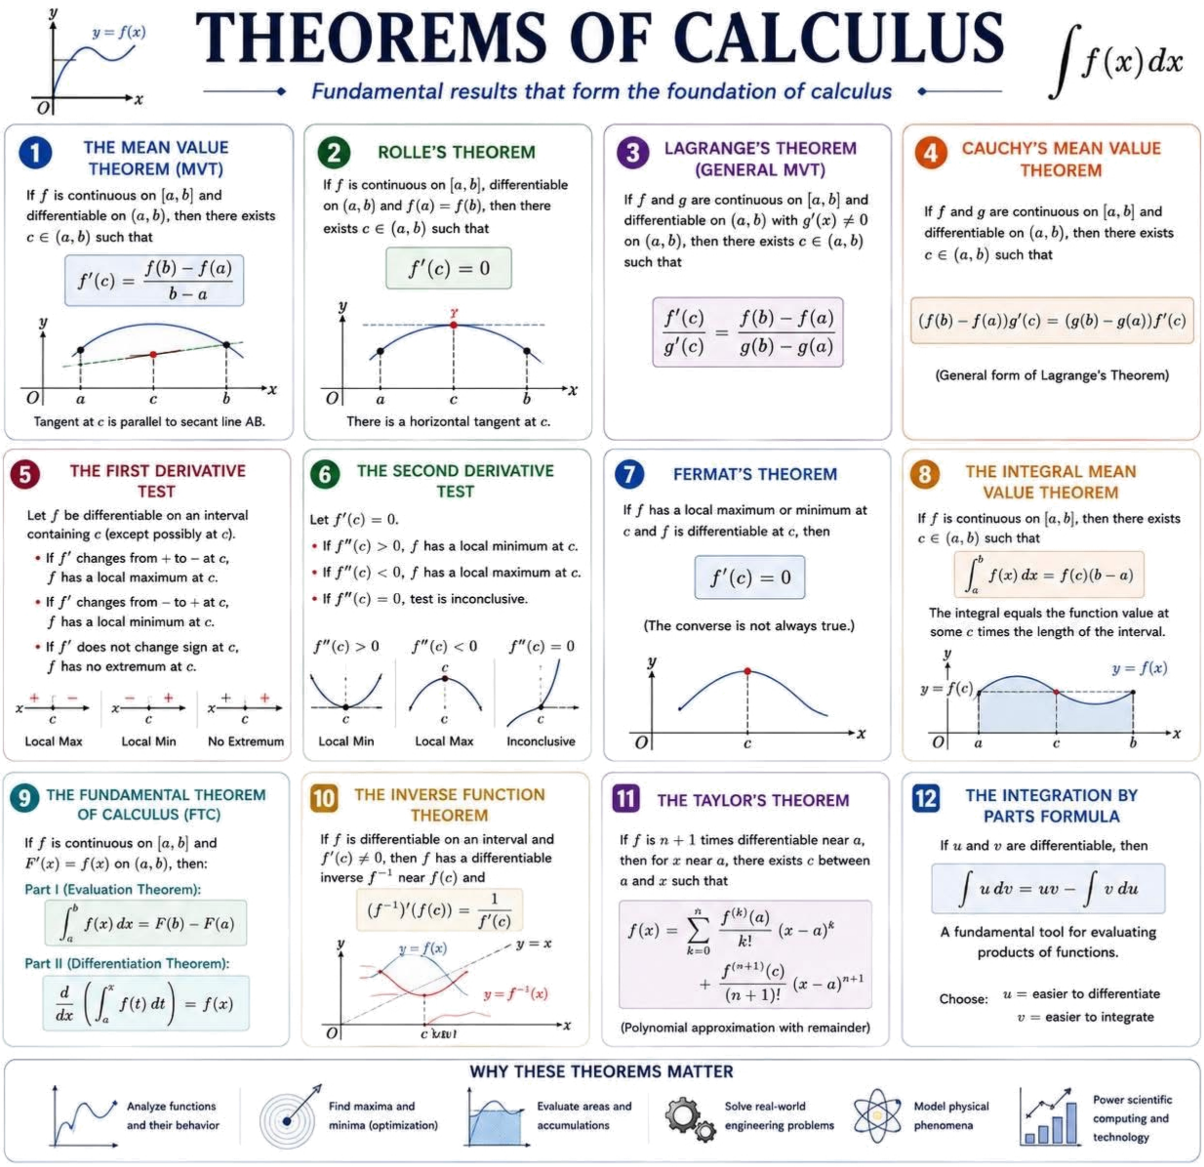
$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}\alpha}I(\alpha) &= \int_0^{\pi/2}\frac{\partial}{\partial\alpha}\left(\frac{\ln(1+\cos(\alpha)\cos(x))}{\cos(x)}\right)\mathrm{d}x = -\int_0^{\pi/2}\frac{\sin(\alpha)}{1+\cos(\alpha)\cos(x)}\mathrm{d}x\\
&= -\int_0^{\pi/2}\frac{\sin(\alpha)}{\left(\cos^2\left(\frac{x}{2}\right)+\sin^2\left(\frac{x}{2}\right)\right)+\cos(\alpha)\left(\cos^2\left(\frac{x}{2}\right)-\sin^2\left(\frac{x}{2}\right)\right)}\mathrm{d}x\\
&= -\frac{\sin(\alpha)}{1-\cos(\alpha)}\int_0^{\pi/2}\frac{1}{\cos^2\left(\frac{x}{2}\right)}\frac{1}{\frac{1+\cos(\alpha)}{1-\cos(\alpha)}+\tan^2\left(\frac{x}{2}\right)}\mathrm{d}x\\
&= -\frac{2\sin(\alpha)}{1-\cos(\alpha)}\int_0^{\pi/2}\frac{\frac{1}{2}\sec^2\left(\frac{x}{2}\right)}{\frac{2\cos^2\left(\frac{\alpha}{2}\right)}{2\sin^2\left(\frac{\alpha}{2}\right)}+\tan^2\left(\frac{x}{2}\right)}\mathrm{d}x\\
&= -\frac{2\left(2\sin\left(\frac{\alpha}{2}\right)\cos\left(\frac{\alpha}{2}\right)\right)}{2\sin^2\left(\frac{\alpha}{2}\right)}\int_0^{\pi/2}\frac{1}{\cot^2\left(\frac{\alpha}{2}\right)+\tan^2\left(\frac{x}{2}\right)}\mathrm{d}\left(\tan\left(\frac{x}{2}\right)\right)\\
&= -2\cot\left(\frac{\alpha}{2}\right)\int_0^{\pi/2}\frac{1}{\cot^2\left(\frac{\alpha}{2}\right)+\tan^2\left(\frac{x}{2}\right)}\mathrm{d}\left(\tan\left(\frac{x}{2}\right)\right)\\
&= -2\arctan\left(\frac{\tan\left(\frac{x}{2}\right)}{\cot\left(\frac{\alpha}{2}\right)}\right)\Bigg|_0^{\pi/2} = -2\arctan\left(\tan\left(\frac{x}{2}\right)\tan\left(\frac{\alpha}{2}\right)\right)\Bigg|_0^{\pi/2}\\
&= -2\arctan\left(\tan\left(\frac{\alpha}{2}\right)\right) = -\alpha
\end{aligned} \tag{6.3.615}$$

Therefore:

$$I(\alpha) = -\frac{\alpha^2}{2}+c^{te} \tag{6.3.616}$$

But $I(\pi/2)=0$ by definition, so we must have $c^{te}=\pi^2/8$ and finally:

$$I(\alpha) = -\frac{\alpha^2}{2}+\frac{\pi^2}{8} \tag{6.3.617}$$



THEOREMS OF CALCULUS

Fundamental results that form the foundation of calculus

$\int f(x)\,dx$

① THE MEAN VALUE THEOREM (MVT)

If f is continuous on $[a,b]$ and differentiable on (a,b), then there exists $c\in(a,b)$ such that

$$f'(c)=\frac{f(b)-f(a)}{b-a}$$

Tangent at c is parallel to secant line AB.

② ROLLE'S THEOREM

If f is continuous on $[a,b]$, differentiable on (a,b) and $f(a)=f(b)$, then there exists $c\in(a,b)$ such that

$$f'(c)=0$$

There is a horizontal tangent at c.

③ LAGRANGE'S THEOREM (GENERAL MVT)

If f and g are continuous on $[a,b]$ and differentiable on (a,b) with $g'(x)\neq 0$ on (a,b), then there exists $c\in(a,b)$ such that

$$\frac{f'(c)}{g'(c)}=\frac{f(b)-f(a)}{g(b)-g(a)}$$

④ CAUCHY'S MEAN VALUE THEOREM

If f and g are continuous on $[a,b]$ and differentiable on (a,b), then there exists $c\in(a,b)$ such that

$$(f(b)-f(a))g'(c)=(g(b)-g(a))f'(c)$$

(General form of Lagrange's Theorem)

⑤ THE FIRST DERIVATIVE TEST

Let f be differentiable on an interval containing c (except possibly at c).

- If f' changes from $+$ to $-$ at c, f has a local maximum at c.
- If f' changes from $-$ to $+$ at c, f has a local minimum at c.
- If f' does not change sign at c, f has no extremum at c.

Local Max Local Min No Extremum

⑥ THE SECOND DERIVATIVE TEST

Let $f'(c)=0$.

- If $f''(c)>0$, f has a local minimum at c.
- If $f''(c)<0$, f has a local maximum at c.
- If $f''(c)=0$, test is inconclusive.

$f''(c)>0$ $f''(c)<0$ $f''(c)=0$

Local Min Local Max Inconclusive

⑦ FERMAT'S THEOREM

If f has a local maximum or minimum at c and f is differentiable at c, then

$$f'(c)=0$$

(The converse is not always true.)

⑧ THE INTEGRAL MEAN VALUE THEOREM

If f is continuous on $[a,b]$, then there exists $c\in(a,b)$ such that

$$\int_a^b f(x)\,dx=f(c)(b-a)$$

The integral equals the function value at some c times the length of the interval.

⑨ THE FUNDAMENTAL THEOREM OF CALCULUS (FTC)

If f is continuous on $[a,b]$ and $F'(x)=f(x)$ on (a,b), then:

Part I (Evaluation Theorem):

$$\int_a^b f(x)\,dx=F(b)-F(a)$$

Part II (Differentiation Theorem):

$$\frac{d}{dx}\left(\int_a^x f(t)\,dt\right)=f(x)$$

10 THE INVERSE FUNCTION THEOREM

If f is differentiable on an interval and $f'(c)\neq 0$, then f has a differentiable inverse f^{-1} near $f(c)$ and

$$(f^{-1})'(f(c))=\frac{1}{f'(c)}$$

11 THE TAYLOR'S THEOREM

If f is $n+1$ times differentiable near a, then for x near a, there exists c between a and x such that

$$f(x)=\sum_{k=0}^{n}\frac{f^{(k)}(a)}{k!}(x-a)^k+\frac{f^{(n+1)}(c)}{(n+1)!}(x-a)^{n+1}$$

(Polynomial approximation with remainder)

12 THE INTEGRATION BY PARTS FORMULA

If u and v are differentiable, then

$$\int u\,dv=uv-\int v\,du$$

A fundamental tool for evaluating products of functions.

Choose: $u=$ easier to differentiate
$v=$ easier to integrate

WHY THESE THEOREMS MATTER

Analyze functions and their behavior

Find maxima and minima (optimization)

Evaluate areas and accumulations

Solve real-world engineering problems

Model physical phenomena

Power scientific computing and technology

6.3.2.8 Integral representation of first kind Bessel's function

A particularly useful and powerful way of treating Bessel functions employs their integral representation as we will see in the section of Wave Optics page 4521.

Remember that in the section of Sequences and Series we have proved that the generating function of Bessel's function was (see page 1791):

$$\begin{aligned}
e^{(x/2)(t-1/t)}G(x,t)&=\sum_{n=-\infty}^{+\infty}\sum_{s=\max(0,-n)}^{+\infty}\frac{(-1)^s}{(n+s)!s!}\left(\frac{x}{2}\right)^{n+2s}t^n\\
&=\sum_{n=-\infty}^{+\infty}\left[\sum_{s=\max(0,-n)}^{+\infty}\frac{(-1)^s}{(n+s)!s!}\left(\frac{x}{2}\right)^{n+2s}\right]t^n
\end{aligned}\qquad(6.3.618)$$

That is:

$$G(x,t)=\sum_{n=-\infty}^{+\infty}J_n(x)t^n \tag{6.3.619}$$

Now remember that (see section Numbers page 251):

$$e^{\mathrm{i}\theta}=\cos(\theta)+\mathrm{i}\sin(\theta) \tag{6.3.620}$$

So if we return to the generating function, and substitute $t=e^{\mathrm{i}\theta}$, we get:

$$\begin{aligned}e^{(x/2)(t-1/t)}&=e^{(x/2)(e^{\mathrm{i}\theta}-e^{-\mathrm{i}\theta})})=e^{(x/2)2\mathrm{i}\sin(x)}=e^{\mathrm{i}x\sin(x)}=\sum_{n=-\infty}^{+\infty}J_n(x)\left(e^{\mathrm{i}\theta}\right)^n=\sum_{n=-\infty}^{+\infty}J_n(x)e^{n\mathrm{i}\theta}\\&=J_0(x)+2\left[J_2(x)\cos(2\theta)+J_4(x)\cos(4\theta)+\ldots\right]+2\mathrm{i}\left[J_1(x)\sin(\theta)+J_3(x)\sin(3\theta)+\ldots\right]\end{aligned} \tag{6.3.621}$$

In which to condensate the result we have used first the property proved during our study of the generating function of Bessel's functions:

$$J_n(x)=(-1)^nJ_{-n}(x) \tag{6.3.622}$$

and also:

$$J_1(x)e^{\mathrm{i}\theta}+J_{-1}(x)e^{-\mathrm{i}\theta}J_1(x)\left(e^{\mathrm{i}\theta}-e^{-\mathrm{i}\theta}\right)=2\mathrm{i}J_1(x)\sin(\theta)J_2(x)e^{2\mathrm{i}\theta}+J_{-2}(x)e^{-2\mathrm{i}\theta}=2J_2(x)\cos(2\theta) \tag{6.3.623}$$

and so on...

Now remember that:

$$e^{\mathrm{i}x\sin(x)}=\cos(x\sin(\theta))+\mathrm{i}\sin(x\sin(\theta)) \tag{6.3.624}$$

Therefore identifying real and imaginary part, we get:

$$\begin{aligned}\cos(x\sin(\theta))&=J_0(x)+2\left[J_2(x)\cos(2\theta)+J_4(x)\cos(4\theta)+\ldots\right]=J_0(x)+2\sum_{n=1}^{+\infty}J_{2n}(x)\cos(2n\theta)\\\sin(x\sin(\theta))&=2\left[J_1(x)\sin(\theta)+J_3(x)\sin(3\theta)+\ldots\right]=2\sum_{n=1}^{+\infty}J_{2n-1}\sin((2n-1)\theta)\end{aligned} \tag{6.3.625}$$

Remember also that we have proved during our study of Fourier series in the section of Sequences and Series (see page 1727) that:

$$(\mathrm{I})\begin{cases}\displaystyle\int_0^T\cos(nx)\cos(kx)\mathrm{d}x=0\\\displaystyle\int_0^T\cos(nx)\sin(kx)\mathrm{d}x=0\\\displaystyle\int_0^T\sin(nx)\sin(kx)\mathrm{d}x=0\end{cases}\qquad(\mathrm{II})\begin{cases}\displaystyle\int_0^T\cos^2(kx)\mathrm{d}x=\frac{T}{2}\\\displaystyle\int_0^T\cos(kx)\sin(kx)\mathrm{d}x=0\\\displaystyle\int_0^T\sin^2(kx)\mathrm{d}x=\frac{T}{2}\end{cases} \tag{6.3.626}$$

with $n,k\in\mathbb{N}$ and $n\neq k$ with $n,k\in\mathbb{N}$ and $n=k$

That is:

$$\int\limits_0^{\pi}\cos(n\theta)\cos(m\theta)\mathrm{d}\theta=\frac{\pi}{2}\delta_{nm}\qquad\int\limits_0^{\pi}\sin(n\theta)\sin(m\theta)\mathrm{d}\theta=\frac{\pi}{2}\delta_{nm}\tag{6.3.627}$$

where δ_{nm} is the Kronecker symbol (see section Tensor Calculus page 2044).

Now let us write:

$$\begin{gathered}\int\limits_0^{\pi}\left(J_0(x)+2\sum_{n=1}^{+\infty}J_{2n}(x)\cos(2n\theta)\right)\cos(n\theta)\mathrm{d}\theta=\int\limits_0^{\pi}\cos(x\sin(\theta))\cos(n\theta)\mathrm{d}\theta\\ \int\limits_0^{\pi}\left(2\sum_{n=1}^{+\infty}J_{2n-1}\sin((2n-1)\theta)\right)\sin(n\theta)\mathrm{d}\theta=\int\limits_0^{\pi}\sin(x\sin(\theta))\sin(n\theta)\mathrm{d}\theta\end{gathered}\tag{6.3.628}$$

Let us focus on the first integral:

$$\int\limits_0^{\pi}J_0(x)\cos(n\theta)\mathrm{d}\theta+2\left(\int\limits_0^{\pi}J_2(x)\cos(2\theta)\cos(n\theta)\mathrm{d}\theta+\int\limits_0^{\pi}J_4(x)\cos(4\theta)\cos(n\theta)\mathrm{d}\theta+\ldots\right)\tag{6.3.629}$$

So we see above that whatever the value for any n, except of $n=0$:

$$\int\limits_0^{\pi}J_0(x)\cos(n\theta)\mathrm{d}\theta=J_0(x)\int\limits_0^{\pi}\cos(n\theta)\mathrm{d}\theta=0\tag{6.3.630}$$

Therefore it only remains for $n>0$:

$$2\left(\int\limits_0^{\pi}J_2(x)\cos(2\theta)\cos(n\theta)\mathrm{d}\theta+\int\limits_0^{\pi}J_4(x)\cos(4\theta)\cos(n\theta)\mathrm{d}\theta+\int\limits_0^{\pi}J_6(x)\cos(6\theta)\cos(n\theta)\mathrm{d}\theta+\ldots\right)\tag{6.3.631}$$

and we see above that if $n>0$ is odd all the integrals vanish but if $n>0$ is even, only the corresponding $J_n(x)$ remains!

Exactly the same analysis can be done for:

$$\int\limits_0^{\pi}\left(2\sum_{n=1}^{+\infty}J_{2n-1}\sin((2n-1)\theta)\right)\sin(n\theta)\mathrm{d}\theta=\int\limits_0^{\pi}\sin(x\sin(\theta))\sin(n\theta)\mathrm{d}\theta\tag{6.3.632}$$

We have therefore for each of the integrals above, especially for each the left term that (recall that $n=0,2,4,\ldots$ is even and $n=1,3,5,\ldots$ is odd):

$$\begin{gathered}\frac{1}{\pi}\int\limits_0^{\pi}\cos(x\sin(\theta))\cos(n\theta)\mathrm{d}\theta=\begin{cases}J_n(x) & n\text{ is even}\\ 0 & n\text{ is odd}\end{cases}\\ \frac{1}{\pi}\int\limits_0^{\pi}\sin(x\sin(\theta))\sin(n\theta)\mathrm{d}\theta=\begin{cases}0 & n\text{ is even}\\ J_n(x) & n\text{ is odd}\end{cases}\end{gathered}\tag{6.3.633}$$

If these two equations are added together we have using trigonometric identities (see section Trigonometry page 2519):

$$\begin{aligned} J_n(x) &= \frac{1}{\pi}\int_0^{\pi}(\cos(x\sin(\theta))\cos(n\theta)+\sin(x\sin(\theta))\sin(n\theta))\mathrm{d}\theta \\ &= \frac{1}{\pi}\cos(n\theta - x\sin(\theta))\mathrm{d}\theta \end{aligned} \tag{6.3.634}$$

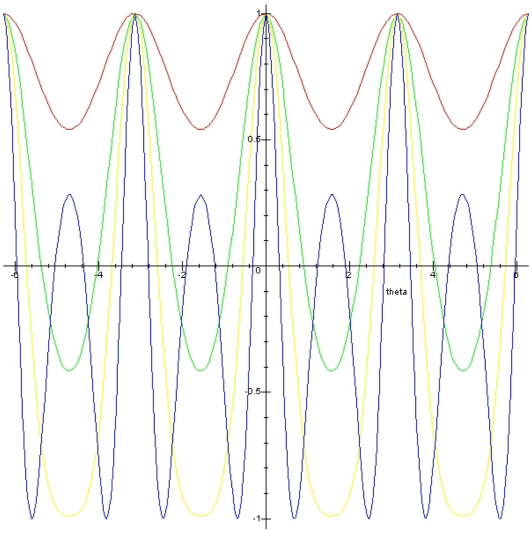
for $n = 0, 1, 2, 3, \ldots$.

If we put $n = 0$ in the above relation, we get:

$$J_0(x) = \frac{1}{\pi}\cos(-x\sin(\theta))\mathrm{d}\theta = \frac{1}{\pi}\cos(x\sin(\theta))\mathrm{d}\theta \tag{6.3.635}$$

If we plot $\cos(x\sin(\theta))$ we see that it repeats itself in all four quadrants (it's an even function):

```
>plot([cos(sin(theta)),cos(2*sin(theta)),cos(3*sin(theta)),cos(5*sin(theta))]
,theta=-2*Pi..2*Pi);
```



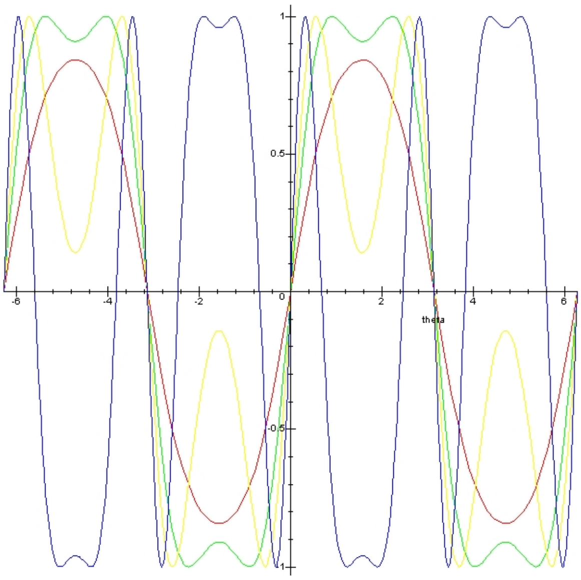
So we can write:

$$\boxed{J_0(x) = \frac{1}{2\pi}\int_0^{2\pi}\cos(x\sin(\theta))\mathrm{d}\theta} \tag{6.3.636}$$

This is the real integral representation of the zero order Bessel function of the first type.

But in many developments we don't use the above expression as there is not phasor that is visible. So the trick is to notice that $\sin(x\sin(\theta))$ reverses its sign in the third a fourth quadrant (it's and odd function):

```
>plot([sin(sin(theta)),sin(2*sin(theta)),sin(3*sin(theta)),sin(5*sin(theta))],
theta=-2*Pi..2*Pi);
```



So we have:

$$\frac{1}{2\pi}\int\limits_0^{2\pi}\sin(x\sin(\theta))\mathrm{d}\theta=0 \tag{6.3.637}$$

Adding the both relations by multiplying the second by i, we have:

$$\begin{aligned}J_0(x)&=\frac{1}{\pi}\int\limits_0^{2\pi}\cos(x\sin(\theta))\mathrm{d}\theta+0=\frac{1}{\pi}\int\limits_0^{2\pi}\cos(x\sin(\theta))\mathrm{d}\theta+\mathrm{i}\frac{1}{2\pi}\int\limits_0^{2\pi}\sin(x\sin(\theta))\mathrm{d}\theta\\&=\frac{1}{2\pi}\int\limits_0^{2\pi}\left(\cos(x\sin(\theta))+\mathrm{i}\sin(x\sin(\theta))\right)\mathrm{d}\theta\end{aligned} \tag{6.3.638}$$

Finally we get the complex representation of the zero order Bessel function of the first type:

$$J_0(x)=\frac{1}{2\pi}\int\limits_0^{2\pi}e^{\mathrm{i}x\sin(\theta)}\mathrm{d}\theta \tag{6.3.639}$$

Let us do a change of variable $\theta=\varphi+\pi/2$, then:

$$J_0(x)=\frac{1}{2\pi}\int\limits_{-\pi/2}^{3/4\pi}e^{\mathrm{i}x\sin(\varphi+\pi/2)}\mathrm{d}\varphi=\frac{1}{2\pi}\int\limits_{-\pi/2}^{3/4\pi}e^{\mathrm{i}x\cos(\varphi)}\mathrm{d}\varphi \tag{6.3.640}$$

But we have proved earlier that for any periodic function:

$$\int\limits_a^{T+a}f(t)\mathrm{d}t=\int\limits_0^T f(t)\mathrm{d}t \tag{6.3.641}$$

Therefore:

$$\boxed{J_0(x)=\frac{1}{2\pi}\int\limits_0^{2\pi} e^{\mathrm{i}x\cos(\varphi)}\mathrm{d}\varphi}\tag{6.3.642}$$

This integral representation my be obtained in various ways but this one seems the most easy one to us. Many other integral representation exists.

6.3.2.9 Dirac Function

The "Dirac function", also named "Dirac peak" or "delta function", plays a very important practical role both in electronic and computer also wave mechanics and quantum field theory (this allows to discretize a continuum!) as well as in the field of civil engineering (see the sections of the same name for examples).

Before going further we could notice that it is wrong to speak about a "function" because a function is an application of a start set (usually the set of real or complex number with one or more dimensions) in an arrival set (usually the set of real or complex numbers in one or more dimensions). While the domain of definition of the Dirac function is not a set of numbers but strictly speaking a set of functions!

More technically the Dirac delta function, or δ function, is a generalized function, or distribution, on the real number line that is zero everywhere except at zero, with an integral of one over the entire real line. The delta function is sometimes thought of as an infinitely high, infinitely thin spike at the origin, with total area one under the spike, and physically represents the density of an idealized point mass or point charge. It was introduced by theoretical physicist Paul Dirac. In the context of signal processing it is often referred to as the "unit impulse symbol" (or function). Its discrete analogue is the "Kronecker delta function", which is usually defined on a discrete domain and takes values 0 and 1.

As always in this textbook we will focus here only on the properties we will need to study Applied Mathematics stuffs of other sections of the book.

To represent mentally in an easy way this function, first consider the function defined by:

$$\begin{aligned}f(x)&=\frac{1}{a}\quad\text{if}\quad -\frac{a}{2}<x<\frac{a}{2}\\ f(x)&=0\quad\text{if}\qquad\quad |x|>\frac{a}{2}\end{aligned}\tag{6.3.643}$$

The representation of $y=f(x)$ above is a rectangle of width a, and of height $1/a$ and unit surface. The Dirac function can be considered as the boundary when $a\rightarrow 0$ of the $f(x)$. So we have:

$$\boxed{\begin{aligned}\delta(x)&=0 &&\text{if}\quad x\neq 0\\ \delta(x)&=+\infty &&\text{if}\quad x=0\end{aligned}}\tag{6.3.644}$$

That is to say (the fact that the arrow stops at 1 is a tradition but its misleading because in reality it should stop at infinity!!! what you see below is the integral of the Dirac function as we will discuss later below):

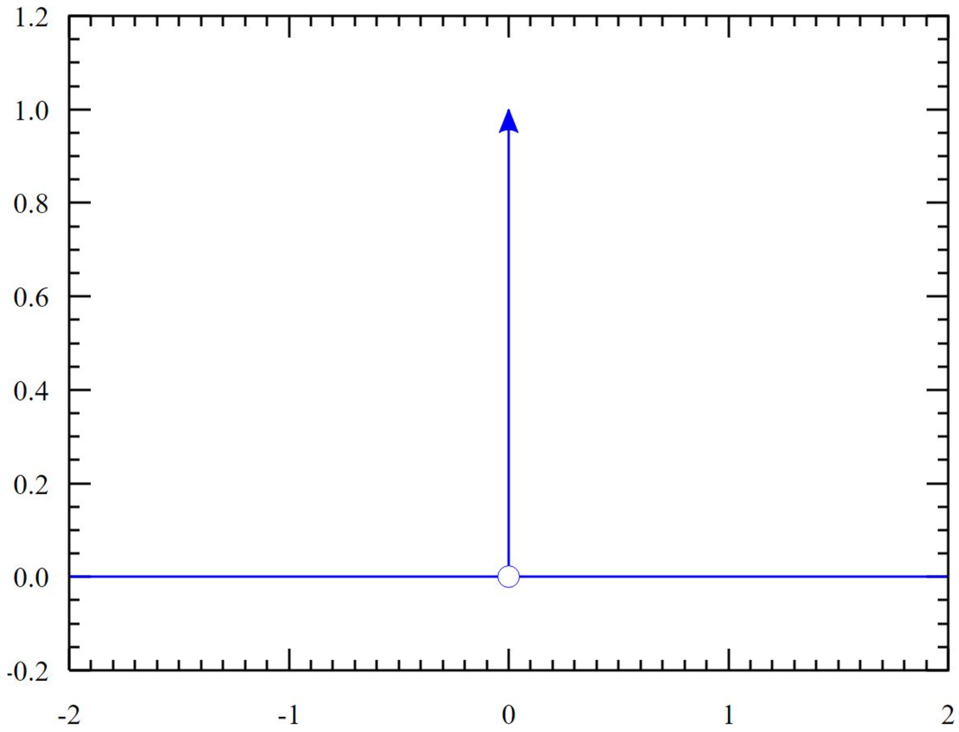


Figure 6.57: Schematic representation of the Dirac delta function by a line surmounted by an arrow (source: Wikipedia)

with:

$$\int_{-\infty}^{+\infty}\delta(x)\mathrm{d}x=\int_{-\varepsilon}^{+\varepsilon}\delta(x)\mathrm{d}x=1 \tag{6.3.645}$$

where ε is a number greater than 0 and as small as we want.

Remark

As the reader will have probably noticed it when we introduced the initial function $f(x)$, the resulting delta Dirac function has therefore the dimension of the inverse of a length!

For a function $g(x)$ continuous on $x=0$, we have:

$$\delta(g)=\int_{-\infty}^{+\infty}g(x)\delta(x)\mathrm{d}x=g(0) \tag{6.3.646}$$

By extension we have:

$$\boxed{\begin{array}{ll}\delta(x-x_0)=0 & \text{if}\quad x\neq x_0\\ \delta(x-x_0)=+\infty & \text{if}\quad x=x_0\end{array}} \tag{6.3.647}$$

and for a function $g(x)$ continue on x_0:

$$\int_{-\infty}^{+\infty}g(x)\delta(x-x_0)\mathrm{d}x=g(x_0) \tag{6.3.648}$$

Or more generally we have the following "regularized delta function":

$$\int_{\alpha}^{\beta} g(x)\delta(x-x_0)\mathrm{d}x = \begin{cases} g(x_0) & \text{if } \alpha < x_0 < \beta \\ 0 & \text{otherwise} \end{cases} \tag{6.3.649}$$

For example:

$$\int_{1}^{6} (3x-1)\delta(x-2)\mathrm{d}x = 5 \tag{6.3.650}$$

It is then relatively easy to define the Dirac function in 3-dimensional space by:

$$\delta(\vec{r}-\vec{r}_0) = \delta(x-x_0)\delta(y-y_0)\delta(y-y_0) \tag{6.3.651}$$

As already mentioned earlier, we will prove the properties of the Dirac function only if we will need them in other sections of this textbook.

To see now the integral representation of the Dirac function (very useful in Quantum Field Theory) let us recall the Fourier transform of a function $f(t)$ (see section Sequences and Series page 1758) using another common notation and convention used by physicists and mathematicians[6] (some of them invert the definition... i.e. the Fourier transform is designated as the Inverse Fourier transform...):

$$\tilde{f}(s) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} f(t)e^{\mathrm{i}t\omega}\mathrm{d}t \tag{6.3.652}$$

This transform is reversible, i.e., you can go back from $\tilde{f}(s)$ to $f(t)$ by:

$$f(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} \tilde{f}(\omega)e^{-\mathrm{i}t\omega}\mathrm{d}\omega \tag{6.3.653}$$

If we set $f(t) = \delta(t)$ in the above equations, we find:

$$\tilde{\delta}(s) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} \delta(t)e^{\mathrm{i}t\omega}\mathrm{d}t = \frac{1}{\sqrt{2\pi}} \tag{6.3.654}$$

$$\delta(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} \frac{1}{\sqrt{2\pi}} e^{-\mathrm{i}t\omega}\mathrm{d}\omega = \int_{-\infty}^{+\infty} \frac{e^{-\mathrm{i}t\omega}}{2\pi}\mathrm{d}\omega \tag{6.3.655}$$

In other words, the delta function and a constant $1/\sqrt{2\pi}$ are Fourier-transform of each other.

---

[6] Instead of using the limit of ever-narrowing rectangular pulse of unit area when defining delta function, any similar functions can be used, provided their integral is unity and their amplitude increase as their pulse-like property narrows.

Another way to see the integral representation of the delta function is again using the limits. For example, using the limit of the Gaussian (and the fact that the Fourier transform of a Gaussian is another Gaussian as proven at page 1765):

$$\delta(t)=\lim_{\sigma\to 0}\frac{1}{\sqrt{2\pi}\sigma}e^{-t^2/2\sigma^2}=\lim_{\sigma\to 0}\int\limits_{-\infty}^{+\infty}\frac{1}{2\pi}e^{-\omega^2\sigma^2/2}e^{-\mathrm{i}\omega t}\mathrm{d}\omega=\int\limits_{-\infty}^{+\infty}\frac{e^{-\mathrm{i}\omega t}}{2\pi}\mathrm{d}\omega \qquad (6.3.656)$$

The first equality is often denoted:

$$\delta(x-a)=\lim_{k\to 0}\frac{1}{k\sqrt{2\pi}}e^{-\frac{1}{2}\left(\frac{x-a}{k}\right)^2} \qquad (6.3.657)$$

and depicted with the following figure (for $a=0$):

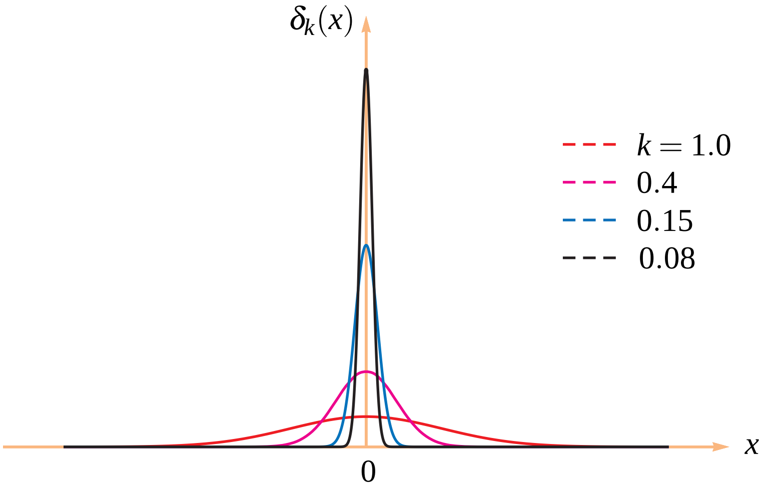

Figure 6.58: **Regularized Gaussian delta Dirac function**

Or more generally:

$$\boxed{\delta(t-x_0)=\frac{1}{2\pi}\int\limits_{-\infty}^{+\infty}e^{-\mathrm{i}\omega(t-x_0)}\mathrm{d}\omega} \qquad (6.3.658)$$

Notice that this definition leads immediately to $\delta(0)=+\infty$.

6.3.2.9.1 Heaviside function

Remember that we have seen just earlier the following property:

$$\int\limits_{\alpha}^{\beta}g(x)\delta(x-x_0)\mathrm{d}x=\begin{cases}g(x_0) & \text{if } \alpha<x_0<\beta\\ 0 & \text{otherwise}\end{cases} \qquad (6.3.659)$$

Notice that the above finite bounded integral leads to:

$$\int_a^b g(x)\delta(x)\mathrm{d}x=\begin{cases}g(0) & \text{if } 0\in[a,b]\\ 0 & \text{if } 0\notin[a,b]\end{cases} \tag{6.3.660}$$

and also to (we put $g(x)=1$):

$$\int_a^b \delta(x)\mathrm{d}x=\begin{cases}1 & \text{if } 0\in[a,b]\\ 0 & \text{if } 0\notin[a,b]\end{cases} \tag{6.3.661}$$

Now, let us put $a=-\infty$ and $b=x$, therefore for every $x\in\mathbb{R}$:

$$\int_{-\infty}^x \delta(x)\mathrm{d}x=\begin{cases}1 & \text{if } 0\in]-\infty,x]\\ 0 & \text{if } 0\notin]-\infty,x]\end{cases} \tag{6.3.662}$$

the latter is equivalent to write:

$$\int_{-\infty}^x \delta(x)\mathrm{d}x=\begin{cases}1 & \text{if } x>0\\ 0 & \text{if } x<0\end{cases} \tag{6.3.663}$$

And now we can do something clever, as $\mathbb{R}$ is dense, we can therefore define a new function named the "Heaviside function" as a function for which every value is computed as the semi-bounded Dirac integral such that:

$$\boxed{H(x)=\int_{-\infty}^x \delta(x-a)dx} \tag{6.3.664}$$

So each valuated point of the Heaviside function $H(x)$ is in fact the evaluation of a semi-bounded Dirac function estimated on point x.

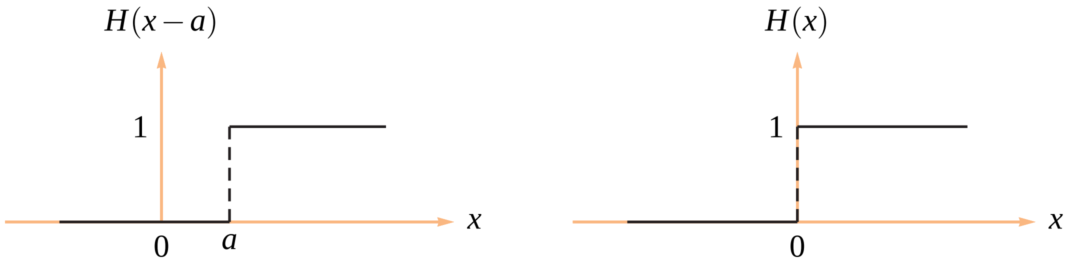

Figure 6.59: **Plot of the Heaviside function**

Differentiation of the above definition with respect to x, yields the following relation:

$$\frac{\mathrm{d}H(x)}{\mathrm{d}x}=\delta(x) \tag{6.3.665}$$

6.3.2.10 Gamma Euler Function

We define the Euler Gamma function (Eulerian integral of the second kind), more commonly named "upper incomplete Gamma function, by the following integral:

$$\boxed{\Gamma_{-1}(x)=\int\limits_0^{+\infty} t^{x-1}e^{-t}\mathrm{d}t} \tag{6.3.666}$$

with x belonging to the set of complex numbers whose real part is positive and non-zero (thus the positive real number are also included in the domain of definition)! Indeed, if we take complex numbers with a zero or negative real part, the integral diverges and is then undefined!

Remark

We have already met this integral and some of its properties (which will be proved here) in our study of the Beta, Gamma, Chi-square, Fisher and Student statistical distribution functions (see section Statistics page 647). We will also use this integral in maintenance (see section Industrial Engineering page 8716), in String theory and other engineering and physics fields (see the corresponding chapters) as for the canonical negative binomial generalized linear regression (see section Numerical Methods page 6316).

Consider we want to solve a quite common related practical case:

$$\int\limits_0^{+\infty} x^{t-1}\,e^{-c^{te}x}\mathrm{d}x \tag{6.3.667}$$

Set:

$$y=c^{te}x \qquad \mathrm{d}y=c^{te} \qquad \mathrm{d}x=\frac{y}{c^{te}} \tag{6.3.668}$$

Hence:

$$\int\limits_0^{+\infty}\left(\frac{y}{c^{te}}\right)^{t-1}\,e^{-y}\,\frac{\mathrm{d}y}{c^{te}} \tag{6.3.669}$$

Arranging we get:

$$\frac{1}{(c^{te})^t}\int\limits_0^{+\infty} y^{t-1}\,e^{-y}\,\mathrm{d}y \tag{6.3.670}$$

That is:

$$\int\limits_0^{+\infty} x^{t-1}\,e^{-c^{te}x}\mathrm{d}x=\frac{\Gamma_{-1}(t)}{(c^{te})^t} \tag{6.3.671}$$

Here is a graphical plot of the module of the Euler Gamma function $\Gamma_{-1}(x)$ for x browsing an interval of real numbers (take care in Maple™ 4.00b to write GAMMA capitalized!!!):

```
>with(plots):
>plot(GAMMA(x),x=-Pi..Pi,y=-5..5);
```

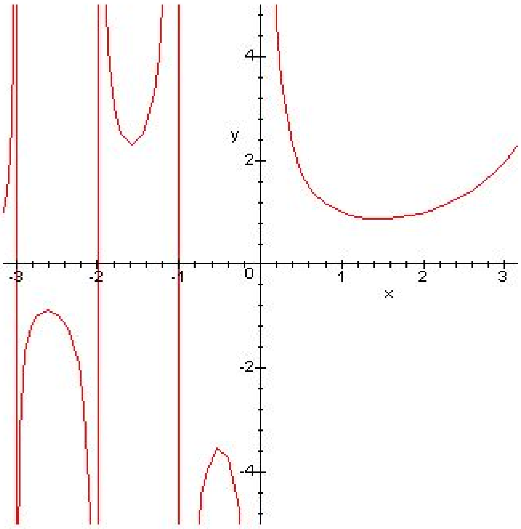

Figure 6.60: **Plot of the Euler Gamma function in Maple™ 4.00b**

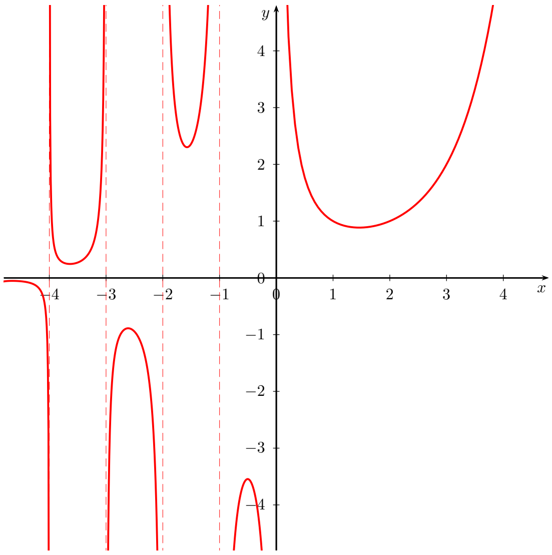
Or in a much better quality with LuaLaTeX/PST:



and always the same function in Maple™ 4.00b but now in the complex plane and always with in ordinate the module of the Gamma Euler function (we can see that there are singularities every time x is a negative integer or zero!):

```
>with(plots):
>plot3d(abs(GAMMA(x+y*I)),x=-Pi..Pi,y=-Pi..Pi,view=0..5,
grid=[30,30],orientation=[-120,45],axes=frame,style=patchcontour);
```

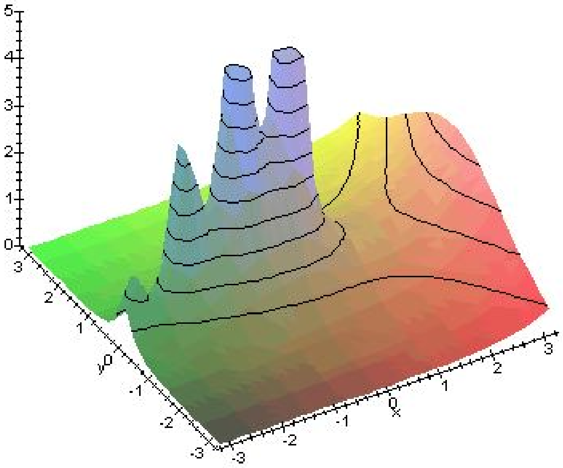


Figure 6.61: **Plot of the Euler Gamma function in the complex plane in Maple™ 4.00b**

This function is interesting if we impose the variable x to belong to the set of integer numbers and that we write it as follows:

$$\Gamma_0(x)=\int\limits_0^{+\infty} t^x e^{-t}\mathrm{d}t \tag{6.3.672}$$

Let us integrate by part the latter function:

$$\begin{aligned}\Gamma_0(x)&=\int\limits_0^{+\infty} t^x e^{-t}\mathrm{d}t=-t^x e^{-t}\Big|_0^{+\infty}+x\int\limits_0^{+\infty} t^{x-1}e^{-t}\mathrm{d}t\\&=-t^x e^{-t}\Big|_0^{+\infty}+x\Gamma_0(x-1)\end{aligned} \tag{6.3.673}$$

Since the exponential function decreases much faster than t^x then we have:

$$\Gamma_0(x)=x\Gamma_0(x-1) \tag{6.3.674}$$

In literature, we frequently find the following notations (there are confusing):

$$\begin{aligned}\Gamma_{-1}(x)=\Gamma_0(x-1)=\Gamma(x)&=\int\limits_0^{+\infty} t^{x-1}e^{-t}\mathrm{d}t\\ \Gamma_0(x)=\Gamma_0(x+1)=\Gamma(x)&=\int\limits_0^{+\infty} t^x e^{-t}\mathrm{d}t\end{aligned} \tag{6.3.675}$$

Which brings us to write the result in a more traditional form:

$$\boxed{\Gamma(x+1)=x\Gamma(x)} \tag{6.3.676}$$

From the relation $\Gamma_0(x)=x\Gamma_0(x-1)$, it comes by induction:

$$\Gamma_0(x)=x(x-1)\Gamma_0(x-2)=\ldots=\Gamma_0(0)x! \tag{6.3.677}$$

But:

$$\Gamma_0(0)=\Gamma(1)=\int\limits_0^{+\infty} t^0e^{-t}\mathrm{d}t=\int\limits_0^{+\infty} e^{-t}\mathrm{d}t=-e^{-t}\Big|_0^{+\infty}=-e^{-\infty}-(-e^{-0})=1 \tag{6.3.678}$$

That gives:

$$\Gamma_0(x)=x\cdot(x-1)\cdot\Gamma_0(x-2)=\ldots=\Gamma_0(0)x!=1\cdot x!=x! \tag{6.3.679}$$

Therefore:

$$\Gamma_0(x+1)=x! \tag{6.3.680}$$

or written in another way for $x\in\mathbb{N}^*$:

$$\boxed{\Gamma(x+1)=x!=\int\limits_0^{+\infty} t^x e^{-t}\mathrm{d}t} \tag{6.3.681}$$

Notice that for $x=0$, we have:

$$\Gamma(1)=0!=\int\limits_0^{+\infty} t^0e^{-t}\mathrm{d}t=\int\limits_0^{+\infty} e^{-t}\mathrm{d}t=-e^{-t}\Big|_0^{+\infty}=-e^{-\infty}-(-e^{-0})=1 \tag{6.3.682}$$

Let us see for the fun what is the value of i! using the Euler formula of complex numbers:

$$\begin{aligned}\mathrm{i}!&=\int\limits_0^{+\infty} t^{\mathrm{i}}e^{-t}\mathrm{d}t=\int\limits_0^{+\infty} e^{\ln\left(t^{\mathrm{i}}\right)}e^{-t}\mathrm{d}t\\&=\int\limits_0^{+\infty} e^{\mathrm{i}\ln(t)}e^{-t}\mathrm{d}t=\int\limits_n^{+\infty}(\cos(\ln(t))+\mathrm{i}\sin(\ln(t)))e^{-t}\mathrm{d}t\\&=\int\limits_0^{+\infty}\cos(\ln(t))e^{-t}\mathrm{d}t+\mathrm{i}\int\limits_0^{+\infty}\sin(\ln(t))e^{-t}\mathrm{d}t\\&\cong 0.498-0.155\mathrm{i}\end{aligned} \tag{6.3.683}$$

where the last integrals have to be computed using numerical methods.

Another interesting and useful result of the Euler gamma function is obtained when we replace t by y^2 and calculate this latter for $x=0.5$.

First we have:

$$\frac{\mathrm{d}t}{\mathrm{d}y}=\frac{\mathrm{d}y^2}{\mathrm{d}y}=2y\Rightarrow \mathrm{d}t=2y\mathrm{d}y \tag{6.3.684}$$

and after:

$$\Gamma_{-1}\left(\frac{1}{2}\right)=\int\limits_0^{+\infty} t^{\frac{1}{2}-1}e^{-t}\mathrm{d}t=\int\limits_0^{+\infty} y^{-1}e^{-y^2}2y\mathrm{d}y=2\int\limits_0^{+\infty} e^{-y^2}\mathrm{d}y \tag{6.3.685}$$

But, as we have proved it in the section Statistics during our study of the Normal distribution (see page 695), we recognize here the Gauss integral that is equal for recall to:

$$\Gamma_{-1}\left(\frac{1}{2}\right)=2\int\limits_{0}^{+\infty}e^{-y^2}\mathrm{d}y=\sqrt{\pi} \tag{6.3.686}$$

Various kinds of relations can be derived using the recurrence relation:

$$\Gamma(x+1)=x\Gamma(x) \tag{6.3.687}$$

and from the previous result. For example the Gamma function for $n+\frac{1}{2}$, where n in an integer will be very useful to us in the section Statistics for the derivation of the non-central chi-square distribution and can be derived as follows:

$$\begin{aligned}\Gamma\left(n+\frac{1}{2}\right)&=\left(n-\frac{1}{2}\right)\Gamma\left(n-\frac{1}{2}\right)\\&=\left(n-\frac{1}{2}\right)\left(n-\frac{3}{2}\right)\Gamma\left(n-\frac{3}{2}\right)\\&=\left(n-\frac{1}{2}\right)\left(n-\frac{3}{2}\right)\ldots\left(\frac{3}{2}\right)\left(\frac{1}{2}\right)\Gamma\left(\frac{1}{2}\right)\\&=\left(\frac{2n-1}{2}\right)\left(\frac{2n-3}{2}\right)\ldots\left(\frac{3}{2}\right)\left(\frac{1}{2}\right)\sqrt{\pi}\\&=\frac{(2n-1)(2n-3)\ldots(3)(1)}{2^n}\sqrt{\pi}\\&=\frac{(2n-1)(2n-2)(2n-3)(2n-4)\ldots(3)(2)(1)}{2^n(2n-2)(2n-4)\ldots2}\\&=\frac{(2n-1)(2n-2)(2n-3)(2n-4)\ldots(3)(2)(1)}{2^n2^{n-1}(n-1)(n-2)\ldots1}\\&=\frac{(2n-1)!}{2^{2n-1}(n-1)!}\sqrt{\pi}\end{aligned} \tag{6.3.688}$$

6.3.2.10.1 Incomplete regularized Gamma function

The "(upper) incomplete regularized Gamma function", useful in the study of the A/B testing for count data (see section Statistics page 999), is defined by:

$$\boxed{Q(\alpha,\beta\lambda)=\frac{\Gamma(\alpha,t)}{\Gamma(\alpha)}=\int\limits_{x}^{+\infty}\frac{\beta^{\alpha}\lambda^{\alpha-1}e^{-\beta\lambda}}{\Gamma(\alpha)}\mathrm{d}\lambda} \tag{6.3.689}$$

Obviously the non-regularized version is defined as:

$$Q(\alpha,\beta\lambda)=\int\limits_{x}^{+\infty}\beta^{\alpha}\lambda^{\alpha-1}e^{-\beta\lambda}\mathrm{d}\lambda \tag{6.3.690}$$

And factoring one β it is also sometimes defined as (with the conventional notation) and putting $t=\beta\lambda$:

$$Q(\alpha,\beta\lambda)=\int\limits_{x}^{+\infty}(\beta\lambda)^{\alpha-1}e^{-\beta\lambda}\beta\mathrm{d}\lambda=Q(\alpha,t)=\int\limits_{x}^{+\infty}t^{\alpha-1}e^{-t}\mathrm{d}t \tag{6.3.691}$$

So whatever which version we choose for the next developments, the results remains the same!

Remark

We also define the "(lower) incomplete regularized Gamma function" by:

$$q(\alpha,\beta\lambda)=\int\limits_{0}^{x}\frac{\beta^{\alpha}\lambda^{\alpha-1}e^{-\beta\lambda}}{\Gamma(\alpha)}\mathrm{d}\lambda \tag{6.3.692}$$

These functions were first investigated by the mathematician Friedrich Prym in 11877 (holocene calendar), and $Q(\alpha,\beta\lambda)$ has also been named "Prym's function".

Before continuing consider the following special case that will be useful to further below:

$$Q(1,\beta\lambda)=\int\limits_{x}^{+\infty}\frac{\beta^{1}\lambda^{1-1}e^{-\beta\lambda}}{\Gamma(1)}\mathrm{d}\lambda=\beta\int\limits_{x}^{+\infty}e^{-\beta\lambda}\mathrm{d}\lambda=\beta\left(-\frac{e^{-\beta\lambda}}{\beta}\bigg|_{x}^{+\infty}\right)=-e^{-\beta\lambda}\bigg|_{x}^{+\infty}=e^{-\beta x} \tag{6.3.693}$$

And we need also to prove as intermediate result a special recursive relation. For this thanks to an integration by part we prove the following relation:

$$\Gamma(\alpha+1,t)=\alpha\Gamma(\alpha,t)+t^{\alpha}e^{-t} \tag{6.3.694}$$

Indeed:

$$\begin{aligned}\Gamma(\alpha,t)&=\int\limits_{t}^{+\infty}x^{\alpha-1}e^{-x}\mathrm{d}x=\frac{x^{\alpha}}{\alpha}e^{-x}\bigg|_{t}^{+\infty}+\frac{1}{\alpha}\int_{t}^{+\infty}x^{\alpha}e^{-x}\mathrm{d}x\\&=-\frac{t^{\alpha}}{\alpha}e^{-t}+\frac{1}{\alpha}\Gamma(\alpha+1,t)\end{aligned} \tag{6.3.695}$$

and multiplying by α in both side of the equal we proved the previous equality!

Knowing that $\Gamma(\alpha+1)=\alpha\Gamma(\alpha)$ and that by definition $Q(\alpha,t)=\Gamma(\alpha,t)/\Gamma(\alpha)$ and dividing:

$$\Gamma(\alpha+1,t)=\alpha\Gamma(\alpha,t)+t^{\alpha}e^{-t} \tag{6.3.696}$$

by $\Gamma(\alpha+1)$ we get:

$$Q(\alpha+1,t)=\alpha\frac{\Gamma(\alpha,t)}{\Gamma(\alpha+1)}+\frac{t^{\alpha}e^{-t}}{\Gamma(\alpha+1)}=Q(\alpha,t)+\frac{t^{\alpha}e^{-t}}{\Gamma(\alpha+1)}$$

From the above relation, we can calculate $Q(\alpha+2,t)$:

$$\begin{aligned}Q(\alpha+2,t)&=Q(\alpha+1,t)+\frac{t^{\alpha+1}e^{-t}}{\Gamma(\alpha+2)}\\&=Q(\alpha,t)+\frac{t^{\alpha}e^{-t}}{\Gamma(\alpha+1)}+\frac{t^{\alpha+1}e^{-t}}{\Gamma(\alpha+2)}\\&=Q(\alpha,t)+t^{\alpha}e^{-t}\left(\frac{1}{\Gamma(\alpha+1)}+\frac{t}{\Gamma(\alpha+2)}\right)\end{aligned} \tag{6.3.697}$$

and $Q(\alpha+3,t)$ for the fun...:

$$\begin{aligned}Q(\alpha+3,t)&=Q(\alpha+2,t)+\frac{t^{\alpha+2}e^{-t}}{\Gamma(\alpha+3)}\\&=Q(\alpha,t)+t^{\alpha}e^{-t}\left(\frac{1}{\Gamma(\alpha+1)}+\frac{t}{\Gamma(\alpha+2)}\right)+\frac{t^{\alpha+2}e^{-t}}{\Gamma(\alpha+3)}\\&=Q(\alpha,t)+t^{\alpha}e^{-t}\left(\frac{1}{\Gamma(\alpha+1)}+\frac{t}{\Gamma(\alpha+2)}+\frac{t^2}{\Gamma(\alpha+3)}\right)\end{aligned} \tag{6.3.698}$$

We show easily by recurrence the following power recursive relation:

$$\boxed{Q(\alpha+n,t)=Q(\alpha,t)+t^{\alpha}e^{-t}\sum_{k=0}^{n-1}\frac{t^k}{\Gamma(\alpha+k+1)}} \tag{6.3.699}$$

Using the identity $Q(1,t)=e^{-t}$ and the previous recursive relationship we can express Q as:

$$Q(n,t)=e^{-t}\sum_{k=0}^{n-1}\frac{t^k}{\Gamma(k+1)} \tag{6.3.700}$$

Indeed, let us put first $\alpha=1$:

$$\begin{aligned}Q(n+1,t)&=Q(1,t)+te^{-t}\sum_{k=0}^{n-1}\frac{t^k}{\Gamma(k+2)}=Q(1,t)+e^{-t}\sum_{k=0}^{n-1}\frac{t^{k+1}}{\Gamma(k+2)}\\&=e^{-t}+e^{-t}\sum_{k=0}^{n-1}\frac{t^{k+1}}{\Gamma(k+2)}\end{aligned} \tag{6.3.701}$$

We put $n=n+1$ (hence we require now that $n>1$), therefore:

$$Q(n,t)=e^{-t}+e^{-t}\sum_{k=0}^{n-2}\frac{t^{k+1}}{\Gamma(k+2)} \tag{6.3.702}$$

We do another change of variable $k=k+1$:

$$Q(n,t)=e^{-t}+e^{-t}\sum_{k=1}^{n-1}\frac{t^k}{\Gamma(k+1)}=e^{-t}\sum_{k=0}^{n-1}\frac{t^k}{\Gamma(k+1)} \tag{6.3.703}$$

6.3.2.10.2 Euler-Mascheroni Constant

This small text is a just curiosity regarding to Euler's constant e and to almost every Differential and Integral calculus tools that we have seen until now. This is a very nice example (almost artistic) of what we can do with mathematics as soon as we have enough tools at our disposal.

Moreover, this constant is useful in some differential equations which we see later.

Remember that we saw in the section of Functional Analysis that the Euler constant e is defined by the limit:

$$e=\lim_{\alpha\to+\infty}\left(1+\frac{1}{\alpha}\right)^{\alpha} \tag{6.3.704}$$

In a more general case we can easily demonstrate in the same way that (you can ask us the details if needed):

$$\lim_{n\to+\infty}\left(1-\frac{t}{n}\right)^{n}=e^{-t} \tag{6.3.705}$$

This obviously suggests:

$$\Gamma_{-1}(x)=\int\limits_{0}^{+\infty}t^{x-1}e^{-t}\mathrm{d}t=\lim_{n\to+\infty}\int\limits_{0}^{+\infty}t^{x-1}\left(1-\frac{t}{n}\right)^{n}\mathrm{d}t \tag{6.3.706}$$

by a change of variable $t=nu$ we write:

$$\Gamma_{-1}(x)=\lim_{n\to+\infty}\int\limits_{0}^{1}(nu)^{x-1}(1-u)^{n}n\mathrm{d}u=\lim_{n\to+\infty}n^{x}\int\limits_{0}^{1}u^{x-1}(1-u)^{n}\mathrm{d}u \tag{6.3.707}$$

And we use the definition of the Beta function (see section Statistics page 761):

$$\begin{aligned}B(x-1,n)&=\int\limits_{0}^{1}u^{x-1}(1-u)^{n}\mathrm{d}u\\&=\frac{u^{x}}{x}(1-u)^{n}\Bigg|_{0}^{1}+\frac{1}{x}n\int\limits_{0}^{1}u^{x}(1-u)^{n-1}\mathrm{d}u\\&=\frac{n}{x}B(x,n-1)=\frac{n(n-1)}{x(x+1)}B(x+1,n-2)\\&=\frac{n!}{x(x+1)\ldots(x+n)}\end{aligned} \tag{6.3.708}$$

Therefore:

$$\Gamma_{-1}(x)=\lim_{n\to+\infty}\frac{n!n^{x}}{x(x+1)\ldots(x+n)} \tag{6.3.709}$$

To transform this expression we can write:

$$\begin{aligned} n^x &= e^{\ln(n^x)} = e^{x \cdot \ln(n)} \\ &= e^{x\left(\cdot \ln(n) - 1 + 1 - \frac{1}{2} + \frac{1}{2} - \ldots - \frac{1}{n} + \frac{1}{n}\right)} \\ &= e^{-x \cdot (1 + \frac{1}{2} + \ldots + \frac{1}{n} - \ln(n))} \cdot e^x \cdot e^{\frac{x}{2}} \cdot \ldots \cdot e^{\frac{x}{n}} \end{aligned} \tag{6.3.710}$$

But the quantity:

$$1 + \frac{1}{2} + \ldots + \frac{1}{n} - \ln(n) \tag{6.3.711}$$

tends to the limit $\gamma = 0.5772$, named "Euler-Mascheroni constant" or also "Euler Gamma constant" when n tends to infinity.

Therefore:

$$\Gamma_{-1}(x) = \lim_{n \to +\infty} \frac{n! \cdot e^{-\gamma x} \cdot e^x \cdot e^{\frac{x}{2}} \cdot \ldots \cdot e^{\frac{x}{n}}}{x(x+1)\ldots(x+n)} = \lim_{n \to +\infty} \frac{n! \cdot e^{-\gamma x} \prod\limits_{k=1}^{n} e^{\frac{x}{k}}}{x(x+1)\ldots(x+n)} \tag{6.3.712}$$

We divide each term of the product $(x+1)\ldots(x+n)$ by the corresponding integer taken into $n!$, so we get (according to a reader request we have put a maximum of details!):

$$\begin{aligned} \frac{1}{\Gamma_{-1}(x)} &= \frac{1}{\lim\limits_{n \to +\infty} \dfrac{n! e^{\lambda x} \prod_{k=1}^{n} e^{\frac{x}{k}}}{x(x+1)(x+2)\ldots(x+n)}} = x \cdot e^{\gamma x} \lim_{n \to +\infty} \frac{(x+1)(x+2)\ldots(x+n)}{n!} \prod_{k=1}^{n} e^{-\frac{x}{k}} \\ &= x \cdot e^{\gamma x} \lim_{n \to +\infty} \frac{(x+1)(x+2)\ldots(x+n)}{1 \cdot 2 \ldots \cdot n} \prod_{k=1}^{n} e^{-\frac{x}{k}} = x \cdot e^{\gamma x} \lim_{n \to +\infty} \frac{(x+1)}{1} \frac{(x+2)}{2} \ldots \frac{(x+n)}{n} \prod_{k=1}^{n} e^{-\frac{x}{k}} \\ &= x \cdot e^{\gamma x} \lim_{n \to +\infty} (x+1) \left(\frac{x}{2} + 1\right) \ldots \left(\frac{x}{n} + 1\right) \prod_{k=1}^{n} e^{-\frac{x}{k}} = x \cdot e^{\gamma x} \lim_{n \to +\infty} \prod_{k=1}^{n} \left(\frac{x}{k} + 1\right) \prod_{k=1}^{n} e^{-\frac{x}{k}} \\ &= x \cdot e^{\gamma x} \lim_{n \to +\infty} \prod_{k=1}^{n} \left(1 + \frac{x}{k}\right) e^{-\frac{x}{k}} = x \cdot e^{\gamma x} \prod_{k=1}^{+\infty} \left(1 + \frac{x}{k}\right) e^{-\frac{x}{k}} \end{aligned} \tag{6.3.713}$$

6.3.2.11 Curvilinear Integrals

The line integrals (curvilinear integrals) are also very important in physics. The reader will thus find see them again in the section of Classical Mechanics, Electrodynamics Magnetostatics and to calculate the work of a force or the "flow field", or in the chapter of Euclidean Geometry to calculate the center of gravity of curves (functions), or in the section of Geometric Shapes to calculate the surface of some bodies of revolution but also in Corpuscular Quantum Physics for the famous "path integral" (which is only the term used by physicists to say "line integral") or for the specific calculation of integrals using the residue theorem proved in the section of Complex Analysis or for transformation states in the section of Thermodynamics. This is why there will not be here examples of line integrals because they are already so many applications in the other chapters of this textbook.

With the definition of these integrals, we can prove two very important results detailed in section of Vector Calculus that are respectively the Green's theorem and Stokes' theorem or even the theorem of residues proved in the section of Complex Analysis and already mentioned in the preceding paragraph (this is important enough to mention it twice!).

More technically a line integral is an integral where the function to be integrated is evaluated along a curve. The terms "path integral", "curve integral", and "curvilinear integral" are also used; "contour integral" as well, although that is typically reserved for line integrals in the complex plane.

6.3.2.11.1 Curvilinear Integral of a scalar field

Consider a parametrized curve C (see section Differential Geometry page 2850) by a vector function $\vec{r}(t)$ with $t\in[a,b]$ of class $\mathcal{C}^1$ piecewise (this condition is necessary so that we can integrate the curve without problems).

Definitions (#6.3.201):

D1. The curve is said to be a "closed curve" if $\vec{r}(a)=\vec{r}(b)$

D2. The curve is said to be a "smooth curve" if $\forall t\in[a,b]\;\vec{r}\,'(t)\neq 0$

Recall that a parametric curve can be written as follows (all vector function can be written in this form):

$$\vec{r}(t)=x(t)\vec{i}+y(t)\vec{j}=\begin{pmatrix}x(t)\\y(t)\end{pmatrix} \tag{6.3.714}$$

Consider a function or a "scalar field" $f(x,y)$ defined in a neighbourhood of C. We subdivide $[a,b]$ into n subintervals of equal length Δt as:

$$t_0=a<t_1<\ldots<t_n=b \tag{6.3.715}$$

We choose on each subinterval a point $t_i^*\in[t_i,t_{i+1}]$. Given δs_i the length of the arc C connecting the point $(x(t_i),y(t_i))$ and $(x(t_{i+1}),y(t_{i+1})$, the integral of f along C is defined as the "line integral" or "path integral":

$$\int\limits_C f(x,y)\mathrm{d}s=\lim_{n\rightarrow+\infty}\sum_{i=0}^{n} f(x(t_i^*),y(t_i^*))\Delta s_i \tag{6.3.716}$$

Which as we know, can be written (see section of Differential Geometry page 2856 of Analytical Mechanics page 3172 and many others):

$$\int\limits_C f(x(t),y(t))\mathrm{d}s=\int\limits_a^b \sqrt{\left(\frac{\mathrm{d}x(t)}{\mathrm{d}t}\right)^2+\left(\frac{\mathrm{d}y(t)}{\mathrm{d}t}\right)^2}\mathrm{d}t \tag{6.3.717}$$

and that can obviously be immediately extended to the case to 3 variables and more.

Or in vector form:

$$\int\limits_C f(x,y)\mathrm{d}s=\int\limits_a^b \left\|\frac{\mathrm{d}\vec{r}}{\mathrm{d}t}\right\|\mathrm{d}t \tag{6.3.718}$$

The line integral is linear, that is to say, if $C=C_1\cup C_2$ and that $C_1\cap C_2$ is a point, then (without going into the strict definition of the union of two curves...):

$$\int\limits_C f(x,y)\mathrm{d}s=\int\limits_{C_1} f(x,y)\mathrm{d}s+\int\limits_{C_2} f(x,y)\mathrm{d}s \tag{6.3.719}$$

6.3.2.11.2 Curvilinear Integral of a vector field

Consider a vector field (e.g. a force field) as:

$$\vec{F}=\begin{pmatrix}F_x(x,y))\\F_y(x,y)\end{pmatrix}=F_x(x,y,)\vec{i}+F_y(x,y,)\vec{j} \tag{6.3.720}$$

and an infinitesimal element of a curve (path) $\mathcal{C}^1$ piecewise as:

$$\mathrm{d}\vec{r}=\begin{pmatrix}\mathrm{d}x\\\mathrm{d}y\end{pmatrix}=\mathrm{d}x\vec{i}+\mathrm{d}y\vec{j} \tag{6.3.721}$$

The idea is then to consider that the dot product (vector field projection on the path element) represents the work along the differential element:

$$\vec{F}\circ\mathrm{d}\vec{r} \tag{6.3.722}$$

Therefore the work on all the path will be given by (using the property of linearity of the curvilinear integral):

$$W=\int_C \vec{F}\circ\mathrm{d}\vec{r}=\int_C (F_x(x,y)\mathrm{d}x+F_y(x,y)\mathrm{d}y)=\int_C F_x(x,y)\mathrm{d}x+\int_C F_y(x,y)\mathrm{d}y \tag{6.3.723}$$

This can obviously be generalized to n dimensions. Let us indicate that when the line integral (path integral) of a vector field is extended to a closed curve, then we speak of "circulation of the vector field".

As:

$$\frac{\mathrm{d}\vec{r}}{\mathrm{d}t}=\vec{r}\,'(t) \tag{6.3.724}$$

We then have write a fairly common notation:

$$\int_C \vec{F}\circ\mathrm{d}\vec{r}=\int_C \vec{F}(\vec{r}(t))\circ\vec{r}\,'(t)\mathrm{d}t=\int_C \big(F_x(x(t),y(t))r_x'(t)+F_y(x(t),y(t))r_y'(t)\big)\,\mathrm{d}t \tag{6.3.725}$$

Remark

In physics many times problems are often in the plane and require the transition to polar coordinates because many academic physic problems are centro-symmetric, which also facilitates the calculations of path integrals.

✍**Example:**

Let us calculate the work of the force of gravity moving a mass M of the point $M_1(a_1,b_1,c_1)$ to the point $M_2(a_2,b_2,c_2)$ along an arbitrary path C. The projections of the force of gravity on the coordinate axes are:

$$F_x=0,F_y=0,F_z=-mg \tag{6.3.726}$$

The work accomplish is then:

$$\begin{aligned}W&=\int_C \vec{F}\circ\mathrm{d}\vec{r}=\int_C (F_x(x,y,z)\mathrm{d}x+F_y(x,y,z)\mathrm{d}y+F_z(x,y,z)\mathrm{d}y)\\&=-\int_C mg\mathrm{d}z=-mg\Delta z\end{aligned} \tag{6.3.727}$$

so we find a very known result of the section of Classical Mechanics.

A line integral of a vector $\vec{F}$ field along a curve C_1 is independent of the path of integration if:

$$\int\limits_{C_1}\vec{F}\circ\mathrm{d}\vec{r}=\int\limits_{C_2}\vec{F}\circ\mathrm{d}\vec{r} \tag{6.3.728}$$

for any non-null curve C_2 having only the same points of departure and arrival. Furthermore if the vector field satisfied (where U in physics is typically a potential):

$$\left.\begin{aligned}F_x(x,y)&=\frac{\partial U}{\partial x}\\F_y(x,y)&=\frac{\partial U}{\partial y}\end{aligned}\right\}\Rightarrow\vec{F}=\overrightarrow{\mathrm{grad}}(U)=\vec{\nabla}(U) \tag{6.3.729}$$

as (the reader will recognize an exact total differential form):

$$\vec{F}\circ\mathrm{d}\vec{r}=F_x(x,y)\mathrm{d}x+F_y(x,y)\mathrm{d}y=\frac{\partial U}{\partial x}\mathrm{d}x+\frac{\partial U}{\partial y}\mathrm{d}y \tag{6.3.730}$$

Then the integral path on an arbitrary curve only depends only on the difference of the values the function U at the two ends! This is the "fundamental theorem for line integrals" or "gradient theorem for line integrals".

Proof 6.14.9. If the differential form of the vector field satisfies a total exact differential, we have:

$$\begin{aligned} W_{A,B} &= \int\limits_A^B \left(\frac{\partial U}{\partial x}\mathrm{d}x + \frac{\partial U}{\partial y}\mathrm{d}y\right) = \int\limits_A^B \left(\frac{\partial U}{\partial x}\frac{\mathrm{d}x}{\mathrm{d}t} + \frac{\partial U}{\partial y}\frac{\mathrm{d}y}{\mathrm{d}t}\right)\mathrm{d}t = \int\limits_{t_1}^{t_2} \frac{\mathrm{d}}{\mathrm{d}t}U(x(t),y(t))\mathrm{d}t \\ &= U(t)|_{t_1}^{t_2} = U(x(t_2),y(t_2)) - U(x(t_1),y(t_1)) = U(B) - U(A) \end{aligned} \tag{6.3.731}$$

That is:

$$\boxed{\int\limits_\Gamma \vec{F}\circ\mathrm{d}\vec{r} \Leftrightarrow \int\limits_\Gamma \vec{\nabla}(U)\circ\mathrm{d}\vec{r}: \quad \int\limits_\Gamma \vec{\nabla}(U)\circ\mathrm{d}\vec{r} = U(b) - U(a)} \tag{6.3.732}$$

■ Q.E.D.

So the line integral of an exact total differential does not depend on the path of integration but only the ends! We also conclude that if $\vec{F}$ is derived from a scalar potential and $A = B$, the line integral is then zero.

In physics this result is interpreted by saying that the work provided by a force $\vec{F}$ derived from a scalar potential acting on an elementary particle in a finite displacement does not depend on the path followed.

Definitions (#6.3.202):

D1. When the curve (path) C is closed and the path integral has a result independent result of the direction in which this path is travelled, we use the following notation (the letter below the symbol representing the path can of course vary...):

$$\oint_C \tag{6.3.733}$$

If this closed integral is always zero, we say that the integrated vector field is a "conservative vector field" and "derives from a scalar potential" (and therefore satisfies the Schwarz's theorem to be written as an exact total differential) since this stems from the proof given already just above.

D2. When the value of the integral of a closed path depends on the orientation (clockwise not equal to counter-clockwise) we use the following notation (the letter below the symbol representing the path can of course vary...):

$$\ointclockwise_C \quad \text{or} \quad \ointctrclockwise_C \tag{6.3.734}$$

Thus if the direction is direct (that is to say "counter-clockwise" or "trigonometric") as the notation on the above, its sign will be positive; if on the contrary the direction is clockwise his sign will be negative (see the proof in the section of Complex Analysis). Therefore we often speak about respectively "negative direction" or "positive direction".

Thus, to summarize, a line integral (path integral) is fully defined by the expression under the symbol of the integral, the form of integration path and the direction of the integration.

Remark

The reader will find some the proofs of very important properties of curvilinear integrals in the section of Vector Calculus as the Green-Riemann theorem or a particular application to study holomorphic functions in the section of Complex Analysis.

6.3.2.12 Surface Integrals

Surface integrals are a natural generalization of line (curvilinear) integrals: instead of integrating over a curve, we integrate over a surface in three space. Such integrals are important in any of the subjects that deal with continuous media (solids, fluids, gases), as well as subjects that deal with force fields, like electromagnetic or gravitational fields.

Though most of our work will be spent seeing how surface integrals can be calculated and what they are used for, we first want to indicate briefly how they are defined. The surface integral of the (continuous) function $f(x,y,z)$ over the surface S is denoted by:

$$\iint_S f(x,y,z)\mathrm{d}S \qquad (6.3.735)$$

You can think of $\mathrm{d}S$ as the area of an infinitesimal piece of the surface S. To define the integral above, we subdivide the surface S into small pieces having area ΔS_i, pick a point (x_i,y_i,z_i) in the i-th piece, and form the Riemann sum:

$$\sum f(x_i,y_i,z_i)\,\Delta S_i \qquad (6.3.736)$$

As the subdivision of S gets finer and finer, the corresponding sums above approach a limit which does not depend on the choice of the points or how the surface was subdivided. The previous surface integral is defined to be this limit (the surface has to be smooth and not infinite in extent, and the subdivisions have to be made reasonably, otherwise the limit may not exist, or it may not be unique).

The most important type of surface integral is the one which calculates the flux of a vector field across S. Earlier, we calculated the flux of a plane vector field $\vec{F}(x,y)$ across a directed curve in the xy-plane. What we are doing now is the analog of this in space.

We assume that S is oriented: this means that S has two sides and one of them has been designated to be the "positive side". At each point of S there are two unit normal vectors, pointing in opposite directions; the positively directed unit normal vector, denoted by $\vec{n}$, is the one standing with its base (i.e., tail) on the positive side. If S is a closed surface, like a sphere or cube - that is, a surface with no boundaries, so that it completely encloses a portion of 3-space - then by convention it is oriented so that the outer side is the positive one, i.e., so that $\vec{n}$ always points towards the outside of S:

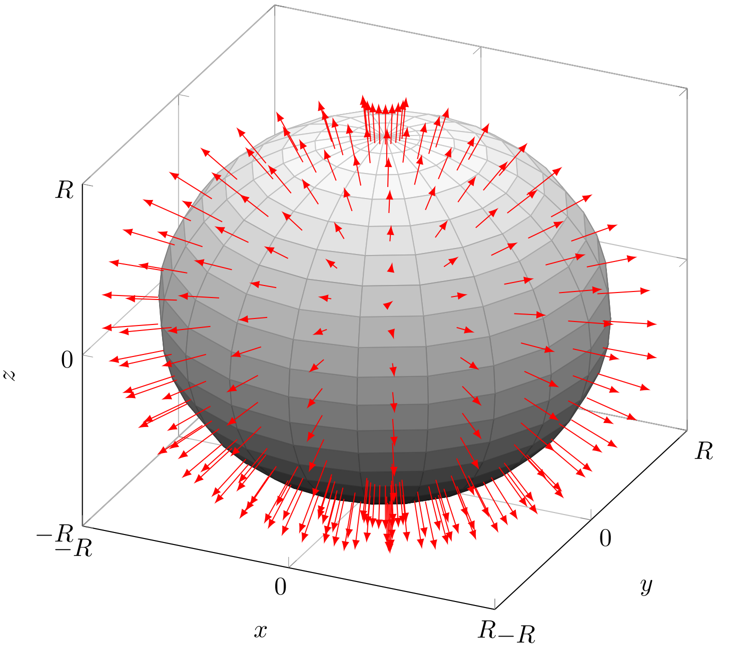

Figure 6.62: **Outgoing flux for surface integral of an entire sphere**

Let $\vec{F}(x,y,z)$ be a continuous vector field in space, and S an oriented surface. We define:

$$\text{flux of } \vec{F} \text{ through } S = \iint_S (\vec{F}\circ\vec{n})dS = \iint_S \vec{F}\circ\mathrm{d}\vec{S} \tag{6.3.737}$$

the two integrals are the same, but the second is written using the common and suggestive abbreviation $\mathrm{d}\vec{S}=\vec{n}\mathrm{d}S$.

If $\vec{F}$ represents the velocity field for the flow of an incompressible fluid of density 1, then $\vec{F}\circ\vec{n}$ represents the component of the velocity in the positive perpendicular direction to the surface, and $\vec{F}\circ\vec{n}\mathrm{d}S$ represents the flow rate across the little infinitesimal piece of surface having area $\mathrm{d}S$. The integral above adds up these flows across the pieces of surface, so that we may interpret it as saying:

$$\text{flux of } \vec{F} \text{ through } S = \text{ net flow rate across } S \tag{6.3.738}$$

where we count flow in the direction of $\vec{n}$ as positive, flow in the opposite direction as negative. More generally, if the fluid has varying density, then the right side of the above relation is the net mass transport rate of fluid across S (per unit area, per time unit).

If $\vec{F}$ is a force field, then nothing is physically flowing, and one just uses the term "flux" to denote the surface integral, as in:

$$\text{flux of } \vec{F} \text{ through } S = \iint_S (\vec{F}\cdot\vec{n})dS = \iint_S \vec{F}\circ\mathrm{d}\vec{S} \tag{6.3.739}$$

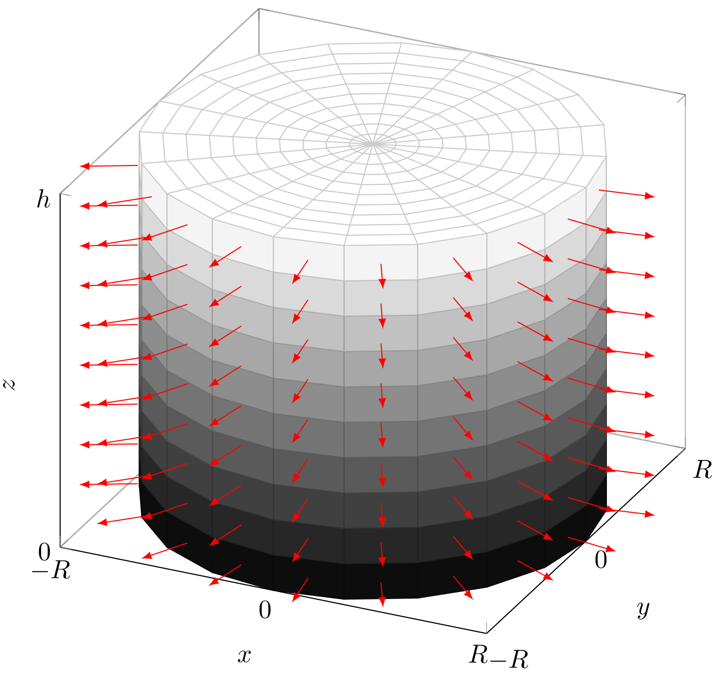

Figure 6.63: **Outgoing flux for surface integral of the side of a cylinder**

✍**Example:**

E1. Let us find the flux of $\vec{F}=z\vec{i}+x\vec{j}+y\vec{k}$ outward through the portion of the cylinder $x^2+y^2=a^2$ in the first octant and below the plane $z=h$.

The piece of cylinder is pictured. The word "outward" suggests that we orient the cylinder so that $\vec{n}$ points outward (as the figure above), i.e., away from the z axis. Since by inspection $\vec{n}$ is radially outward and horizontal:

$$\vec{n}=\frac{x\vec{i}+y\vec{j}}{a} \tag{6.3.740}$$

This is the outward normal to the circle $x^2+y^2=a^2$ in the xy-plane; $\vec{n}$ has no z-component since it is horizontal. We divide by a to make its length 1.

To get $\mathrm{d}S$, the infinitesimal element of surface area, we use cylindrical coordinates to parametrize the cylinder:

$$x=a\cos(\theta),\quad y=a\sin(\theta)\quad z=z \tag{6.3.741}$$

As the parameters θ and z vary, the whole cylinder is traced out ; the piece we want satisfies $0\leq\theta\leq\pi/2, 0\leq z\leq h$. The natural way to subdivide the cylinder is to use little pieces of curved rectangle, bounded by two horizontal arc of circles and two vertical lines on the surface. Its area $\mathrm{d}S$ is the product of its height and width:

$$\mathrm{d}S=\mathrm{d}z\cdot a\mathrm{d}\theta \tag{6.3.742}$$

Having obtained $\vec{n}$ and $\mathrm{d}S$, the rest of the work is routine. We express the integrand of our surface integral:

$$\Phi_S=\iint_S(\vec{F}\circ\vec{n})\mathrm{d}S=\iint_S\vec{F}\circ\mathrm{d}\vec{S} \tag{6.3.743}$$

in terms of z and θ :

$$\begin{aligned}\vec{F}\circ\vec{n}\mathrm{d}S&=\dfrac{zx+xy}{a}\cdot a\mathrm{d}z\mathrm{d}\theta\\&=\left(az\cos(\theta)+a^2\sin(\theta)\cos(\theta)\right)\mathrm{d}z\mathrm{d}\theta\end{aligned}\tag{6.3.744}$$

This last step is essential, since the $\mathrm{d}z$ and $\mathrm{d}\theta$ tell us the surface integral will be calculated in terms of z and θ, and therefore the integrand must use these variables also. We can now calculate the flux through S :

$$\begin{aligned}\iint_S \vec{F}\circ\vec{n}\mathrm{d}S&=\int\limits_0^{\pi/2}\int\limits_0^{h}\left(az\cos(\theta)+a^2\sin(\theta)\cos(\theta)\right)\mathrm{d}z\mathrm{d}\theta\\ \text{inner integral }&=\dfrac{ah^2}{2}\cos(\theta)+a^2h\sin(\theta)\cos(\theta)\\ \text{outer integral }&=\left[\dfrac{ah^2}{2}\sin(\theta)+a^2h\dfrac{\sin^2(\theta)}{2}\right]_0^{\pi/2}=\dfrac{ah}{2}(a+h)\end{aligned}\tag{6.3.745}$$

We can notice quickly that on the whole lateral surface of the cylinder the surface integral is equal to zero.

E2. Let us found the flux of $\vec{F}=xz\vec{i}+yz\vec{j}+z^2\vec{k}$ outward through that part of the sphere $x^2+y^2+z^2=a^2$ lying in the first octant $(x,y,z,\geq 0)$.

Once again, we begin by finding $\vec{n}$ and $\mathrm{d}S$ for the sphere. We take the outside of the sphere as the positive side, so $\vec{n}$ points radially outward from the origin; we see by inspection therefore that:

$$\vec{n}=\dfrac{x\vec{i}+y\vec{j}+z\vec{k}}{a}\tag{6.3.746}$$

where we have divided by a to make $\vec{n}$ a unit vector.

To do the integration, we use spherical coordinates ρ,ϕ,θ. On the surface of the sphere of radius $\rho=a$, so the coordinates are just the two angles ϕ and θ. The area element $\mathrm{d}S$ is most easily found using the famous spherical volume element:

$$\mathrm{d}V=\rho^2\sin(\phi)\mathrm{d}\rho\mathrm{d}\phi\mathrm{d}\theta=\mathrm{d}S\cdot\mathrm{d}\rho=\text{ area }\cdot\text{ thickness}\tag{6.3.747}$$

so that dividing by the thickness $\mathrm{d}\rho$ and setting $\rho=a$, we get:

$$\mathrm{d}S=a^2\sin(\phi)\mathrm{d}\phi\mathrm{d}\theta\tag{6.3.748}$$

Finally since the area element $\mathrm{d}S$ is expressed in terms of ϕ and θ, the integration will be done using these variables, which means we need to express x,y,z in terms of ϕ and θ. We use the formulas expressing Cartesian in terms of spherical coordinates (setting $\rho=a$ since (x,y,z) is on the sphere):

$$x=a\sin(\phi)\cos(\theta),\quad y=a\sin(\phi)\sin(\theta),\quad z=a\cos(\phi)\tag{6.3.749}$$

We can now calculate the flux integral:

$$\Phi_S=\iint_S(\vec{F}\circ\vec{n})\mathrm{d}S=\iint_S\vec{F}\circ\mathrm{d}\vec{S} \tag{6.3.750}$$

By:

$$\vec{n}=\frac{x\vec{i}+y\vec{j}+z\vec{k}}{a} \tag{6.3.751}$$

and:

$$\mathrm{d}S=a^2\sin(\phi)\mathrm{d}\phi\mathrm{d}\theta \tag{6.3.752}$$

the integrand is:

$$\vec{F}\circ\vec{n}\mathrm{d}S=\frac{1}{a}\left(x^2z+y^2z+z^2z\right)\cdot a^2\sin(\phi)\mathrm{d}\phi\mathrm{d}\theta \tag{6.3.753}$$

Using:

$$x=a\sin(\phi)\cos(\theta),\quad y=a\sin(\phi)\sin(\theta),\quad z=a\cos(\phi) \tag{6.3.754}$$

and noting that $x^2+y^2+z^2=a^2$, the integral becomes (we put $u=\sin(\phi)\longrightarrow\mathrm{d}u=\cos(\phi)\mathrm{d}\phi$):

$$\begin{aligned}\iint_S\vec{F}\circ\vec{n}\mathrm{d}S&=a^4\int\limits_0^{\pi/2}\int\limits_0^{\pi/2}\cos(\phi)\sin(\phi)\mathrm{d}\phi\mathrm{d}\theta=a^4\frac{\pi}{2}\int\limits_0^{\pi/2}\int\limits_0^{\pi/2}\cos(\phi)\sin(\phi)\mathrm{d}\phi\\&=a^4\frac{\pi}{2}\int\limits_0^{\pi/2}u\mathrm{d}u=a^4\frac{\pi}{2}\frac{1}{2}\sin^2(\phi)\Big]_0^{\pi/2}=\frac{\pi a^4}{4}\end{aligned} \tag{6.3.755}$$

6.3.2.13 Integrals involving parametric equations

Now that we have seen how to calculate the derivative of a plane curve, the next question is this: How do we find the area under a curve defined parametrically?

To derive an expression for the area under a parametric curve defined by the functions:

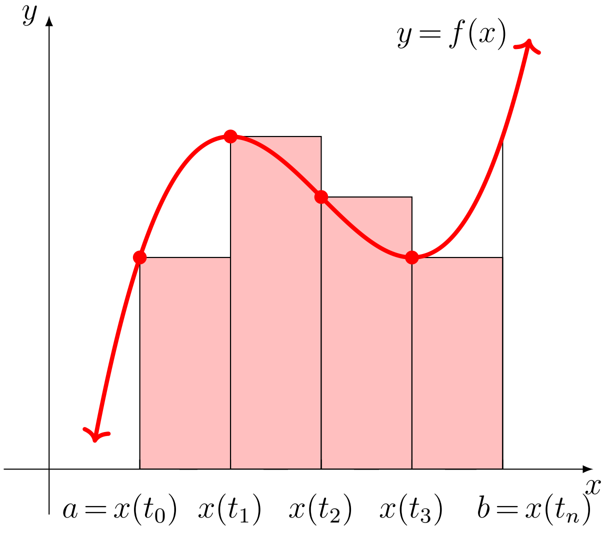
$$x = x(t) \qquad y = y(t) \tag{6.3.756}$$

with $a \leq t \leq b$, we assume that $x(t)$ is differentiable and start with an equal partition of the interval $a \leq t \leq b$.

Let us suppose:

$$t_0 = a < t_1 < t_2 < \ldots < t_n = b \tag{6.3.757}$$

and consider the following figure:



We use rectangles to approximate the area under the curve. The height of a typical rectangle in this parametrization is $y(x(\overline{t_i}))$ for some value $\overline{t_i}$ in the i-th subinterval, and the width can be calculated as $x(t_i) - x(t_{i-1})$. Thus the area of the i-th rectangle is given by:

$$S_i = y(x(\overline{t_i}))(x(t_i) - x(t_{i-1})) \tag{6.3.758}$$

Then a Riemann sum for the area is:

$$S_n = \sum_{i=1}^{n} y(x(\overline{t_i}))(x(t_i) - x(t_{i-1})) \tag{6.3.759}$$

Multiplying and dividing each area by $t_i - t_{i-1}$ gives:

$$S_n = \sum_{i=1}^{n} y(x(\overline{t_i}))\frac{(x(t_i) - x(t_{i-1}))}{x(t_i) - x(t_{i-1})}(x(t_i) - x(t_{i-1})) = \sum_{i=1}^{n} y(x(\overline{t_i}))\frac{(x(t_i) - x(t_{i-1}))}{\Delta t}\Delta t \tag{6.3.760}$$

Taking the limit as n approaches infinity gives:

$$\boxed{S=\lim_{n\rightarrow+\infty}=\int\limits_a^b y(t)x'(t)\mathrm{d}t} \tag{6.3.761}$$

And it is obvious that applying Pythagoras's theorem on an infinitesimal length of the parametric curve we have:

$$\boxed{L=\int\limits_{t_1}^{t_2}\sqrt{\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2+\left(\frac{\mathrm{d}y}{\mathrm{d}t}\right)^2}\mathrm{d}t} \tag{6.3.762}$$

with $x=x(t)$, $y=y(t)$ and $t_1<t<t_2$. This gives the arc length of the parametric curve between two points on the curve.

It comes also immediately:

$$L=\int\limits_{t_1}^{t_2}\frac{\mathrm{d}x}{\mathrm{d}t}\sqrt{1+\left(\frac{\mathrm{d}y}{\mathrm{d}x}\right)^2}\mathrm{d}t=\int\limits_{t_1}^{t_2}x'(t)\sqrt{1+y'(t)^2}\mathrm{d}t \tag{6.3.763}$$

The chain rule gives:

$$\mathrm{d}x=x'(t)\mathrm{d}t \tag{6.3.764}$$

Therefore:

$$\boxed{L=\int\limits_a^b\sqrt{1+y'(t)^2}\mathrm{d}x} \tag{6.3.765}$$

We will meet again this relation in the section of Analytical Mechanics.

In astronomy we often have to deal with closed curved and calculated the distance travel on that curve. But working in cartesian coordinates is not always is the best. This is why it is better to change in polar coordinates.

The idea is to suppose that we are able to express our curve of interest in the following form:

$$r=f(\theta) \tag{6.3.766}$$

where $\alpha\leq\theta\leq\beta$. In order to adapt the arc length relation for a polar curve, we use the relations:

$$x=r\cos(\theta)=f(\theta)\cos(\theta)\qquad y=r\sin(\theta)=f(\theta)\sin(\theta) \tag{6.3.767}$$

and we replace the parameter t by θ. Then:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}\theta}&=f'(\theta)\cos(\theta)-f(\theta)\sin(\theta)\\ \frac{\mathrm{d}y}{\mathrm{d}\theta}&=f'(\theta)\sin(\theta)+f(\theta)\cos(\theta)\end{aligned} \tag{6.3.768}$$

We replace $\mathrm{d}t$ by $\mathrm{d}\theta$, and the lower and upper limits of integration are α and β respectively. Then the arc length formula becomes:

$$\begin{aligned}L&=\int\limits_a^b\sqrt{\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2+\left(\frac{\mathrm{d}y}{\mathrm{d}t}\right)^2}\mathrm{d}t=\int\limits_\alpha^\beta\sqrt{\left(\frac{\mathrm{d}x}{\mathrm{d}\theta}\right)^2+\left(\frac{\mathrm{d}y}{\mathrm{d}\theta}\right)^2}\mathrm{d}t\\&=\int\limits_\alpha^\beta\sqrt{(f'(\theta)\cos(\theta)-f(\theta)\sin(\theta))^2+(f'(\theta)\sin(\theta)+f(\theta)\cos(\theta))^2}\mathrm{d}\theta\\&=\int\limits_\alpha^\beta\sqrt{(f'(\theta))^2(\cos^2(\theta)+\sin^2(\theta))+(f(\theta))^2(\cos^2(\theta)+\sin^2(\theta))}\mathrm{d}\theta\\&=\int\limits_\alpha^\beta\sqrt{(f'(\theta))^2+(f(\theta))^2}\mathrm{d}\theta=\int\limits_\alpha^\beta\sqrt{r^2+\left(\frac{\mathrm{d}r}{\mathrm{d}t}\right)^2}\mathrm{d}\theta\end{aligned}\tag{6.3.769}$$

So finally in polar coordinates:

$$\boxed{L=\int\limits_\alpha^\beta\sqrt{r^2+\left(\frac{\mathrm{d}r}{\mathrm{d}t}\right)^2}\mathrm{d}\theta}\tag{6.3.770}$$

6.3.2.14 Improper Integrals

Improper integrals are definite integrals where one or both of the boundaries is at infinity, or where the integrand has a vertical asymptote in the interval of integration. As crazy as it may sound, we can actually calculate some improper integrals using some clever methods that involve limits.

By abuse of notation, improper integrals are often written symbolically just like standard definite integrals, perhaps with infinity among the limits of integration. When the definite integral exists (in the sense of either the Riemann integral or the more advanced Lebesgue integral), this ambiguity is resolved as both the proper and improper integral will coincide in value and this is what will the most occur through all applications of integrals in physics, chemistry and engineering through this textbook!

For the Riemann integral (or the Darboux integral, which is equivalent to it as we have seen earlier above), improper integration is necessary both for unbounded intervals (since one cannot divide the interval into finitely many subintervals of finite length) and for unbounded functions with finite integral (since, supposing it is unbounded above, then the upper integral will be infinite, but the lower integral will be finite)!

An "improper integral" of a function $f(x)>0$ is given basically by:

$$\int\limits_a^{+\infty}f(x)\mathrm{d}x=\lim_{N\rightarrow+\infty}\int\limits_a^N f(x)\mathrm{d}x\tag{6.3.771}$$

And we say that the improper integral converge if this limit exists and diverges otherwise.

More generally, improper integrals are given by the following pairs of possibilities:

$$\boxed{\lim_{b\rightarrow+\infty}\int\limits_a^b f(x)\mathrm{d}x \qquad \lim_{a\rightarrow-\infty}\int\limits_a^b f(x)\mathrm{d}x} \tag{6.3.772}$$

or:

$$\boxed{\lim_{c\rightarrow b^-}\int\limits_a^c f(x)\mathrm{d}x \qquad \lim_{c\rightarrow a^+}\int\limits_c^b f(x)\mathrm{d}x} \tag{6.3.773}$$

in which one takes a limit in one or the other (or sometimes both) endpoints.

Remark

By abuse of notation, improper integrals are often written symbolically just like standard definite integrals, perhaps with infinity among the limits of integration. When the definite integral exists (in the sense of either the Riemann integral or the more advanced Lebesgue integral), this ambiguity is resolved as both the proper and improper integral will coincide in value.

Geometrically then the improper integral represents the total area under a curve stretching to infinity. If the integral $\int_a^{+\infty} f(x)\mathrm{d}x$ converges the total area under the curve is finite; otherwise it's infinite.

But how can an area that extends to infinity be finite? Obviously the area between a and N (i.e. $\int_a^N f(x)\mathrm{d}x$) is finite. As N goes to infinity this quantity will either grow without bound or it will converge to some finite value.

The domains where improper integrals are the most used, without even be noticeable most of time by students or engineering practitioners, are respectively:

- Statistics (see corresponding section) when we normalize or check the condition of convergence to a cumulated probability of 1 of a density function (most of time in statistics one or the both boundaries are equal to infinity)
- Wave Quantum Physics (see corresponding section) where we deal sometimes with free propagating particles from infinity to infinity (this also happens sometimes in General Relativity)
- Differential equations, especially when we solve them by using Fourier Transform or Laplace transform (we have many examples using this transforms across the book) for practical application in physics and high level financial engineering.
- In astrophysics or electrostatics when dealing with any punctual potential field source of the type $1/r^2$ for which we want to calculate the work necessary to bring an object from infinity to that source (calculation of the type $\int_{+\infty}^{r} f(r)\mathrm{d}r$).

✍**Examples:**

E1. We want compute the very important integral (to introduce Laplace Transforms):

$$I=\int\limits_{0}^{+\infty} e^{-at}\mathrm{d}t \tag{6.3.774}$$

with $a\in\mathbb{R}$.

Following the definition above we need to first compute a definite integral and the take a limit. So from the definition:

$$I=\int\limits_{0}^{+\infty} e^{-at}\mathrm{d}t=\lim_{N\rightarrow+\infty}\int\limits_{0}^{N} e^{-at}\mathrm{d}t \tag{6.3.775}$$

We first compute the definite integral. We start with the case $a=0$:

$$I_{a=0}=\lim_{N\rightarrow+\infty}\int\limits_{0}^{N}\mathrm{d}t=\lim_{N\rightarrow+\infty} t\Big|_{0}^{N}=\lim_{N\rightarrow+\infty} N=+\infty \tag{6.3.776}$$

therefore for $a=0$ the improper integral I does not exist. When $a\neq 0$ we have:

$$I_{a\neq 0}=\lim_{N\rightarrow+\infty}-\frac{1}{a}\left(e^{-aN}-1\right) \tag{6.3.777}$$

In the case $a<0$, that is $a=-|a|$, we have that:

$$I_{a<0}=\lim_{N\rightarrow+\infty}-\frac{1}{a}\left(e^{-aN}-1\right)=-\infty \tag{6.3.778}$$

therefore for $a<0$ the improper integral I does not exist. In the case $a>0$ we have:

$$I_{a>0}=\lim_{N\rightarrow+\infty}-\frac{1}{a}\left(e^{-aN}-1\right)=-\frac{1}{a}(0-1)=\frac{1}{a} \tag{6.3.779}$$

E2. We want to compute:

$$I=\int\limits_{-2}^{3}\frac{1}{x^3}\mathrm{d}x \tag{6.3.780}$$

The integrand is not continuous at $x=0$ and so we will need to split the integral up at that point:

$$I=\int\limits_{-2}^{3}\frac{1}{x^3}\mathrm{d}x=\int\limits_{-2}^{0}\frac{1}{x^3}\mathrm{d}x+\int\limits_{0}^{3}\frac{1}{x^3}\mathrm{d}x \tag{6.3.781}$$

Now we need to look at each of these integrals and see if they are convergent:

$$\int\limits_{-2}^{0}\frac{1}{x^3}\mathrm{d}x=\lim_{t\rightarrow 0^-}\int\limits_{-2}^{t}\frac{1}{x^3}\mathrm{d}x=\lim_{t\rightarrow 0^-}\left(-\frac{1}{2x^2}\right)\Bigg|_{-2}^{t}=\lim_{t\rightarrow 0^-}\left(-\frac{1}{2t^2}+\frac{1}{8}\right)=-\infty \tag{6.3.782}$$

At this point we're done. One of the integrals is divergent that means the integral that we were asked to look at is divergent. We don't even need to bother with the second integral.

On a side note, notice that the area under the curve of this infinite interval was not infinity as the reader may have suspected it to be (perhaps). In fact, it was a surprisingly small number. Of course this won't always be the case, but it is important enough to point out that not all areas on an infinite interval will yield infinite areas.

Let's now get some definitions out of the way. We will name these integrals "convergent integrals" if the associated limit exists and is a finite number (i.e. it's not plus or minus infinity) and "divergent integrals" if the associated limit either doesn't exist or is equal to plus or minus infinity.

Notice that the similar integral:

$$\int_{-1}^{+1} \frac{\mathrm{d}x}{x} \tag{6.3.783}$$

cannot be assigned a value in the previous way, as the integrals above and below zero do not independently converge. However there is another possibility that we will see in the section of Functional Analysis during our study of the Hilbert transform (see page 2376).

6.3.2.15 Elliptic Integrals

"Elliptic integrals" originally arose in connection with the problem of giving the arc length of an ellipse. They were first studied by Giulio Fagnano and Leonhard Euler. Modern mathematics defines an "elliptic integral" as any function f which can be expressed in the form:

$$f(x)=\int\limits_{c}^{x} R\left(t,\sqrt{P(t)}\right)\mathrm{d}t \qquad (6.3.784)$$

where R is a rational function of its two arguments, P is a polynomial of degree 2 to 4 with no repeated roots, and c is a constant.

In general, integrals in this form cannot be expressed in terms of elementary functions. Exceptions to this general rule are when P has repeated roots, or when $R(x,y)$ contains no odd powers of t. However, with the appropriate reduction formula, every elliptic integral can be brought into a form that involves integrals over rational functions and the three Legendre canonical forms (i.e. the elliptic integrals of the first, second and third kind).

Let us inform now the reader that we will in this textbook, encounter the following Elliptic Integrals:

- In the section of Non-Euclidean Geometry at page 2678 (complete elliptic integral of second kind):

$$E(k)=\int\limits_{0}^{\pi/2}\sqrt{1-k^2\sin^2(\tau)}\mathrm{d}x \qquad (6.3.785)$$

- In the section of Geometric Shapes at page 2919 (second-order elliptic integral):

$$J(a,b)=\int\limits_{0}^{\pi/2}\sqrt{a^2\cos^2(\theta)+b^2\sin^2(\theta)}\mathrm{d}\theta \qquad (6.3.786)$$

- In the section of Classical Mechanics for the study of the pendulum 3412 (elliptic integral of the first kind):

$$T=4\sqrt{\frac{L}{g}}\int\limits_{0}^{\pi/2}\frac{\mathrm{d}\theta}{\sqrt{1-p^2\sin^2(\theta)}}=4\sqrt{\frac{L}{g}}F\left(\frac{\pi}{2},p^2\right) \qquad (6.3.787)$$

6.3.2.15.1 Incomplete Elliptic Integrals

It is common first to consider three types integrals that we name "incomplete[7] elliptic integrals".

Definitions (#6.3.203):

D1. The "incomplete elliptic integral of the first kind" depends of two parameters, that are the amplitude ϕ and the angle α:

$$F(\phi,\alpha)=\int_0^{\phi}\frac{\mathrm{d}\theta}{\sqrt{1-\sin^2(\alpha)\sin^2(\theta)}} \tag{6.3.788}$$

We can do the following simple change of variables:

$$\begin{aligned} t&=\sin(\theta)\\ \mathrm{d}t&=\cos(\theta)\mathrm{d}\theta=\sqrt{1-t^2}\mathrm{d}\theta \end{aligned} \tag{6.3.789}$$

Hence:

$$F(\phi,\alpha)=\int_0^{\sin(\phi)}\frac{\mathrm{d}t}{\sqrt{(1-\sin^2(\alpha)t^2)(1-t^2)}} \tag{6.3.790}$$

We then use also sometimes instead the parameter $k=\sin(\alpha)$, $(\leq m\leq 1)$, by writing:

$$F(\phi,k)=\int_0^{\phi}\frac{\mathrm{d}\theta}{\sqrt{1-k^2\sin^2(\theta)}}=\int_0^{\sin(\phi)}\frac{\mathrm{d}t}{\sqrt{(1-k^2t^2)(1-t^2)}} \tag{6.3.791}$$

named the "Jacobi's form" of the elliptic integral.

✍**Example:**

Using (see section Trigonometry page 2519):

$$\cos(x)=\cos(\tfrac{1}{2}x+\tfrac{1}{2}x)=\cos^2(\tfrac{1}{2}x)-\sin^2(\tfrac{1}{2}x)=1-2\,\sin^2(\tfrac{1}{2}x) \tag{6.3.792}$$

Then:

$$\int_0^{x}\frac{1}{\sqrt{\cos(x)}}\mathrm{d}x=\int_0^{x}\frac{\mathrm{d}x}{\sqrt{1-2\sin^2(\frac{1}{2}x)}}=2\int_0^{x/2}\frac{\mathrm{d}\theta}{\sqrt{1-2\sin^2(\theta)}}=2F\left(\tfrac{1}{2}x,\sqrt{2}\right) \tag{6.3.793}$$

D2. The "incomplete elliptic integral of the second type" is define we the same both parameters:

$$E(\phi,\alpha)=\int_0^{\phi}\sqrt{1-\sin^2(\alpha)\sin^2(\theta)}\mathrm{d}\theta \tag{6.3.794}$$

---

[7] The term "incomplete integral" seems to be an old fashioned way to name a primitive function...

We can also do the following simple change of variable:

$$\begin{aligned} t &= \sin(\theta) \\ \mathrm{d}t &= \cos(\theta)\mathrm{d}\theta = \sqrt{1-t^2}\mathrm{d}\theta \end{aligned} \tag{6.3.795}$$

and $k = \sin(\alpha)$ to get same as previously:

$$E(\phi,\alpha) = \int\limits_0^{\phi} \sqrt{1-k^2\sin^2(\theta)}\mathrm{d}\theta = \int\limits_0^{x} \frac{\sqrt{1-k^2t^2}}{\sqrt{1-t^2}}\mathrm{d}t \tag{6.3.796}$$

D3. The "incomplete elliptic integral of the third kind":

$$\Pi(\phi,\alpha,n) = \int\limits_0^{\phi} \frac{\mathrm{d}\theta}{(1-n\sin^2(\theta))\sqrt{1-\sin^2(\alpha)\sin^2(\theta)}} \tag{6.3.797}$$

or:

$$\Pi(\phi,k,n) = \int\limits_0^{\phi} \frac{\mathrm{d}\theta}{(1-n\sin^2(\theta))\sqrt{1-k^2\sin^2(\theta)}} \tag{6.3.798}$$

for $n > 0$. We can do the same type of change of variable, and therefore:

$$\Pi(\phi,k,n) = \int\limits_0^{\sin(\phi)} \frac{\mathrm{d}\theta}{(1-nt^2)\sqrt{(1-t^2)(1-kt^2)}} \tag{6.3.799}$$

6.3.2.15.2 Complete Elliptic Integrals

When the amplitude is equal to $\pi/2$ (hence $t = 1$), we write the following "complete elliptic integrals".

Definitions (#6.3.204):

D1. The "complete elliptic integral of the first kind" may thus be defined from the incomplete elliptic integral of the first kind:

$$K(k) = F(\pi/2,k) = \int\limits_0^{\pi/2} \frac{\mathrm{d}\theta}{\sqrt{1-k^2\sin^2(\theta)}} = \int\limits_0^{1} \frac{\mathrm{d}t}{\sqrt{(1-t^2)(1-k^2t^2)}} \tag{6.3.800}$$

D2. The "complete elliptic integral of the second kind" may thus be defined from the incomplete elliptic integral of the second kind also:

$$E(k) = E(\pi/2,k) = \int\limits_0^{\frac{\pi}{2}} \sqrt{1-k^2\sin^2(\theta)}\mathrm{d}\theta = \int\limits_0^{1} \frac{\sqrt{1-k^2t^2}}{\sqrt{1-t^2}}\mathrm{d}t \tag{6.3.801}$$

D3. The "complete elliptic integral of the third kind" may thus be defined from the incomplete elliptic integral of the third kind also:

$$\Pi(k,n)=\Pi(\pi/2,k,n)=\int\limits_0^{\pi/2}\frac{\mathrm{d}\theta}{(1-n\sin^2(\theta))\sqrt{1-\sin^2(\alpha)\sin^2(\theta)}}=\int\limits_0^{1}\frac{\mathrm{d}\theta}{(1-nt^2)\sqrt{(1-t^2)(1-kt^2)}} \tag{6.3.802}$$

6.3.3 Differential Equations

Definition (#6.3.205): In mathematics, a "differential equation" (D.E.) is a relation between one or more unknown functions and their derivatives up to order n. The "order" of a differential equation corresponding to the maximum degree of differentiation which one of the functions is subjected.

Compared to our goal of trying to see how the math describes the sensible reality, differential equations are a great success but are also the source of many troubles. First there are modelling difficulties (see for example the differential equation system of General Relativity in the corresponding section of the book...) resolution difficulties (there is no general method even with numerical computer methods as you can see in the corresponding section!), then their are proper mathematical difficulties (that's why some D.E. have million dollar price in case or resolution), finally difficulties related to the fact that certain differential equations are unstable by nature and give chaotic solutions (see the section Population Dynamics or Meteorology for flagrant simple examples!).

Remark

The differential equations are used to construct mathematical models of physical or biological phenomena, such as for the study of radioactivity, celestial mechanics, electronic circuits, population development or even financial stochastic process. Therefore, differential equations represent a vast field of study, both in pure and Applied Mathematics.

> ❞ *Since Newton, mankind has come to realize that the laws of physics are always expressed in the language of differential equations.* ❞
>
> Steven Strogatz

quote 6.3:1603.#54

The most general differential equation of order n can always be written in the form:

$$F\left(x,y,y',\ldots,y^{(n)}\right)=0 \qquad (6.3.803)$$

We consider in this textbook only the cases where x and y have their values in $\mathbb{R}$. A solution to such a D.E. on the interval $I\in\mathbb{R}$ is a function $y\in\mathcal{C}^n(I,\mathbb{R})$ (a function $y:I\rightarrow\mathbb{R}$ which is n times continuously differentiable) such that for any $x\in I$, we have:

$$F\left(x,y(x),y'(x),\ldots,y^{(n)}(x)\right)=0 \qquad (6.3.804)$$

Name differential equation	Notation	Parameters involved
Laplace	$\nabla^2 f = 0$	$f(x,y,z)$
Diffusion (conduction)	$\frac{\partial f}{\partial t} = D\nabla^2 f$	Diffusion coefficient D
Helmholtz	$\nabla^2 f + \alpha^2 f = 0$	Constant α
Wave	$\nabla^2 f = \frac{1}{c^2}\frac{\partial^2 f}{\partial t^2}$	Wave speed c
Legendre	$\frac{\mathrm{d}}{\mathrm{d}x}\left[(1-x^2)\frac{\mathrm{d}y}{\mathrm{d}x}\right] + l(l+1)y = 0$	Integer l
Associated Legendre	$\frac{\mathrm{d}}{\mathrm{d}x}\left[(1-x^2)\frac{\mathrm{d}y}{\mathrm{d}x}\right] + \left[l(l+1) - \frac{m^2}{1-x^2}\right]y = 0$	Integers l, m
Bessel	$x^2\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} + x\frac{\mathrm{d}y}{\mathrm{d}x} + (x^2 - m^2)y = 0$	Constant m
Hermite	$\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} - 2x\frac{\mathrm{d}y}{\mathrm{d}x} + 2\alpha y = 0$	Constant α
Laguerre	$x\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} + (1-x)\frac{\mathrm{d}y}{\mathrm{d}x} + \alpha y = 0$	Constant α
Associated Laguerre	$x\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} + (1+k-x)\frac{\mathrm{d}y}{\mathrm{d}x} + \alpha y = 0$	Integer k , constant α
Chebyshev	$(1-x^2)\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} - x\frac{\mathrm{d}y}{\mathrm{d}x} + n^2 y = 0$	Integer n
Euler (or Cauchy)	$x^2\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} + ax\frac{\mathrm{d}y}{\mathrm{d}x} + by = f(x)$	Constants a, b
Bernoulli	$\frac{\mathrm{d}y}{\mathrm{d}x} + p(x)y = q(x)y^a$	
Airy	$\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} = xy$	
Blach & Scholes	$\frac{\partial F}{\partial t} + \frac{1}{2}\sigma^2 S^2\frac{\partial^2 F}{\partial S^2} + rS\frac{\partial F}{\partial S} - rF = 0$	Constant σ, S, r
Fuchs	$x^n y^{(n)} + p_1(x)x^{n-1}y^{(n-l)} + \ldots + p_n(x)y = 0$	p_i holomorph

Table 6.12: **Some of the most famous differential equations we will build and use in this textbook in practical cases**

Remarks

R1. For reasons that will be developed later, we also say "integrate a D.E." instead of saying "finding a solution to the D.E.". The first expression is particularly found in the American literature.

R2. Since all this textbook is full examples of differential equations with initial conditions (we speak then about a "Cauchy problem") and methods of resolutions in the section of Classical Mechanics, Atomic Physics, Cosmology, Econometry, Sequences and series, Industrial Engineering, Statistics, etc., we will not give any application examples here and will focus only on the minimum theoretical useful aspect.

6.3.3.1 First order differential equations

A differential equation of the first order is therefore a D.E. which involves only the first derivative y'.

Definition (#6.3.206): A first order differential equation is named "D.E. of order 1 with separate variables" if it can be written as:

$$f(y)y' = g(x) \tag{6.3.805}$$

Such a differential equation can be easily integrated. Indeed, we write:

$$y' = \frac{\mathrm{d}y}{\mathrm{d}x} \tag{6.3.806}$$

Then symbolically:

$$f(y)\mathrm{d}y = g(x)\mathrm{d}x \Leftrightarrow \int f(y)\mathrm{d}y = \int g(x)\mathrm{d}x + c^{te} \tag{6.3.807}$$

Remark

We write explicitly here the arbitrary integration constant $c^{te} \in \mathbb{R}$ (which is normally implicitly present in the indefinite integrals) to not forget it!

So the purpose is first to find the primitives F and G of f and g, and then to express y in terms of x (and of c^{te}):

$$F(y) = G(x) + c^{te} \Leftrightarrow y = F^{-1}\left(G(x) + c^{te}\right) \tag{6.3.808}$$

The integration constant is fixed when asked for a given $x = x_0$, we get a particular value of $y(x) = y(x_0) = y_0$. We speak then of "initial value problem" or of "initial conditions" also abbreviated: IC. So, in other words, initial conditions are values of the solution and/or its derivative(s) at specific points. As we will see eventually, solutions to ... nice enough ... differential equations are unique and hence only one solution will meet the given conditions. The number of initial conditions that are required for a given differential equation will depend upon the order of the differential equation as we will see.

6.3.3.2 Linear differential equations

Definition (#6.3.207): A differential equation of order n is named "linear differential equation L.D.E." if and only if it is of the form:

$$L(y) = f(x) \tag{6.3.809}$$

with:

$$L(y) = a_0(x)y + a_1(x)y' + a_2(x)y'' + \ldots + a_n(x)y^{(n)} \tag{6.3.810}$$

Hence a differential equation is linear if the dependent variable $(y, y', y'', \ldots)$ appears only linearly.

Let us now see a property that may seem insignificant at first glance but which will become very important later!

We will prove now that L is a linear application:

$$L(y+z)=\sum_{i=0}^{n}a_i(x)(y+z)^{(i)}=\sum_{i=0}^{n}a_i(x)y^{(i)}+\sum_{i=0}^{n}a_i(x)z^{(i)}=L(y)+L(z) \quad (6.3.811)$$

and for all $\lambda\in\mathbb{R}$:

$$L(\lambda y)=\sum_{i=0}^{n}a_i(x)(\lambda y)^{(i)}=\lambda\sum_{i=0}^{n}a_i(x)y^{(i)}=\lambda L(y) \quad (6.3.812)$$

Then we say that the linear D.E. represent a linear model if the multiples of this function (or any linear combination) are also a solution. Thus, in physics, for a linear system, the amplification of the cause involves an amplification of the effect (the systems are often linear in high-school problems but in reality they are rather the exception!).

For example, the ordinary differential equation of order 2 of the simple pendulum proved in the section of Classical Mechanics is not linear because it contains a sine term that is not separable.

Definition (#6.3.208): The linear differential equation (which is the most common in physics):

$$L(y)=0 \quad (6.3.813)$$

is named "homogeneous equation H.E." or " equation without second member E.W.S.M." (and sometimes "complementary equation") associated to:

$$L(y)=f(x) \quad (6.3.814)$$

In other words, a differential equation is homogeneous if $y=0$ is a solution.

Theorem 6.15. We will now prove an important property of H.E.: the set $\{S_0\}$ of solutions of the H.E. is the kernel of the linear application L (which means for refresh: $L(S_0)=0$) and the set $\{S\}$ of solutions to $L(y)=f(x)$ is given by:

$$S=y_p+S_0=\left\{y_p+y_h\middle|y_h\in\{S_0\}\right\} \text{ with } L(y_p)=f(x) \quad (6.3.815)$$

that is to say that the solutions of the form:

$$y=y_p+y_h \quad (6.3.816)$$

where y_p is a "particular/specific solution" to $L(y)=f(x)$ and y_h the "homogeneous solution" give all the D.E. solutions.

Proof 6.15.1. The first statement will be assumed obvious.

As regards to the second part, any function of the form y_p+y_h is solution of $L(y)=f(x)$.

Indeed it is trivial and it follows from the definition of the kernel concept (see section Set Theory page 404):

$$L(y_p+y_h)=L(y_p)+L(y_h)=f(x)+0=f(x) \quad (6.3.817)$$

■ Q.E.D.

What is important also to understand with the linear D.E. with second member, it is that if we find solutions to $L(y)$ with a second given member and solutions to the same D.E. with another different second member, then the sum of all these solutions will be a solution of the D.E. with the sum of the second members!!!

6.3.3.3 Resolution methods of linear differential equations

There are many ways to solve accurately or approximately linear or non-linear differential equations. Let us give the list of the few methods we will analyse further below by the example (but who are already many, many times in the chapters of Mechanics, Cosmology, Social Sciences and Quantum Physics):

- The "method of characteristic polynomial of D.E." (see below) used a bit in every section of the chapter of Mechanics/Quantum Physics/Cosmology/Chemistry and Social Sciences of this textbook.
- The "method of integrating factor" (see also below) for general knowledge but used to this date for practical cases in this textbook.
- The "method of variation of the constant" (see below) and used to this date only in the section of Industrial Engineering in this textbook.
- The "method of disturbances of D.E." (see below) useful for the wave quantum physics and quantum field theory.

Note also other widely used methods (classical high-school techniques) but that are treated case by case in the individual sections of this textbook because solving approaches are too numerous and specific to each problem:

- The "separation of variables method of D.E." as we will see a very specific and simple case just further below but for which it is best to refer to the mentioned sections (the heat equation in the section of Thermodynamics, wave equation in the section Marine & Weather Engineering, Schrödinger evolution equation in the section of Wave Quantum Physics, vibration of a drum in the section of Wave Mechanics, etc.) for concrete examples.
- The "matrix method for solving D.E." and "trivial solution of D.E." (Lotka-Volterra model in the section of Populations Dynamics, electron or nuclear spin resonance in the section of Relativistic Quantum Physics, Lorenz model in the section of Marine & Weather Engineering, etc.).
- The "spectral method" using the spectral theorem proved in the section of Linear Algebra page 2004 (see the section of Industrial Engineering for the calculation of system reliability by Markov chains for a concrete example).

- The "method of the Fourier transform of the D.E." or "method of the Laplace transform of the D.E." (see the heat equation in the section Thermodynamics, the resolution of the Black & Scholes equation in the section of Economy, the beam equation under point load in the section of Civil Engineering for practical applications).
- "Numerical methods for D.E." to solve the differential equations using computer when the D.E. have no known analytic solutions or when they have but we need a visual three dimensional view of the solutions (heat equation in the section of Numerical Methods).
- The "Frobenius method" named after Ferdinand Georg Frobenius and also "power series solutions", that is a way to find an infinite series solution for a second-order ordinary differential equation of a special form. We will use this technique in the section of Sequences and Series for our study of the Bessel series and also introduce Bessel series by solving in the section of Mechanical Engineering the problem of the self-buckling column with the power series solutions.

Remark

The first differential equations were solved around the end of the 117th century (holocene calendar) and beginning of the 118th century. By the middle of the 118th century people realized that the first methods we listed above had reached a dead end. One reason was the lack of functions to write the solutions of differential equations. The elementary functions we use in calculus, such as polynomials, quotient of polynomials, trigonometric functions, exponentials, and logarithms, were simply not enough. People even started to think of differential equations as sources to find new functions. It was matter of little time before mathematicians started to use power series expansions to find solutions of differential equations. Convergent power series define functions far more general than the elementary functions from calculus.

6.3.3.3.1 Method of characteristic polynomial

Solving simple differential equations (with constant coefficients and without second member most of the time...) uses a technique using a characteristic polynomial of the differential equation which we will see the details in the developments that follow on few special cases very frequent in physics.

It is a relatively simple method to implement when we seek solutions to the homogeneous differential equation without second member (E.W.S.M.). In the contrary case, the presence of a second member, we add the solutions of the homogeneous equation to the particular solutions.

6.3.3.3.1.1 Resolution of the H.E. of the first order L.D.E. with constant coefficients

Consider the following L.D.E. with constant coefficients:

$$\frac{\mathrm{d}y}{\mathrm{d}x}+ay=f(x) \tag{6.3.818}$$

which is a simplified version of the following general L.D.E. with constant coefficients:

$$a'\frac{\mathrm{d}y}{\mathrm{d}x}+b'y=f(x) \tag{6.3.819}$$

where:

$$a=\frac{b'}{a'} \tag{6.3.820}$$

We write its associated homogeneous equation (E.W.S.M.):

$$\frac{\mathrm{d}y}{\mathrm{d}x}+ay=0 \tag{6.3.821}$$

Which can be written:

$$\frac{\mathrm{d}y}{y}=-a\mathrm{d}x \tag{6.3.822}$$

Therefore:

$$\ln(y)=-ax+c^{te}\Rightarrow y_h=e^{-ax+c^{te}}=e^{c^{te}}a^{-ax}=Ce^{-ax} \tag{6.3.823}$$

There is behind this homogeneous solution infinite solutions: to each value given to the constant C there is a solution.

We still need to add to this homogeneous solution the particular solution y_p and for that we have a collection of recipes, depending on the type of the function $f(x)$ of the second member of the differential equation. We will see in each case in the various chapters this textbook as already mentioned.

6.3.3.3.1.2 Resolution of the H.E. of the first order L.D.E. with non-constant coefficients

The general solution of homogeneous linear differential equations (E.W.S.M.) of order 1 with non constant coefficients:

$$a(x)y'+b(x)y=0 \tag{6.3.824}$$

can always be reduced to the following form:

$$y'+g(x)y=0 \tag{6.3.825}$$

where:

$$g(x)=\frac{b(x)}{a(x)} \tag{6.3.826}$$

Well obviously there is the solution $y=0$... but let us try to do better. So we have:

$$\frac{y'}{y}=-g(x) \tag{6.3.827}$$

It comes therefore:

$$\ln(y)=-G(x)+c^{te} \tag{6.3.828}$$

where $G(x)$ is a primitive of $g(x)$. Since then:

$$y=e^{c^{te}}e^{-G(x)}=Ae^{-G(x)} \tag{6.3.829}$$

It is also common to find these developments in another notation a little bit more explicit.

So we start again of the differential equation without second member with non-constant coefficients:

$$a(x)\frac{\mathrm{d}y}{\mathrm{d}x}+b(x)y=0 \tag{6.3.830}$$

after rearrangement:

$$\frac{\mathrm{d}y}{y}=-\frac{b(x)}{a(x)}\mathrm{d}x \tag{6.3.831}$$

And then:

$$\ln(y_0)+c^{te}=-\int\frac{b(x)}{a(x)}\mathrm{d}x \tag{6.3.832}$$

Therefore:

$$y_0=c^{te}e^{-\int\frac{b(x)}{a(x)}\mathrm{d}x} \tag{6.3.833}$$

This result will be very useful to calculate the Fourier transform of a Gaussian function (see section Sequences and Series page 1765), Fourier transform, which is essential to resolve in a fairly general way the heat equation (see section Thermodynamics page 3684) resolution that will finally allow us to prove the Black & Scholes equation (see section Economy page 7804).

6.3.3.3.1.3 Resolution of the H.E. of the second order L.D.E. with constant coefficients

Consider the L.D.E. with constant coefficients:

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2}+a\frac{\mathrm{d}y}{\mathrm{d}x}+by=f(x) \tag{6.3.834}$$

which is a simplified version of the following general L.D.E. with constant coefficients:

$$a'\frac{\mathrm{d}^2y}{\mathrm{d}x^2}+b'\frac{\mathrm{d}y}{\mathrm{d}x}+c'y=f(x) \tag{6.3.835}$$

where:

$$a=\frac{b'}{a'} \qquad b=\frac{c'}{a'} \tag{6.3.836}$$

We write its homogeneous associated equation (E.W.S.M.):

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2}+a\frac{\mathrm{d}y}{\mathrm{d}x}+by=0 \tag{6.3.837}$$

wherein the function of the second member is zero. We can quite quickly consider a solution of the type (inspiring of the form of the solutions of the first order differential equations):

$$y=\lambda e^{Kx+\tau} \tag{6.3.838}$$

where τ is a constant. Which gives us therefore:

$$\lambda K^2e^{Kx+\tau}+a\lambda Ke^{Kx+\tau}+b\lambda e^{Kx+\tau}=0 \tag{6.3.839}$$

What we can simplify by:

$$K^2+aK+b=0 \tag{6.3.840}$$

If our starting assumption is correct, we only have to solve in K this "characteristic equation (CHARE)" or "characteristic polynomial" of the homogeneous equation to find the homogeneous solution:

$$K_{1,2}=\frac{-a\pm\sqrt{a^2-4b}}{2} \tag{6.3.841}$$

whose solutions depend on the sign of the discriminant of the characteristic polynomial:

$$\Delta=a^2-4b \tag{6.3.842}$$

- If the discriminant is strictly positive, that is to say $\Delta>0$:

  So we know that the characteristic polynomial has two distinct roots and then we have:

  $$y_h=Ae^{K_1(x+\tau)}+Be^{K_2(x+\delta)} \tag{6.3.843}$$

  where $K_1\tau=c^{te}$ and $K_2\delta=c^{te'}$. Then we say that the solution is "delayed" or "advanced" by the values of these constants. But the key is to note that if $y_h(x)$ is a solution, then $y_h(x\pm\Delta x)$ is always a solution!

  We then speak of "general solution of the homogeneous equation". There is behind this result an infinity of solutions: to each value given to the constants A,B corresponds a solution.

  Physicists also write sometimes this in a particular form by putting:

  $$\alpha=\frac{K_1+K_2}{2}\qquad\beta=\frac{K_1-K_2}{2} \tag{6.3.844}$$

  with then:

  $$\alpha+\beta=K_1\qquad\alpha-\beta=K_2 \tag{6.3.845}$$

  And using the hyperbolic trigonometric functions (see section Trigonometry page 2532):

  $$\begin{aligned}\cosh(\beta x)&=\frac{e^{\beta x}+e^{-\beta x}}{2}\\ \sinh(\beta x)&=\frac{e^{\beta x}-e^{-\beta x}}{2}\end{aligned} \tag{6.3.846}$$

where finally the possibility to write the homogeneous solution in the form (when we omit the advance or delay $\delta=\tau=0$):

$$y_h=e^{\alpha x}\left(C_1\cosh(\beta t)+C_2\sinh(\beta t)\right) \tag{6.3.847}$$

In addition, let us show that the solutions of the E.W.S.M. form a vector space of dimension 2 (corresponding to the order of our differential equation)!

Indeed:

- The zero function: $y=0$ is a solution of the E.W.S.M. (this is unnecessary to prove because obvious...!)
- The sum or subtraction of solutions remains a solution (this we have already proved it before)
- The elements of the basis of a vector space (the solutions of the E.W.S.M.) are linearly independent (that's an interesting property that we will need later!)

Let us put:

$$y_h=\lambda_1 f_1(x)+\lambda_2 f_2(x) \tag{6.3.848}$$

Then:

$$\begin{aligned}y'_h&=\lambda_1 f'_1+\lambda_2 f'_2\\ y''_h&=\lambda_1 f''_1+\lambda_2 f''_2\end{aligned} \tag{6.3.849}$$

These relations injected into the E.W.S.M. in generalized form:

$$a'\frac{\mathrm{d}^2y}{\mathrm{d}x^2}+b'\frac{\mathrm{d}y}{\mathrm{d}x}+c'y=0 \tag{6.3.850}$$

Then gives:

$$\begin{aligned}a'y''_h+b'y'_h+c'y_h&=a'\left[\lambda_1 f''_1+\lambda_2 f''_2\right]+b'\left[\lambda_1 f'_1+\lambda_2 f'_2\right]+c'\left[\lambda_1 f_1+\lambda_2 f_2\right]\\ &=\lambda_1\left(a'f''_1+b'f'_1+c'f_1\right)+\lambda_2\left(a'f''_2+b'f'_2+c'f_2\right)=\lambda_1\cdot 0+\lambda_2\cdot 0=0\end{aligned} \tag{6.3.851}$$

We do have indeed a vector space structure.

Let us recall that conversely two functions are linearly dependent if:

$$\forall t\quad f_1(x)=\lambda f_2(x) \tag{6.3.852}$$

- If the discriminant is strictly zero, that is to say $\Delta=0$:

  The characteristic equation has a real double root K.

  By going a little fast we would say then:

$$y_h=A^{K(x+\tau)} \tag{6.3.853}$$

and that it is over... but that it is forget that the vector base must be formed of two independent solutions!

So the second option is probably... of the form:

$$y_{h2}=z(x)A^{K(x+\tau)} \tag{6.3.854}$$

Then:

$$\begin{aligned}y'_{h2}&=Ke^{K(x+\tau)}z(x)+z'(x)e^{K(x+\tau)}\\ y''_{h2}&=K^2e^{K(x+\tau)}z(x)+Ke^{K(x+\tau)}z'(x)+Kz'(x)e^{K(x+\tau)}+z''(x)e^{K(x+\tau)}\\ &=K^2e^{K(x+\tau)}z(x)+2Ke^{K(x+\tau)}z'(x)+z''(x)e^{K(x+\tau)}\end{aligned} \tag{6.3.855}$$

If we inject it into the E.W.S.M. in generalized form:

$$a'\frac{\mathrm{d}^2y}{\mathrm{d}x^2}+b'\frac{\mathrm{d}y}{\mathrm{d}x}+c'y=0 \tag{6.3.856}$$

Then:

$$\begin{aligned}&a'\left(K^2e^{K(x+\tau)}z+2Ke^{K(x+\tau)}z'+z''e^{K(x+\tau)}\right)+b'\left(Ke^{K(x+\tau)}z+z'e^{K(x+\tau)}\right)+c'ze^{K(x+\tau)}=0\\ &e^{K(x+\tau)}\left(a'K^2+b'K+c'\right)z+e^{K(x+\tau)}(2a'K+b')z'+a'e^{K(x+\tau)}z''=0\\ &\Rightarrow\left(a'K^2+b'K+c'\right)z+(2a'K+b')z'+a'z''=0\end{aligned} \tag{6.3.857}$$

That is to say in our case:

$$(K^2+aK+b)z+(2K+a)z'+z''=0 \tag{6.3.858}$$

But, both actual real values of K are precisely solutions of:

$$K^2+aK+b=0 \tag{6.3.859}$$

The prior-previous relation is reduced to:

$$(2K+a)z'+z''=0 \tag{6.3.860}$$

and as we are in the case of study where the discriminant is zero, we have:

$$K_{1,2}=\frac{-a\pm\Delta}{2}=\frac{-a}{2} \tag{6.3.861}$$

Therefore and finally the prior-previous relation reduces to:

$$z''=0 \tag{6.3.862}$$

We deduce from it that:

$$z''=0\Rightarrow z'=c^{te}\Rightarrow z=Bx+c^{te} \tag{6.3.863}$$

Therefore finally:

$$y_{h2}=(Bx+c^{te})e^{K(x+c^{te})} \tag{6.3.864}$$

Which gives for the general solution of the E.W.S.M.:

$$y_h=(C_1x+C_2)e^{K(x+\tau)} \tag{6.3.865}$$

- If the discriminant is strictly negative, that is to say $\Delta < 0$:

  The characteristic equation has two complex conjugate roots (see section Calculus page 1383):

  $$K_1 = \alpha + \mathrm{i}\beta \qquad K_2 = \alpha - \mathrm{i}\beta \tag{6.3.866}$$

  Therefore:

  $$\begin{aligned} y_h &= Ae^{(\alpha+\mathrm{i}\beta)(x+\tau)} + Be^{(\alpha-\mathrm{i}\beta)(x+\delta)} \\ &= Ae^{\alpha(x+\tau)}e^{\mathrm{i}\beta(x+\tau)} + Be^{\alpha(x+\delta)}e^{-\mathrm{i}\beta(x+\delta)} = e^{\alpha(x+\tau)}Ae^{\mathrm{i}\beta(x+\tau)} + e^{\alpha(x+\delta)}B^{-\mathrm{i}\beta(x+\delta)} \\ &= Ae^{\alpha(x+\tau)}\left(\cos(\beta x + \tau\beta) + \mathrm{i}\sin(\beta x + \tau\beta)\right) + Be^{\alpha(x+\delta)}\left(\cos(\beta x + \delta\beta) + \mathrm{i}\sin(\beta x + \delta\beta)\right) \\ &= y_{h1} + y_{h2} \end{aligned} \tag{6.3.867}$$

  But if we look instead for real solutions, we can always put A and B as being equal such as:

  $$\begin{aligned} y'_h &= \frac{1}{2}(y_{h1} + y_{h2}) + \frac{1}{2\mathrm{i}}(y_{h1} - y_{h2}) = e^{\alpha(x+\tau)}\cos(\beta x + \tau\beta) + e^{\alpha(x+\delta)}\sin(\beta x + \delta\beta) \\ &= e^{\alpha x}e^{\alpha\tau}\cos(\beta x + \tau\beta) + e^{\alpha x} + e^{\alpha\delta}\sin(\beta x + \delta\beta) = e^{\alpha x}\left(A'\cos(\beta x + \tau\beta) + B'\sin(\beta x + \delta\beta)\right) \end{aligned} \tag{6.3.868}$$

  And if we set the delay and advance respectively as being zero ($\delta = \tau = 0$), so we find the relation available in most books without proof:

  $$y'_h = e^{\alpha x}\left(A'\cos(\beta x) + B'\sin(\beta x)\right) \tag{6.3.869}$$

  where A' and B' are any two real constants. There is another important form of this last relation (often used in electronics, for example). Indeed, it is possible for any A' and $B' \in \mathbb{R}$, to find C' and ϕ also in $\mathbb{R}$ such as the following equality holds:

  $$A'\cos(\beta x) + B'\sin(\beta x) = C'\cos(\beta t - \phi) \tag{6.3.870}$$

  We put:

  $$C' = \sqrt{A'^2 + B'^2} \tag{6.3.871}$$

  Then:

  $$A'\cos(\beta x) + B'\sin(\beta x) = C'\left[\frac{A'}{M}\cos(\beta x) + \frac{B'}{M}\sin(\beta x)\right] \tag{6.3.872}$$

  It is then possible to find ϕ such as:

  $$\frac{A'}{M} = \cos(\phi) \qquad \frac{B'}{M} = \sin(\phi) \tag{6.3.873}$$

  Therefore our initial expression (proposition) can be written as:

  $$A'\cos(\beta x) + B'\sin(\beta x) = C'\left[\cos(\phi)\cos(\beta x) + \sin(\phi)\sin(\beta x)\right] = C'\cos(\beta t - \phi) \tag{6.3.874}$$

  Finally:

  $$y_h = C'e^{\alpha x}\cos(\beta t - \phi) \tag{6.3.875}$$

So we can make the following summary:

Discriminant	Roots	Homogeneous solution
$\Delta > 0$	$K_{1,2} = \dfrac{-a \pm \sqrt{a^2 - 4b}}{2}$	$y_h = Ae^{K_1(x+\tau)} + Be^{K_2(x+\delta)}$
$\Delta = 0$	$K_{1,2} = \dfrac{-a \pm \sqrt{a^2 - 4b}}{2}$	$y_h = (C_1 x + C_2)e^{K(x+\tau)}$
$\Delta < 0$	$K_{1,2} = \dfrac{-a \pm \sqrt{a^2 - 4b}}{2}$	$y_h = e^{\alpha x}(A' \cos(\beta x) + B' \sin(\beta x))$

Table 6.13: **Typical solutions of H.E. of The L.D.E. with constant coefficients**

6.3.3.3.2 Integrating Factor Method (Euler's Method)

The technique of integrating factor is useful when it comes to solve differential equations of the form:

$$y' + f(x)y = g(x) \tag{6.3.876}$$

We will us that technique during our study of the RC circuit response to a linear increase in voltage (see section Electric Engineering page 8471).

The basic idea is to find a function $M(x)$, named "integration factor", by which can be multiplied by our differential equation to bring the left-hand side of equality to a simple derivative. For example, for a linear differential equation as the one above, we choose often the following integration factor (but this is by far not the only possibility and this choice does not solve everything!):

$$\text{IF} = e^{F(x)} = e^{\int f(x)\mathrm{d}x} \tag{6.3.877}$$

Therefore we have:

$$e^{F(x)}(y' + f(x)y) = g(x)e^{F(x)} \tag{6.3.878}$$

or by distributing:

$$y'e^{F(x)} + f(x)ye^{F(x)} = g(x)e^{F(x)} \tag{6.3.879}$$

Which can therefore be seen as:

$$y'e^{F(x)} + F'(x)ye^{F(x)} = g(x)e^{F(x)} \tag{6.3.880}$$

or even better (and therein lies the whole trick)...:

$$\left(ye^{F(x)}\right)' = g(x)e^{F(x)} \tag{6.3.881}$$

We can then take the primitive with respect to x:

$$\int \left(ye^{F(x)}\right)' \mathrm{d}x = \int g(x)e^{F(x)}\mathrm{d}x \tag{6.3.882}$$

and trivially (!) we have the left primitive that is immediate:

$$ye^{F(x)} = \int g(x)e^{F(x)}\mathrm{d}x \tag{6.3.883}$$

Which is sometimes written as:

$$y = \frac{1}{e^{F(x)}} \int g(x)e^{F(x)}\mathrm{d}x = \frac{1}{e^{\int f(x)\mathrm{d}x}} \int g(x)e^{\int f(x)\mathrm{d}x}\mathrm{d}x \tag{6.3.884}$$

✍**Example:**

Consider the following differential equation:

$$y'+\frac{y}{x}-4=0 \tag{6.3.885}$$

That we will rewrite as:

$$\frac{\mathrm{d}y}{\mathrm{d}x}+\frac{1}{x}y=4 \tag{6.3.886}$$

We see then that (assuming x is positive):

$$f(x)=\frac{1}{x}\Rightarrow F(x)=\ln(x) \tag{6.3.887}$$

Then we have:

$$e^{\ln(x)}\left(\frac{\mathrm{d}y}{\mathrm{d}}x+\frac{1}{x}y\right)=e^{\ln(x)}4 \tag{6.3.888}$$

Hazard making sometimes things good (the example is purposely very simple), we have this equality that simplified as:

$$e^{\ln(x)}=x \tag{6.3.889}$$

in:

$$x\left(\frac{\mathrm{d}y}{\mathrm{d}}x+\frac{1}{x}y\right)=4x \tag{6.3.890}$$

Which may be condense in:

$$(xy)'=4x \tag{6.3.891}$$

By integrating:

$$\int(xy)'\mathrm{d}x=\int 4x\mathrm{d}x \tag{6.3.892}$$

It then comes immediately:

$$xy=2x^2+c^{te} \tag{6.3.893}$$

Finally:

$$y=2x+\frac{x}{c^{te}} \tag{6.3.894}$$

6.3.3.3.3 Method of separation of variables

The method of separation of variables (also known as the "Fourier method") is any of several methods for solving ordinary and partial differential equations, in which algebra allows one to rewrite an equation so that each of two variables occurs on a different side of the equation.

In mathematics, a "partial differential equation PDE" is a differential equation that contains unknown multivariable functions and their partial derivatives (a special case are ordinary differential equations, which deal with functions of a single variable and their derivatives). PDEs are used to formulate problems involving functions of several variables, and are either solved by hand, or used to create a relevant computer model.

PDEs can be used to describe a wide variety of phenomena such as sound, heat, electrostatics, electrodynamics, fluid dynamics, elasticity, or quantum mechanics. These seemingly distinct physical phenomena can be formalized similarly in terms of PDEs. Just as ordinary differential equations often model one-dimensional dynamical systems, partial differential equations often model multidimensional systems. PDEs find their generalization in stochastic partial differential equations.

A partial differential equation (PDE) for the function $U(x_1,\cdots,x_n)$ is an equation of the form:

$$\boxed{f\left(x_1,\ldots,x_n,U,\frac{\partial U}{\partial x_1},\ldots,\frac{\partial U}{\partial x_n},\frac{\partial^2 U}{\partial x_1\partial x_1},\ldots,\frac{\partial^2 U}{\partial x_1\partial x_n},\ldots\right)=0} \qquad (6.3.895)$$

If f is a linear function of U and its derivatives, then the PDE is named a "linear partial differential equation". Common examples of linear PDEs include the heat equation, the wave equation, Laplace's equation, Helmholtz equation, Klein–Gordon equation, and Poisson's equation (see the chapters of Mechanics, Electrodynamics and Quantum Physics for the study of most of them!).

The method of separation of variables is a very common technique used in physics when we have second-order differential equations. Many useful examples and very detailed are already in the various chapters already mentioned above. Here we will just present a special case just for doing things good but with the minimum subsistence level!

Consider the common case of physical partial differential equation of the type:

$$\frac{\partial^2 U}{\partial x^2}-\frac{\partial U}{\partial y}=0 \qquad (6.3.896)$$

The solution of this equation therefore requires finding a function U which depends on x and y such that:

$$U=U(x,y) \qquad (6.3.897)$$

In physics, the idea is then to put that we can always find a said a "separable" solution of the form:

$$U(x,y)=X(x)Y(y) \qquad (6.3.898)$$

Thus, the differential equation can be written as:

$$\frac{\partial^2 X(x)Y(y)}{\partial x^2}-\frac{\partial X(x)Y(y)}{\partial y}=0 \qquad (6.3.899)$$

Which can be rewritten as:

$$Y(y)\frac{\partial^2 X(x)}{\partial x^2}=X(x)\frac{\partial Y(y)}{\partial y} \qquad (6.3.900)$$

Or:

$$\frac{1}{X(x)}\frac{\partial^2 X(x)}{\partial x^2}=\frac{1}{Y(y)}\frac{\partial Y(y)}{\partial y} \qquad (6.3.901)$$

After rearrangement it is use in physics to note this last equality in condensed form:

$$\frac{X''}{X}=\frac{Y''}{Y} \qquad (6.3.902)$$

This equality can only take place if each term is a constant since X depends only on x and Y only on y. It comes then:

$$\frac{X''}{X}=c^{te} \qquad \frac{Y''}{Y}=c^{te} \qquad (6.3.903)$$

And each differential equation can then be solved independently of the other and once the solutions found we multiplied them determine the expression of U.

Remark

Probably the most beautiful example is the section of Quantum Chemistry.

How do we know that this technique of separation of variables is valid? When the differential operators in various variables are additive in the partial differential equation, that is, when there are no products of differential operators in different variables, the separation method usually works. We are proceeding in the spirit of *let's try and see if it works*... If our attempt succeeds, then this technique will be justified. If it does not succeed, we shall find out soon enough and then we shall try another attack, such as Green's functions, integral transforms, or brute-force numerical analysis!

6.3.3.3.4 Method of constant variation

The variation of constants, is a general method to solve inhomogeneous linear ordinary differential equations.

For first-order inhomogeneous linear differential equations it is usually possible to find solutions via integrating factors or undetermined coefficients with considerably less effort, although those methods leverage heuristics that involve guessing and don't work for all inhomogeneous linear differential equations.

Variation of parameters extends to linear partial differential equations as well, specifically to inhomogeneous problems for linear evolution equations like the heat equation, wave equation, and vibrating plate equation. In this setting, the method is more often known as "Duhamel's principle", named after Jean-Marie Duhamel who first applied the method to solve the inhomogeneous heat equation.

The idea of the method of variation of the constant is as follows: if we have a particular solution affected by constants, we know that depending of the initial conditions thereof are well determined. The idea is then to generalize by putting that these constants are functions. In some cases obviously mathematical developments will show that the functions are necessarily constant.

The underlying idea behind this method is to say that the solutions of the (linear) differential equation with the second member will look like the solutions of the homogeneous equation. As the term on the right will disrupt this solution, we vary only constants (which will therefore no longer be constants), but we remain on the "base" of homogeneous solutions, to seek close solutions. After we check that this "physicist reasoning" gives out all the solutions of the differential equation.

Let us see before studying to the general case a simple example by considering the following differential equation:

$$y'(t)+by(t)=1 \tag{6.3.904}$$

for which the particular solution of the homogeneous equation (E.W.S.M.) is (if you need the details not hesitate to ask!):

$$y_0(t)=Ae^{-bt} \tag{6.3.905}$$

The method of variation of the constant consists then to put that:

$$A=A(t) \tag{6.3.906}$$

and therefore:

$$y_0'(t)=A'e^{-bt}-bA(t)e^{-bt} \tag{6.3.907}$$

But by the differential equation with the second member, we have:

$$y_0'(t)+by_0(t)=1\Rightarrow y_0'(t)=1-by_0(t)=1-bA^{-bt} \tag{6.3.908}$$

So using the last two relations it comes:

$$\left.\begin{array}{l} y_0'(t)=A'(t)e^{-bt}-bA(t)e^{-bt} \\ y_0'(t)=1-bAe^{-bt} \end{array}\right\}\Rightarrow A'(t)=e^{bt} \tag{6.3.909}$$

and it follows that:

$$A(t)=\frac{1}{b}e^{bt} \tag{6.3.910}$$

where we eliminated the integration constant because what we want is a particular solution! The particular general solution (pg) is then the sum of the particular solution and the homogeneous one and this with the variation of the constant:

$$y_{0,\mathbf{pg}}(t)=Ae^{-bt}+A'(t)e^{-bt}=A^{-bt}+\frac{1}{b}e^{bt}e^{-bt}=Ae^{-bt}+\frac{1}{b} \tag{6.3.911}$$

Thus, generalizing the previous example, so we have a differential equation of the form:

$$y'(t)+by(t)=c \tag{6.3.912}$$

The general particular solution will then be:

$$C_0y_0(t):=C_0(t)y_0(t) \tag{6.3.913}$$

Then we have:

$$y_0'(t)=C_0'y_0(t)+C_0(t)y_0'(t) \tag{6.3.914}$$

hence injected into the original differential equation:

$$\underbrace{C_0'y_0(t)+C_0(t)y_0'(t)}_{y'(t)}+b(t)\underbrace{C_0(t)y_0(t)}_{y(t)}=c(t) \tag{6.3.915}$$

Therefore after factoring similar terms:

$$C_0'y_0(t)+C_0(t)\left(y_0'(t)+b(t)C_0(t)y_0(t)\right)=c(t) \tag{6.3.916}$$

So we have the above relation and the particular solution to the homogeneous differential equation (therefore without second member):

$$\left.\begin{array}{l} C_0'y_0(t)+C_0(t)\left(y_0'(t)+b(t)C_0(t)y_0(t)\right)=c(t) \\ y_0'(t)=-b(t)C_0(t)y_0(t) \end{array}\right\}\Rightarrow C_0'y_0(t)=c(t) \tag{6.3.917}$$

Therefore we find:

$$C_0'=\frac{c(t)}{y_0(t)} \tag{6.3.918}$$

and it sufficient then to integrate this equation to find $C_0(t)$. Then, the particular general solution (pg) will be the sum of the particular homogeneous solution and that with the variation of the constant.

6.3.3.4 Classification of differential equations

Before we begin, the reader may wonders what classifying differential equations can be used for, well, here are the two main arguments for the usefulness of a classification in the order of importance:

- Many books have authors who systematically speak of a differential equation by categorizing it, so it is more pleasant to know what they are talking about.
- Some finite element modelling software (including MATLAB®) requires that the differential equation category be chosen before anything else can be done as a calculation.

First a reminder of what we have seen so far:

- **Ordinary Differential Equation:** It is a differential equation that involves one or more ordinary derivatives but without having partial derivatives. Like for example:

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2}=f(x)$$

- **Partial Differential Equation:** It is a differential equation that involves partial derivatives. It has two or more independent variables. Like for example:

$$\frac{\partial^2 u}{\partial x^2}+4xy\frac{\partial^2 u}{\partial y^2}+u=2\left(\frac{\partial^2 u}{\partial x^2}\right)^2+4\frac{\partial^3 u}{\partial x\partial y^2}=10x$$

- **Linear Differential Equation:** It is first degree with respect to the dependent variable(s) and its derivatives that can be expressed in the form:

$$\frac{\mathrm{d}y}{\mathrm{d}x}+p(x)y=q(x)$$

- **Non-Linear Differential Equation:** It is second degree or higher differential equation with respect to dependent variables and its derivatives. Like for example

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2}-\left(\frac{\mathrm{d}y}{\mathrm{d}x}\right)^2+12y=\cos(x)$$

- **Non-homogeneous Differential Equation:** It is a differential equation whose right-hand side is not equal to zero. A second order non-homogeneous differential equation can be written in this form:

$$y''+f(x)y'+g(x)y=r(x)$$

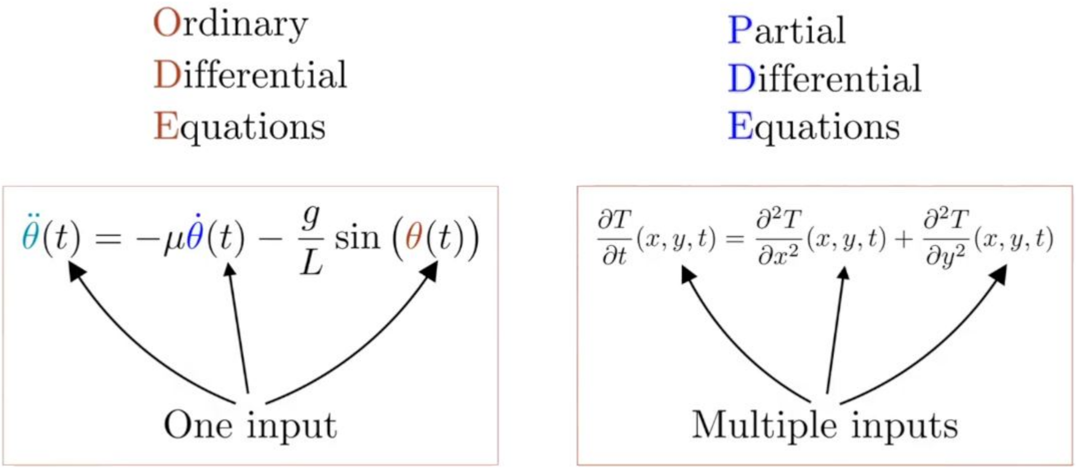
So this being said, formally, we name "partial differential equation PDE" of order less than or equal to 2 in a domain $\Omega\subset\mathbb{R}^n$ and of unknown:

$$\Phi(x)=\Phi(x_1,x_2,\ldots,x_N):\Omega\mapsto\mathbb{R} \qquad (6.3.919)$$

an equation of the following general type:

$$\boxed{\sum_{i,j}^{n}\left(a_{ij}(x)\frac{\partial^2\Phi(x)}{\partial x_i\partial x_j}\right)+\sum_{i}^{n}\left(b_i(x)\frac{\partial\Phi(x)}{\partial x_i}\right)+c(x)\Phi(x)=s(x)} \tag{6.3.920}$$

where $s(x)$ is often named a "source term" in analogy with the main situation in physics concerned.



Ordinary
Differential
Equations
$\ddot{\theta}(t)=-\mu\dot{\theta}(t)-\frac{g}{L}\sin\left(\theta(t)\right)$
One input
Partial
Differential
Equations
$\frac{\partial T}{\partial t}(x,y,t)=\frac{\partial^2 T}{\partial x^2}(x,y,t)+\frac{\partial^2 T}{\partial y^2}(x,y,t)$
Multiple inputs

It is now important to generalize the latter equation in vector form. Thus, we introduce the following notations:

- $A=[a_{ij}]$ the $n\times n$ symmetric matrix of the coefficients in front of the terms of order 2
- $B=(f_i(x))$ the vector of size n of the coefficients in front of the terms of order 1
- $[H\Phi(x)]$ the $n\times n$ symmetric Hessian matrix (see section Sequences and Series page 1715) of Φ:

$$H\Phi(x)_{ij}=\frac{\partial^2\Phi(x)}{\partial x_i\partial x_j} \tag{6.3.921}$$

- $\vec{\nabla}(\Phi(x))$ the vector of size n of Φ:

$$\vec{\nabla}(\Phi(x))=\left(\frac{\partial\Phi(x)}{\partial x_i}\right) \tag{6.3.922}$$

- The notation (named "Frobenius (matrix) dot product"):

$$A:B=\text{tr}\left(A^TB\right)=\sum_{i,j}^{n}a_{ij}b_{ij} \tag{6.3.923}$$

also sometimes denoted as the classical dot product: $\langle A,B\rangle$.

Remark

The "Frobenius norm" (very useful to derive the generalised singular value decomposition used massively in Data Science) of a matrix $\mathbb{R}^{m\times n}$ is given by:

$$\|X\|_F=\left(\text{tr}\left(X^TX\right)\right)^{1/2}=\left(\sum_{i=1}^{m}\sum_{j=1}^{n}x_{ij}^2\right)^{1/2}\tag{6.3.924}$$

More explicitly let A be an $m\times n$ matrix in $\mathbb{C}$ (i.e. $A_{mn}\mathbb{C}()$) and denote by a_{ij} the entry of A at row i and column j. Hence, we have:

$$A^TA=\begin{bmatrix}\sum_{i=1}^m|a_{i1}|^2 & \sum_{i=1}^m\bar{a}_{i1}a_{i2} & \ldots & \sum_{i=1}^m\bar{a}_{i1}a_{in}\\ \sum_{i=1}^m\bar{a}_{i2}a_{i1} & \sum_{i=1}^m|a_{i2}|^2 & \ldots & \sum_{i=1}^m\bar{a}_{i2}a_{in}\\ \vdots & \vdots & \ddots & \vdots\\ \sum_{i=1}^m\bar{a}_{n1}a_{i1} & \sum_{i=1}^m\bar{a}_{n1}a_{i2} & \ldots & \sum_{i=1}^m|a_{in}|^2\end{bmatrix}$$

Then obviously:

$$\text{tr}\left(A^TA\right)=\sum_{j=1}^{n}\sum_{i=1}^{m}|a_{ij}|^2=\left(\sqrt{\sum_{j=1}^{n}\sum_{i=1}^{m}|a_{ij}|^2}\right)^2=\|A\|_F^2$$

With this, the previous relation:

$$\sum_{i,j}^{n}\left(a_{ij}(x)\frac{\partial^2\Phi(x)}{\partial x_i\partial x_j}\right)+\sum_{i}^{n}\left(b_i(x)\frac{\partial\Phi(x)}{\partial x_i}\right)+c(x)\Phi(x)=s(x)\tag{6.3.925}$$

can be rewritten as:

$$\boxed{A(x):[H\Phi(x)]+B(x)\circ(\vec{\nabla}(\Phi(x)))+c(x)\Phi(x)=s(x)}\tag{6.3.926}$$

What is often (abusively) written in a very condensed way:

$$AH\Phi+B\vec{\nabla}\Phi+c\Phi=s\tag{6.3.927}$$

✍**Example:**

E1. Let us consider the following PDE:

$$\frac{\partial^2\Phi}{\partial x^2}(x,y)+\frac{\partial^2\Phi}{\partial x}+\frac{\partial\Phi}{\partial x}(x,y)=\sin(x,y)\tag{6.3.928}$$

First, it is easy to determine (because it is a definition) that:

$$[H\Phi(x)]=\begin{bmatrix}\dfrac{\partial^2\Phi}{\partial^2x}(x,y) & \dfrac{\partial^2\Phi}{\partial x\partial y}(x,y)\\ \dfrac{\partial^2\Phi}{\partial y\partial x}(x,y) & \dfrac{\partial^2\Phi}{\partial^2y}(x,y)\end{bmatrix}\qquad\vec{\nabla}(\Phi(x))=\begin{pmatrix}\dfrac{\partial\Phi}{\partial x}(x,y)\\ \dfrac{\partial\Phi}{\partial y}(x,y)\end{pmatrix}\tag{6.3.929}$$

It is also trivial that:

$$c(x,y)=0 \tag{6.3.930}$$

and that:

$$s(x,y)=\sin(x+y) \tag{6.3.931}$$

It is also trivial that:

$$B=\begin{pmatrix}1\\0\end{pmatrix} \tag{6.3.932}$$

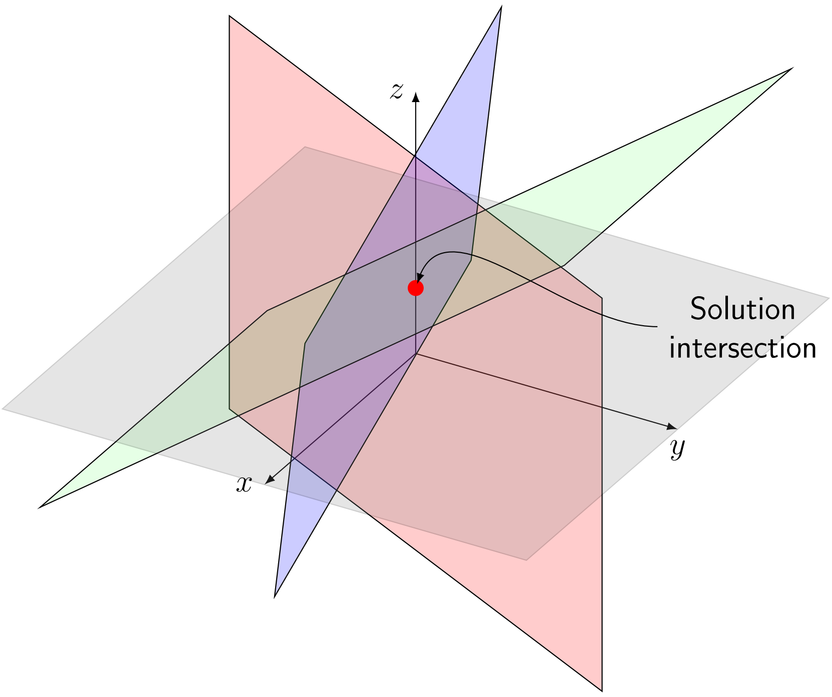
Finally, the minor difficulties are to find:

$$a=\begin{pmatrix}1 & \frac{1}{2}\\ \frac{1}{2} & 0\end{pmatrix} \tag{6.3.933}$$

E2. Let us consider the following system:

$$\begin{cases} 2x-\ \ y \quad\quad =0\\ -x+2y-\ \ z=-1\\ \quad -3y+4z=4\end{cases} \tag{6.3.934}$$

That has a unique solution that can be depicted by the following crossing of planes (this time made with TikZ rather than Maple™):



For linear PDE of order 2, the matrix A is non-zero and is symmetric. It is therefore diagonalizable with real eigenvalues (see section Linear Algebra page 1997) and their study provides elements of classification of linear PDE systems of order 2 under the denomination of "elliptic", "hyperbolic" or "parabolic" PDE (see section Analytical Geometry page 2794).

It is often customary to say in physics that the elliptics PDE characterize problems of equilibrium or stationarity, that hyperbolics PDE characterize problems of wave propagations (the Einstein field equations can in some special cases be reduced to this class of PDE) and finally that parabolic PDE characterize diffusion problems (see examples further below).

That latter terminology comes from the fact that when the matrix A is constant, the curves:

$$x^TAx=c^{te} \tag{6.3.935}$$

are respectively ellipsoids, hyperboloid and paraboloid (see section Analytical Geometry page 2798).

Indeed, we have proved in the section of Analytical Geometry that following the determinant of A, we had:

- If $\det(A)=ac-b^2>0$, the curve Γ is either empty, reduced to a point, or an ellipse.
- If $\det(A)=ac-b^2<0$, the curve Γ is the union of two intersecting lines, that is to say a hyperbola.
- If $\det(A)=ac-b^2=0$, the curve Γ is either empty, a line, or two distinct parallel lines, or a parabola.

More explicitly what we have seen above can be reformulated as following. If we have the following PDE:

$$a\frac{\partial^2\Phi}{\partial x^2}+b\frac{\partial^2\Phi}{\partial x\partial y}+c\frac{\partial^2\Phi}{\partial y^2}+d\frac{\partial\Phi}{\partial x}+e\frac{\partial\Phi}{\partial y}+fu=0 \tag{6.3.936}$$

where a, b, c, d, e and f are real constants, that latter is said to be:

- An "elliptical partial differential equation" if $ac-b^2>0$ that is to say if the eigenvalues are all positive or all negative (see section Analytical Geometry page 2798).
- A "hyperbolic partial differential equation" if $ac-b^2<0$ that is to say there is only one negative eigenvalue and all the others are positive, or there is only one positive eigenvalue and all the others are negative (see section Analytical Geometry page 2798).
- A "parabolic partial differential equation" if $ac-b^2=0$ that is to say if the eigenvalues are all positive or all negative, save one that is zero (see section Analytical Geometry page 2798).

✍**Example:**

The Laplace's equation:

$$\nabla^2\phi=0 \tag{6.3.937}$$

is an elliptic PDE.

The wave equation:

$$\frac{\partial^2 U}{\partial t^2}=v^2\frac{\partial^2 U}{\partial x^2} \tag{6.3.938}$$

is a hyperbolic PDE.

The heat equation:

$$\frac{\partial U}{\partial t}=k\frac{\partial^2 U}{\partial x^2} \tag{6.3.939}$$

is a parabolic PDE.

6.3.3.5 Systems of Differential Equations

Let us study now special developments that will also be useful for the study of quantum physics or for the resolution of particular systems of differential equations (see corresponding section in this textbook for the details on these examples) and especially one which is well known in Chaos Theory!

Let us first indicate to the reader before going further that more complex inhomogeneous case (with second member) and with unknown coefficients is treated directly by an example in the section of Industrial Engineering during the study of the reliability of a repairable system as a Markov chain with resolution using the determinants and eigenvalues/eigenvectors.

To start this first approach, we will have to introduce the concept of exponentiation of a matrix!

6.3.3.5.1 Matrix exponentiation method

The set of matrices $n \times n$ with coefficients in $\mathbb{C}$ denoted $M_n(\mathbb{C})$ is a vector space for the addition of matrices and multiplication by a scalar. We will as always denote by $\mathbb{1}_n$ the identity matrix of dimension n.

We will admit that a sequence of matrices A_n converges to a matrix A if and only if the sequences of coefficients of the matrices A_n converges towards the corresponding coefficients of A.

✍**Example:**

In $M_2(\mathbb{C})$ the sequence of matrices:

$$\begin{pmatrix} \dfrac{1}{n} & 2 \\ 0 & \dfrac{n+1}{n} \end{pmatrix} \tag{6.3.940}$$

converges to:

$$\begin{pmatrix} 0 & 2 \\ 0 & 1 \end{pmatrix} \tag{6.3.941}$$

when $n \rightarrow +\infty$. If $x \in \mathbb{C}$, we saw in our study of complex numbers (see section on Numbers page 251) that the series:

$$\sum_{k=0}^{+\infty} \frac{x^k}{k!} \tag{6.3.942}$$

does converge and its limit is denoted by e^x. In fact here there is no difficulty in replacing x by a matrix A since we know (we have proved it during our study of complex numbers) that any complex number can be written as follows (the body of complex numbers is isomorphic to the field of real matrices of square dimensions 2 having this form):

$$x = a + \mathrm{i}b = a\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} + \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix} b = \begin{bmatrix} a & -b \\ b & a \end{bmatrix} \tag{6.3.943}$$

and that a complex number is equivalent to put his matrix form also to the square:

$$x^2=(a+\mathrm{i}b)(a+\mathrm{i}b)=a^2+aib+aib-b^2=(a^2-b^2)+2ab\mathrm{i}=\begin{bmatrix} a^2-b^2 & 2ab \\ 2ab & a^2-b^2 \end{bmatrix} \tag{6.3.944}$$

Indeed:

$$\begin{bmatrix} a & -b \\ b & a \end{bmatrix}^2=\begin{bmatrix} a & -b \\ b & a \end{bmatrix}\begin{bmatrix} a & -b \\ b & a \end{bmatrix}=\begin{bmatrix} a^2-b^2 & 2ab \\ 2ab & a^2-b^2 \end{bmatrix} \tag{6.3.945}$$

We then define the "exponential of a matrix" $A\in M_n(\mathbb{C})$ as the matrix limit of the sequence:

$$e^A=\sum_{k=0}^{+\infty}\frac{A^k}{k!} \tag{6.3.946}$$

If the matrix A is diagonal obviously its exponential is easy to calculate. Indeed, if:

$$A=\begin{bmatrix} \lambda_1 & & 0 \\ & \ddots & \\ 0 & & \lambda_n \end{bmatrix}\Rightarrow A^k=\begin{bmatrix} \lambda_1^k & & 0 \\ & \ddots & \\ 0 & & \lambda_n^k \end{bmatrix} \tag{6.3.947}$$

It follows:

$$e^A=\sum_{k=0}^{+\infty}\frac{1}{k!}\begin{bmatrix} \lambda_1^k & & 0 \\ & \ddots & \\ 0 & & \lambda_n^k \end{bmatrix}=\begin{bmatrix} \displaystyle\sum_{k=0}^{+\infty}\frac{\lambda_1^k}{k!} & & 0 \\ & \ddots & \\ 0 & & \displaystyle\sum_{k=0}^{+\infty}\frac{\lambda_n^k}{k!} \end{bmatrix}=\begin{bmatrix} e^{\lambda_1} & & 0 \\ & \ddots & \\ 0 & & e^{\lambda_n} \end{bmatrix} \tag{6.3.948}$$

This property of diagonal matrices will also be very useful to us in the section of General Relativity during our study of the variation of the metric determinant.

However, it is clear that a non-diagonal matrix will be much more complicated to deal with! We will then use a diagonalization technique or an endomorphisms reduction[8] (see section Linear Algebra page 1934) to simplify our problem.

So notice that if $S\in M_n(\mathbb{C})$ is reversible and if $A\in M_n(\mathbb{C})$ then:

$$e^{SAS^{-1}}=Se^AS^{-1} \tag{6.3.949}$$

This follows from the fact that (think to the change of basis of a linear application as it has been studied in the section of Linear Algebra page 1992... perhaps it may help):

$$\left(SAS^{-1}\right)^k=SA\underbrace{S^{-1}S}_{=1}A\underbrace{S^{-1}S}_{=1}AS^{-1}\ldots\underbrace{S^{-1}S}_{=1}AS^{-1}=SA^kS^{-1} \tag{6.3.950}$$

---

[8] In linear algebra, an "endomorphism reduction" aims to express matrices and endomorphisms in a simpler form, for example to facilitate calculations. This consists essentially in finding a decomposition of the vector space into a direct sum of stable subspaces on which the induced endomorphism is simpler. Less geometrically, this corresponds to finding a basis of the space in which the endomorphism is simply expressed like for example the spectral theorem (see section Linear Algebra page 2004).

Therefore:

$$e^{SAS^{-1}}=\sum_{k=0}^{+\infty}\frac{SA^kS^{-1}}{k!}=S\left(\sum_{k=0}^{+\infty}\frac{A^k}{k!}\right)S^{-1} \tag{6.3.951}$$

This development will enable us to bring the computing of the exponential of a diagonalizable matrix in search of its eigenvalues and its eigenvectors.

✍Examples:

Let us calculate e^A where:

$$A=\begin{pmatrix}3 & -4\\ -6 & 1\end{pmatrix} \tag{6.3.952}$$

The eigenvalues of A are $\lambda_1=-3$, $\lambda_2=7$, and associated eigenvectors are:

$$\vec{v}_1=\begin{pmatrix}2\\ 3\end{pmatrix}\qquad \vec{v}_2=\begin{pmatrix}1\\ -1\end{pmatrix} \tag{6.3.953}$$

Indeed:

$$\begin{pmatrix}3 & -4\\ -6 & 1\end{pmatrix}\begin{pmatrix}2\\ 3\end{pmatrix}=-3\begin{pmatrix}2\\ 3\end{pmatrix}\text{ and }\begin{pmatrix}3 & -4\\ -6 & 1\end{pmatrix}\begin{pmatrix}1\\ -1\end{pmatrix}=7\begin{pmatrix}1\\ -1\end{pmatrix} \tag{6.3.954}$$

By putting:

$$S=\begin{pmatrix}2 & 1\\ 3 & -1\end{pmatrix} \tag{6.3.955}$$

We get:

$$A=S\begin{pmatrix}\lambda_1 & 0\\ 0 & \lambda_2\end{pmatrix}S^{-1}=S\begin{pmatrix}-3 & 0\\ 0 & 7\end{pmatrix}S^{-1} \tag{6.3.956}$$

with:

$$S^{-1}=S\begin{pmatrix}\frac{1}{5} & \frac{1}{5}\\ \frac{3}{5} & -\frac{2}{5}\end{pmatrix} \tag{6.3.957}$$

Therefore:

$$\begin{aligned}e^A&=e^{S\begin{pmatrix}-3 & 0\\ 0 & 7\end{pmatrix}S^{-1}}=Se^{\begin{pmatrix}-3 & 0\\ 0 & 7\end{pmatrix}}S^{-1}=S\begin{pmatrix}e^{-3} & 0\\ 0 & e^7\end{pmatrix}S^{-1}\\ &=\frac{1}{5}\begin{pmatrix}2e^{-3}+3e^7 & 2e^{-3}-2e^7\\ 2e^{-3}-3e^7 & 2e^{-3}+2e^7\end{pmatrix}\end{aligned} \tag{6.3.958}$$

Now, let us recall that in the case of real numbers we know that if $x,y\in\mathbb{R}$ then:

$$e^{x+y}=e^xe^y \tag{6.3.959}$$

In the case of matrices we can prove that if $A,B\in M_n(\mathbb{C})$ are two matrices that commute with one another, that is to say such that $AB=BA$, then:

$$e^{A+B}=e^Ae^B \tag{6.3.960}$$

The condition of commutativity comes from the fact that the addition in the exponential is itself commutative. The proof is therefore intuitive.

An important corollary of this proposition is that for any matrix $A\in M_n(\mathbb{C})$, e^A is reversible. Indeed the matrices A and $-A$ commute and therefore:

$$e^Ae^{-A}=e^{A-A}=e^0=I_n=\mathbb{1} \tag{6.3.961}$$

We recall that a matrix A with complex coefficients is unitary if:

$$AA^\dagger=I_n \tag{6.3.962}$$

The following theorem will serve us later:

Theorem 6.16. Let us prove that if A is a Hermitian matrix (also named "self-adjoint") (see section Linear Algebra page 1953) then for any $t\in\mathbb{R}$, $e^{\mathrm{i}tA}$ is unitary.

Proof 6.16.1.

$$\left(e^{\mathrm{i}tA}\right)^\dagger=e^{(\mathrm{i}tA)^\dagger}=e^{-\mathrm{i}tA^\dagger}=e^{-\mathrm{i}tA} \tag{6.3.963}$$

Therefore:

$$\left(e^{\mathrm{i}tA}\right)^\dagger\cdot e^{\mathrm{i}tA}=e^{-\mathrm{i}tA}e^{\mathrm{i}tA}=e^{\mathrm{i}t(A-A)}=I \tag{6.3.964}$$

■ Q.E.D.

Remember that this condition for a self-adjoint matrix is linked to the definition of linear group of order n (see section Set Algebra page 1424).

One of the first applications of the exponentation of matrices is the resolution of ordinary differential equations. Indeed, from the linear differential equation below using as initial condition $y(0)=0$ and where A is a matrix:

$$y'(t)+Ay(t)=0 \tag{6.3.965}$$

the solution is given by (as seen previously):

$$y(t)=Ce^{-At} \tag{6.3.966}$$

We frequently find that kind of systems of differential equations in biology (population dynamics), astrophysics (study of plasmas) or in fluid mechanics (chaos theory) and in classical mechanics (coupled systems), astronomy (coupled orbits), in electrical engineering, etc.

✍**Example:**

Suppose we have the following homogeneous system of differential equations (without constant terms):

$$\begin{aligned} x' &= 3x - 4y \\ y' &= -6x + y \end{aligned} \tag{6.3.967}$$

The associated matrix is then:

$$A = \begin{pmatrix} 3 & 4 \\ -6 & 1 \end{pmatrix} \tag{6.3.968}$$

and its exponential (see developments made above):

$$e^{-At} = \frac{1}{5}\begin{pmatrix} 2e^{-3t} + 3e^{7t} & 2e^{-3t} - 2e^{7t} \\ 2e^{-3t} - 3e^{7t} & 2e^{-3t} + 2e^{7t} \end{pmatrix} \tag{6.3.969}$$

The general solution of the system is:

$$\begin{pmatrix} x \\ y \end{pmatrix} = C_1 \begin{pmatrix} 2e^{-3t} + 3e^{7t} \\ 2e^{-3t} - 3e^{7t} \end{pmatrix} + C_2 \begin{pmatrix} 2e^{-3t} - 2e^{7t} \\ 2e^{-3t} + 2e^{7t} \end{pmatrix} \tag{6.3.970}$$

So we have:

$$\begin{aligned} x &= C_1(2e^{-3t} + 3e^{7t}) + C_2(2e^{-3t} - 2e^{7t}) = A'e^{-3t} + B'e^{7t} \\ y &= C_1(2e^{-3t} - 3e^{7t}) + C_2(2e^{-3t} + 2e^{7t}) = D'e^{-3t} + E'e^{7t} \end{aligned} \tag{6.3.971}$$

By calculating the derivative of the previous relations and comparing to:

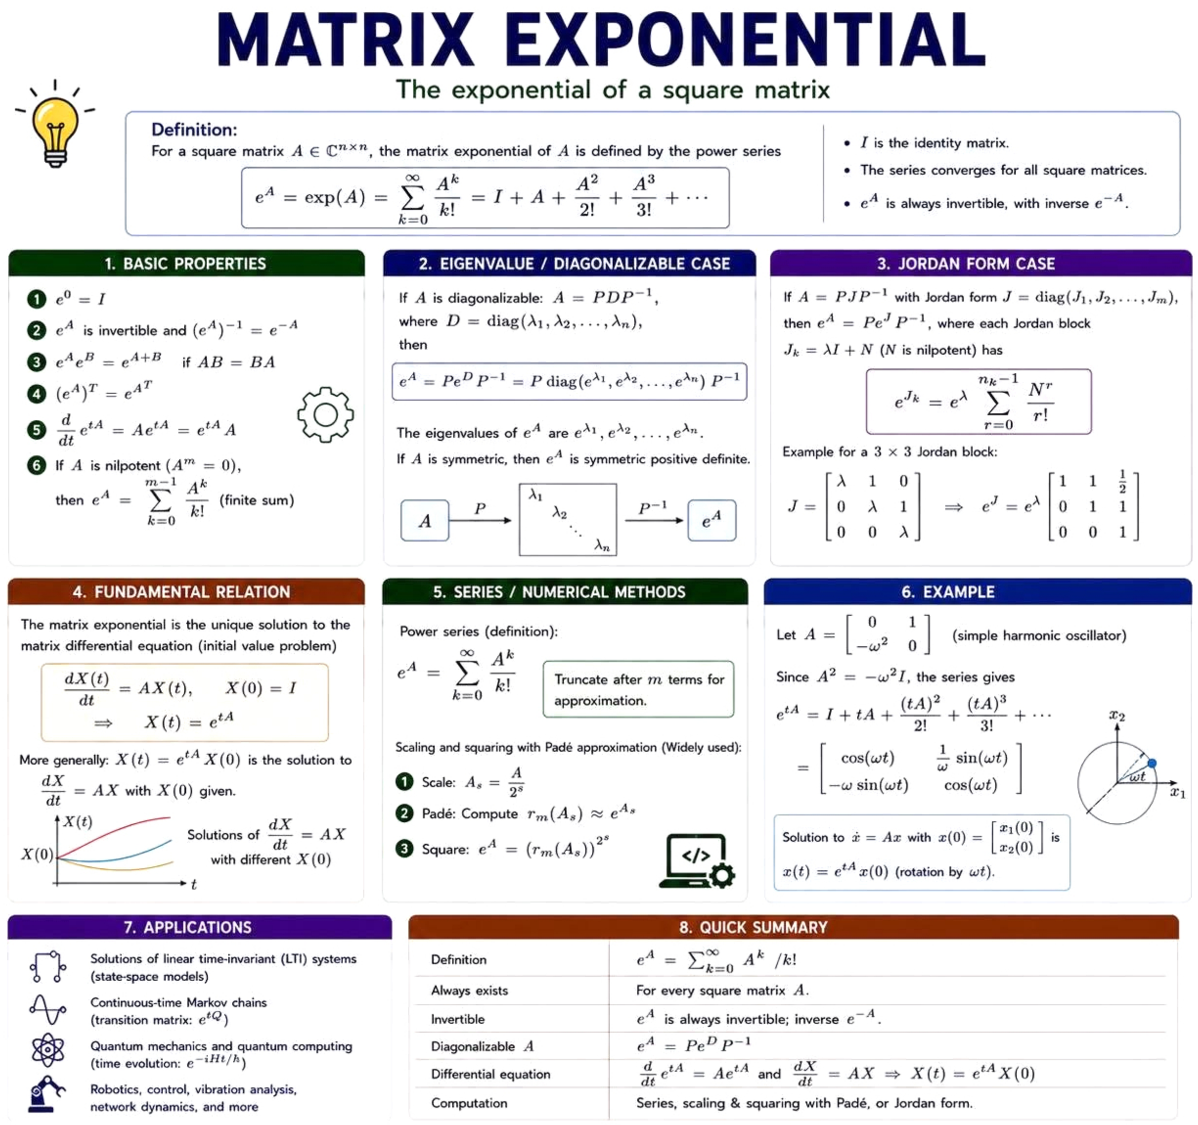
$$\begin{aligned} x' &= 3x - 4y \\ y' &= -6x + y \end{aligned} \tag{6.3.972}$$

we easily determine the constants to get:

$$\begin{aligned} E' - 6B' = 7E' \Rightarrow -6E' = 6B' \Rightarrow E' &= -B' \\ -6A' + F' = -3F' \Rightarrow 4F' = 6A' \Rightarrow F' &= \frac{3}{2}A' \end{aligned} \tag{6.3.973}$$

which finally gives us:

$$\begin{aligned} x &= A'e^{-3t} + B'e^{7t} \\ y &= \frac{3}{2}A'e^{-3t} - B'e^{7t} \end{aligned} \tag{6.3.974}$$



MATRIX EXPONENTIAL

The exponential of a square matrix

Definition:

For a square matrix $A \in \mathbb{C}^{n\times n}$, the matrix exponential of A is defined by the power series

$$\boxed{e^A = \exp(A) = \sum_{k=0}^{\infty} \frac{A^k}{k!} = I + A + \frac{A^2}{2!} + \frac{A^3}{3!} + \cdots}$$

- I is the identity matrix.
- The series converges for all square matrices.
- e^A is always invertible, with inverse e^{-A}.

1. BASIC PROPERTIES

❶ $e^0 = I$

❷ e^A is invertible and $(e^A)^{-1} = e^{-A}$

❸ $e^A e^B = e^{A+B}$ if $AB = BA$

❹ $(e^A)^T = e^{A^T}$

❺ $\frac{d}{dt} e^{tA} = Ae^{tA} = e^{tA}A$

❻ If A is nilpotent ($A^m = 0$),
then $e^A = \sum_{k=0}^{m-1} \frac{A^k}{k!}$ (finite sum)

2. EIGENVALUE / DIAGONALIZABLE CASE

If A is diagonalizable: $A = PDP^{-1}$,
where $D = \operatorname{diag}(\lambda_1, \lambda_2, \ldots, \lambda_n)$,
then

$$\boxed{e^A = Pe^D P^{-1} = P \operatorname{diag}(e^{\lambda_1}, e^{\lambda_2}, \ldots, e^{\lambda_n})\, P^{-1}}$$

The eigenvalues of e^A are $e^{\lambda_1}, e^{\lambda_2}, \ldots, e^{\lambda_n}$.

If A is symmetric, then e^A is symmetric positive definite.

$$\boxed{A} \xrightarrow{P} \begin{bmatrix} \lambda_1 & & \\ & \lambda_2 & \\ & & \ddots \ \lambda_n \end{bmatrix} \xrightarrow{P^{-1}} \boxed{e^A}$$

3. JORDAN FORM CASE

If $A = PJP^{-1}$ with Jordan form $J = \operatorname{diag}(J_1, J_2, \ldots, J_m)$, then $e^A = Pe^J P^{-1}$, where each Jordan block $J_k = \lambda I + N$ (N is nilpotent) has

$$\boxed{e^{J_k} = e^{\lambda} \sum_{r=0}^{n_k-1} \frac{N^r}{r!}}$$

Example for a 3×3 Jordan block:

$$J = \begin{bmatrix} \lambda & 1 & 0 \\ 0 & \lambda & 1 \\ 0 & 0 & \lambda \end{bmatrix} \Rightarrow e^J = e^{\lambda} \begin{bmatrix} 1 & 1 & \frac{1}{2} \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{bmatrix}$$

4. FUNDAMENTAL RELATION

The matrix exponential is the unique solution to the matrix differential equation (initial value problem)

$$\boxed{\begin{aligned} &\frac{dX(t)}{dt} = AX(t), \qquad X(0) = I \\ &\Rightarrow \qquad X(t) = e^{tA} \end{aligned}}$$

More generally: $X(t) = e^{tA}X(0)$ is the solution to $\frac{dX}{dt} = AX$ with $X(0)$ given.

Solutions of $\frac{dX}{dt} = AX$ with different $X(0)$

5. SERIES / NUMERICAL METHODS

Power series (definition):

$$e^A = \sum_{k=0}^{\infty} \frac{A^k}{k!}$$

Truncate after m terms for approximation.

Scaling and squaring with Padé approximation (Widely used):

❶ Scale: $A_s = \frac{A}{2^s}$

❷ Padé: Compute $r_m(A_s) \approx e^{A_s}$

❸ Square: $e^A = (r_m(A_s))^{2^s}$

6. EXAMPLE

Let $A = \begin{bmatrix} 0 & 1 \\ -\omega^2 & 0 \end{bmatrix}$ (simple harmonic oscillator)

Since $A^2 = -\omega^2 I$, the series gives

$$e^{tA} = I + tA + \frac{(tA)^2}{2!} + \frac{(tA)^3}{3!} + \cdots$$

$$= \begin{bmatrix} \cos(\omega t) & \frac{1}{\omega}\sin(\omega t) \\ -\omega \sin(\omega t) & \cos(\omega t) \end{bmatrix}$$

Solution to $\dot{x} = Ax$ with $x(0) = \begin{bmatrix} x_1(0) \\ x_2(0) \end{bmatrix}$ is $x(t) = e^{tA}x(0)$ (rotation by ωt).

7. APPLICATIONS

- Solutions of linear time-invariant (LTI) systems (state-space models)
- Continuous-time Markov chains (transition matrix: e^{tQ})
- Quantum mechanics and quantum computing (time evolution: $e^{-iHt/\hbar}$)
- Robotics, control, vibration analysis, network dynamics, and more

8. QUICK SUMMARY

Definition	$e^A = \sum_{k=0}^{\infty} A^k / k!$
Always exists	For every square matrix A.
Invertible	e^A is always invertible; inverse e^{-A}.
Diagonalizable A	$e^A = Pe^D P^{-1}$
Differential equation	$\frac{d}{dt} e^{tA} = Ae^{tA}$ and $\frac{dX}{dt} = AX \Rightarrow X(t) = e^{tA}X(0)$
Computation	Series, scaling & squaring with Padé, or Jordan form.

6.3.3.5.2 Phase space

If we are given a general nth order differential equation of the form:

$$a_n(x)y^{(n)}+a_{n-1}y^{(n-1)}+\cdots+a_1(x)y'+a_0(x)y=f(x) \tag{6.3.975}$$

and we have a solution y, then we can plot a graph of y versus x, and see how y evolves with x.

However, one problem is that for such an equation, the solution is not just determined by the initial condition $y(x_0)$, but also $y'(x_0)$, $y''(x_0)$ etc. So if we just have a snapshot of the value of y at a particular point x_0, we have completely no idea how it would evolve in the future.

So how much information do we actually need? At any point x_0, if we are given the first $n-1$ derivatives, i.e. $y(x_0)$, $y'(x_0)$, $\ldots$, $y^{(n-1)}(x_0)$, we can then get the nth derivative and also any higher derivatives from the differential equation.

Thus we are led to consider the "solution vector":

$$\vec{Y}(x)=\left(y(x),y'(x),\cdots,y^{n-1}(x)\right) \tag{6.3.976}$$

We say such a vector lies in the "phase space", which is an n-dimensional space (obviously this tool is quite limited for humans as we have huge difficulties to deal with spaces having more than three dimensions...). So for each x, we thus get a point $\vec{Y}(x)$ lying in the n-dimensional space. Moreover, given any point in the phase space, if we view it as the initial conditions for our differential equation, we get a unique trajectory in the phase space.

Remark

Honestly as authors of this textbook we have never seen the subject treated and the next one on "stability theory" used in real application cases in engineering nowadays. Maybe it was useful before computers? However the topic leads to quite beautiful concepts so why not...

✍**Example:**

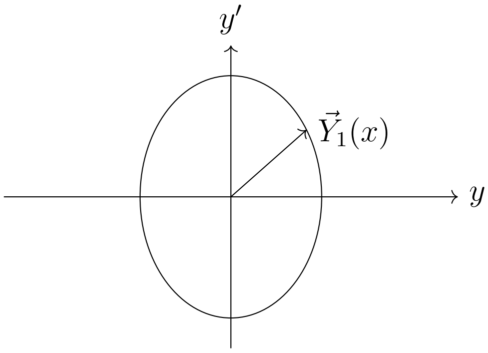
Consider:

$$y''+4y=0$$

Suppose we have an initial condition of:

$$y_1(0)=1,y_1'(0)=0$$

Then we can solve the equation to obtain $y_1(x)=\cos(2x)$. Thus the initial solution vector is $\vec{Y}_1(0)=(1,0)$, and the trajectory as x varies is given by $\vec{Y}_1(x)=(\cos(2x),-2\sin(2x))$. Thus as x changes, we trace out an ellipse in the clockwise direction:



Another possible initial condition is $y_2(0)=0, y_2'(0)=2$. In this case, we obtain the solution $y(x)=\sin(2x)$, with a solution vector $\vec{Y}_2(x)=(\sin(2x), 2\cos(2x))$.

Note that as vectors, our two initial conditions $(1,0)$ and $(0,2)$ are independent (we will see further below what is exactly means). Moreover, as x changes, the two solution vectors $\vec{Y}_1(x), \vec{Y}_2(x)$ remain independent.

In general, for a 2nd order equation, the phase space is a 2-dimensional space, and we can take the two complementary functions $\vec{Y}_1$ and $\vec{Y}_2$ as basis vectors for the phase space at each particular value of x. Of course, we need the two solutions to be linearly independent.

Definition (#209): Given a differential equation with solutions y_1, y_2, the "Wronskian" is the determinant (this definition will be motivated soon below!):

$$W(x)=\begin{vmatrix} y_1 & y_2 \\ y_1' & y_2' \end{vmatrix}=y_1y_2'-y_2y_1' \tag{6.3.977}$$

Intuitively, as we will see further below the Wronskian checks that y_1 and y_2 are linearly independent (i.e. that y_1 is not a multiple of y_2 other than trivially when $x_1=x_2=0$), that the vector (y_1,y_2) is linearly independent from $(\partial_x y_1, \partial_x y_2)$ and equivalently that $\partial_x y_1$ is not a multiple of $\partial_x y_2$.

The Wronskian requirement is in fact not any stricter than linear independence. We can show that linear dependence implies vanishing of the Wronskian. If y_1 and y_2 are two linearly dependent solutions, then there exist nonzero scalars a_1, a_2 such that:

$$a_1y_1+a_2y_2=0 \tag{6.3.978}$$

Differentiating, we get:

$$a_1\partial_x y_1+a_2\partial_x y_2=0 \tag{6.3.979}$$

so that:

$$a_2\partial_x y_2=-a_1\partial_x y_1 \tag{6.3.980}$$

Multiplying the first equation by $a_2\partial_x y_2$ gives:

$$\begin{aligned} 0&=a_1a_2y_1\partial_x y_2+a_2^2y_2\partial_x y_2\\ &=a_1a_2\left(y_1y_xy_2-y_2\partial_x y_1\right)\\ &\rightarrow y_1\partial_x y_2-y_2\partial_x y_1=0 \end{aligned} \tag{6.3.981}$$

In other words: To show that the two functions φ_1 and φ_2 are linearly independent you make:

$$Ay_1(x)+By_2(x)=0 \tag{6.3.982}$$

and you want to prove that A an B are null.

But you need another condition to force A and B to be zero. And you get it by deriving:

$$Ay_1'(x)+By_2'(x)=0 \tag{6.3.983}$$

This is a linear homogeneous system:

$$\begin{cases} Ay_1(x)+By_2(x)=0 \\ Ay_1'(x)+By_2'(x)=0 \end{cases} \tag{6.3.984}$$

which have only the solution $A=B=0$ if the determinant is non-null. But this determinant is precisely the Wronskian!!

Definition (#210): Two solutions $y_1(x)$ and $y_2(x)$ are "independent solutions" solutions of the differential equation if and only if $\vec{Y}_1$ and $\vec{Y}_2$ are linearly independent as vectors in the phase space for some x, i.e. if and only if the Wronskian is non-zero for some x.

In both cases, the Wronskian is never zero. Is it possible that it is zero for some x while non-zero for others? The answer is: No! And the proof given below is named the "Abel's Theorem".

Theorem 6.17. Given a differential equation $y''+p(x)y'+q(x)y=0$ (the theorem can be generalized to nth order linear ordinary differential equations), either $W=0$ for all x, or $W\neq 0$ for all x. i.e. if two solutions are independent for some particular x, then they are independent for all x.

Proof 6.17.1. If y_1 and y_2 are both solutions, then:

$$\begin{gathered} y_2(y_1''+py_1'+qy_1)=0 \\ y_1(y_2''+py_2'+qy_2)=0 \end{gathered} \tag{6.3.985}$$

Subtracting the two equations, we have:

$$y_1y_2''-y_2y_1''+p(y_1y_2'-y_2y_1')=0 \tag{6.3.986}$$

Note that (this is what motivates the definition of the Wronskian!):

$$W=y_1y_2'-y_2y_1' \tag{6.3.987}$$

and:

$$W'=y_1y_2''+y_1'y_2'-(y_2'y_1'+y_2y_1'')=y_1y_2''-y_2y_1'' \tag{6.3.988}$$

There we these definition we can write:

$$W'+pW=0 \tag{6.3.989}$$

And the solution is immediate:

$$W(x)=W_0e^{-\int p\mathrm{d}x} \tag{6.3.990}$$

Where $W_0=c^{te}$. Since the exponential function is never zero, either $W_0=0$, in which case $W=0$, or $W_0\neq 0$ and $W\neq 0$ for any value of x!

In other words: The Wronskian is always either identically zero, always positive, or always negative.

■ Q.E.D.

6.3.3.5.2.1 Stability theory

In studying systems of differential equations, it is often useful to study the of solutions without obtaining an algebraic form for the solution. This is done by exploring equilibrium solutions and solutions nearby equilibrium solutions. Such techniques will be seen to be useful in studying nonlinear systems.

"Stability theory" addresses the stability of solutions of differential equations and of trajectories of dynamical systems under small perturbations of initial conditions. The heat equation, for example, is a stable partial differential equation because small perturbations of initial data lead to small variations in temperature at a later time.

Many parts of the qualitative theory of differential equations and dynamical systems deal with asymptotic properties of solutions and the trajectories - what happens with the system after a long period of time. The simplest kind of behaviour is exhibited by equilibrium points, or fixed points, and by periodic orbits. If a particular orbit is well understood, it is natural to ask next whether a small change in the initial condition will lead to similar behaviour. Stability theory addresses the following questions: Will a nearby orbit indefinitely stay close to a given orbit? Will it converge to the given orbit? In the former case, the orbit is said to be "stable"; in the latter case, it is said to be "asymptotically stable" and the given orbit is said to be "attracting".

Ok now let us dive into the maths! Consider two dependent variables $y_1(t), y_2(t)$ related by the following "nonautonomous system[9]" of a couple system of first order differential equations in the plane (as there are two differentials equations it's also named a "planar system"):

$$\begin{aligned}\dot{y}_1 &= P(y_1,y_2,t) = ay_1+by_2+f_1(t)\\ \dot{y}_2 &= Q(y_1,y_2,t) = cy_1+dy_2+f_2(t)\end{aligned} \tag{6.3.991}$$

An autonomous system being by definition explicitly independent of time:

$$\begin{aligned}\dot{y}_1 &= ay_1+by_2\\ \dot{y}_2 &= cy_1+dy_2\end{aligned} \tag{6.3.992}$$

We can write this in vector notation by:

$$\begin{pmatrix}\dot{y}_1\\ \dot{y}_2\end{pmatrix} = \begin{bmatrix}a & b\\ c & d\end{bmatrix}\begin{pmatrix}y_1\\ y_2\end{pmatrix}+\begin{pmatrix}f_1\\ f_2\end{pmatrix} \tag{6.3.993}$$

or:

$$\dot{\vec{Y}} = M\vec{Y}+\vec{F} \tag{6.3.994}$$

We can convert this to a higher-order equation by:

$$\begin{aligned}\ddot{y}_1 &= a\dot{y}_1+b\dot{y}_2+\dot{f}_1\\ &= a\dot{y}_1+b(cy_1+dy_2+f_2)+\dot{f}_1\\ &= a\dot{y}_1+bcy_1+d(\dot{y}_1-ay_1-f_1)+bf_2+\dot{f}_1\end{aligned} \tag{6.3.995}$$

---

[9] An "autonomous system" or "autonomous differential equation" is a system of ordinary differential equations which does not explicitly depend on the independent variable. When the variable is time, they are also called "time-invariant systems". Many laws in physics, where the independent variable is usually assumed to be time, are expressed as autonomous systems because it is assumed the laws of nature which hold now are identical to those for any point in the past or future.

so:

$$\ddot{y}_1-(a+d)\dot{y}_1+(ad-bc)y_1=bf_2-df_1+\dot{f}_1 \tag{6.3.996}$$

However, this actually complicates the equation...

So what we usually do is the other way round: if we have a high-order equation, we can do this to change it to a system of first-order equations!

If:

$$\ddot{y}+a\dot{y}+by=f \tag{6.3.997}$$

write $y_1=y$ and $y_2=\dot{y}$. Then let:

$$\vec{Y}=\begin{pmatrix}y\\ \dot{y}\end{pmatrix} \tag{6.3.998}$$

Our system of equations becomes:

$$\begin{aligned}\dot{y}_1&=y_2\\ \dot{y}_2&=f-ay_2-by_1\end{aligned} \tag{6.3.999}$$

or:

$$\dot{\vec{Y}}=\begin{bmatrix}0&1\\-b&-a\end{bmatrix}\begin{pmatrix}y_1\\y_2\end{pmatrix}\begin{pmatrix}0\\f\end{pmatrix} \tag{6.3.1000}$$

Now consider the general equation:

$$\dot{\vec{Y}}=M\vec{Y}+\vec{F} \tag{6.3.1001}$$

Rearranging:

$$\dot{\vec{Y}}-M\vec{Y}=\vec{F} \tag{6.3.1002}$$

We first look for a complementary solution $\vec{Y}_c=\vec{v}e^{\lambda t}$, where $\vec{v}$ is a constant vector. So we get:

$$\lambda\vec{v}-M\vec{v}=\vec{0} \tag{6.3.1003}$$

We can write this as:

$$M\vec{v}=\lambda\vec{v} \tag{6.3.1004}$$

So λ is the eigenvalue of M and $\vec{v}$ is the corresponding eigenvector!!!

We can solve this by solving the characteristic equation:

$$\det(M-\lambda I)=0 \tag{6.3.1005}$$

Then for each λ, we find the corresponding $\vec{v}$. The corresponding eigenvalues equation is therefore:

$$\lambda^2-(a+d)\lambda+(ad-bc)=0 \tag{6.3.1006}$$

The eigenvalues are not determined by the four numbers (a,b,c,d), but only two numbers $(a+d, ad-bc)$.

For a matrix $\begin{bmatrix} a & b \\ c & d \end{bmatrix}$, the trace is $\text{tr}(M) = a+d$, and the determinant is $\det(M) = ad-bc$.

If λ_1 and λ_2 are roots of:

$$\lambda^2 - \text{tr}(M)\lambda + \det(M) = (\lambda-\lambda_1)(\lambda-\lambda_2) = 0 \tag{6.3.1007}$$

then:

$$\lambda_1+\lambda_2 = \text{tr}(M), \lambda_1\lambda_2 = \det(M), \lambda_{1,2} = \frac{\text{tr}(M) \pm \sqrt{\text{tr}(M)^2 - 4\det(M)}}{2} \tag{6.3.1008}$$

and as a reminder, we have:

- $\text{tr}(M)^2 - 4\det(M) > 0$, two real roots (related to "overdamped systems" since the system leads to exponential decay). Then the solution is commonly written as ($\vec{v}_1$ and $\vec{v}_2$ are the eigenvectors):

$$\vec{Y} = A\vec{v}_1 e^{\lambda_1 t} + B\vec{v}_2 e^{\lambda_2 t} \tag{6.3.1009}$$

- $\text{tr}(M)^2 - 4\det(M) = 0$, one (repeated) root (related to "critically damped systems" - there are no oscillations). Then the solution is commonly written as:

$$\vec{Y} = A\vec{v}_1 e^{\lambda t} + B\vec{v}_2 e^{\lambda t}(\vec{v}_2 + t\vec{v}_1) \tag{6.3.1010}$$

- $\text{tr}(M)^2 - 4\det(M) < 0$, two complex conjugated roots (related to "underdamped oscillating systems" consisting of decaying exponential time oscillations). Then the solution is commonly written as:

$$\vec{Y} = A\Re\left(e^{\alpha t}\vec{v}(\cos(\beta t) + \mathrm{i}\sin(\beta t)\right) + B\Im\left(e^{\alpha t}\vec{v}(\cos(\beta t) + \mathrm{i}\sin(\beta t)\right) \tag{6.3.1011}$$

Let us see an example:

✍**Example:**

Consider the following system:

$$\dot{\vec{Y}} = \begin{bmatrix} -4 & 24 \\ 1 & -2 \end{bmatrix} \vec{Y} + \begin{pmatrix} 4 \\ 1 \end{pmatrix} e^t$$

The characteristic equation of M is:

$$\begin{vmatrix} -4-\lambda & 24 \\ 1 & -2-\lambda \end{vmatrix} = 0$$

which gives:

$$(\lambda+8)(\lambda-2) = 0$$

and therefore:

$$\lambda_{1,2} = 2, -8$$

When $\lambda = 2$, $\vec{v}$ satisfies:

$$\begin{bmatrix} -6 & 24 \\ 1 & -4 \end{bmatrix} \begin{pmatrix} v_1 \\ v_2 \end{pmatrix} = \vec{0}$$

and we get $\vec{v}_1 = \begin{pmatrix} 4 \\ 1 \end{pmatrix}$.

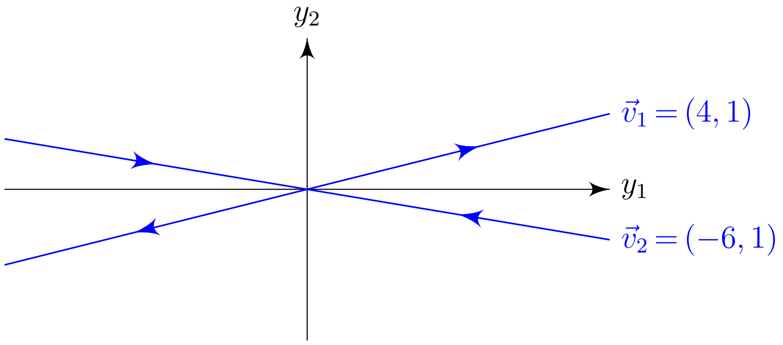
When $\lambda = -8$, we have:

$$\begin{pmatrix} 4 & 24 \\ 1 & 6 \end{pmatrix} \begin{pmatrix} v_1 \\ v_2 \end{pmatrix} = \vec{0}$$

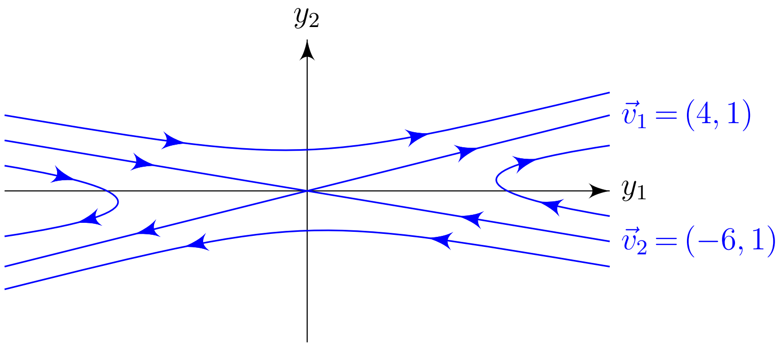
and there $\vec{v}_2 = \begin{pmatrix} -6 \\ 1 \end{pmatrix}$. So the complementary solution is:

$$\vec{Y} = A \begin{pmatrix} 4 \\ 1 \end{pmatrix} e^{2t} + B \begin{pmatrix} -6 \\ 1 \end{pmatrix} e^{-8t}$$

To plot the phase-space trajectories, we first consider the cases where $\vec{Y}$ is an eigenvector. If $\vec{Y}$ is an integer multiple of $\begin{pmatrix} 4 \\ 1 \end{pmatrix}$, then it will keep moving outwards in the same direction. Similarly, if it is an integer multiple of $\begin{pmatrix} -6 \\ 1 \end{pmatrix}$, it will move towards the origin.



We can now add more (curved) lines based on these two:



To find the particular solution, we try $\vec{Y}_p = \vec{u}e^t$. Then:

$$\begin{pmatrix} u_1 \\ u_2 \end{pmatrix} - \begin{bmatrix} -4 & 24 \\ 1 & -2 \end{bmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} = \begin{pmatrix} 4 \\ 1 \end{pmatrix}$$

$$\begin{bmatrix} 5 & -24 \\ -1 & 3 \end{bmatrix}\begin{pmatrix} u_1 \\ u_2 \end{pmatrix}=\begin{pmatrix} 4 \\ 1 \end{pmatrix}$$
$$\begin{pmatrix} u_1 \\ u_2 \end{pmatrix}=-\frac{1}{9}\begin{bmatrix} 3 & 24 \\ 1 & 5 \end{bmatrix}\begin{pmatrix} 4 \\ 1 \end{pmatrix}=\begin{pmatrix} -4 \\ -1 \end{pmatrix}$$

So the general solution is:

$$\vec{Y}=A\begin{pmatrix} 4 \\ 1 \end{pmatrix}e^{2t}+B\begin{pmatrix} -6 \\ 1 \end{pmatrix}e^{-8t}-\begin{pmatrix} 4 \\ 1 \end{pmatrix}e^{t}=\begin{bmatrix} 4e^{2t} & -6e^{-8t} \\ 1e^{2t} & 1e^{-8t} \end{bmatrix}\begin{pmatrix} A \\ B \end{pmatrix}-\begin{pmatrix} 4 \\ 1 \end{pmatrix}e^{t}$$

Often denoted in the general case:

$$\vec{Y}=\Phi(t)\vec{C}+\vec{x}_p(t)$$

Remark

Notice that if the system above was autonomous, i.e. independent of time such that:

$$\frac{\mathrm{d}y_1}{\mathrm{d}t}=-4y_1+42y_2$$
$$\frac{\mathrm{d}y_2}{\mathrm{d}t}=1y_1-2y_2$$

then we can get the slopes of the phase diagram by just computing:

$$\frac{\mathrm{d}y_2}{\mathrm{d}y_1}=\frac{\frac{\mathrm{d}y_2}{\mathrm{d}t}}{\frac{\mathrm{d}y_1}{\mathrm{d}t}}=\frac{1y_1-2y_2}{-4y_1+42y_2}$$

Consider the general solution of a autonomous system known as being like (as seen in the example above):

$$\vec{Y}=\Phi(t)\vec{C} \qquad (6.3.1012)$$

We are now ready to solve the initial value problem:

$$\dot{\vec{Y}}=M\vec{Y}, \quad \vec{Y}(t_0)=\vec{Y}_0 \qquad (6.3.1013)$$

Starting with the general solution, we have that:

$$\vec{Y}_0=\vec{Y}(t_0)=\Phi(t_0)\vec{C} \qquad (6.3.1014)$$

As usual, we need to solve for the c_k (i.e. the components of $\vec{C}$). Using matrix methods, this is very easy. Since the Wronskian is not zero, then we can invert Φ at any value of t. So, we have:

$$\vec{C}=\Phi^{-1}(t_0)\vec{Y}_0 \qquad (6.3.1015)$$

Putting $\vec{C}$ back into the general solution, we get the solution to the initial value problem:

$$\vec{Y}(t) = \Phi(t)\Phi^{-1}(t_0)\,\vec{Y}_0 \qquad (6.3.1016)$$

As always we can (and should always!) easily verify that this is a solution of the system and satisfies the initial condition at $t = t_0$.

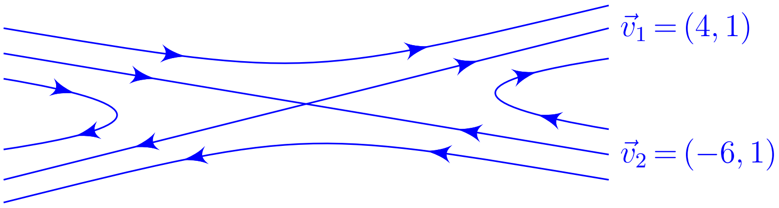
The matrix combination $\Phi(t)\Phi^{-1}(t_0)$ is useful. So, we will define the resulting product to be the "principal matrix solution", denoting it by:

$$\Psi(t) = \Phi(t)\Phi^{-1}(t_0) \qquad (6.3.1017)$$

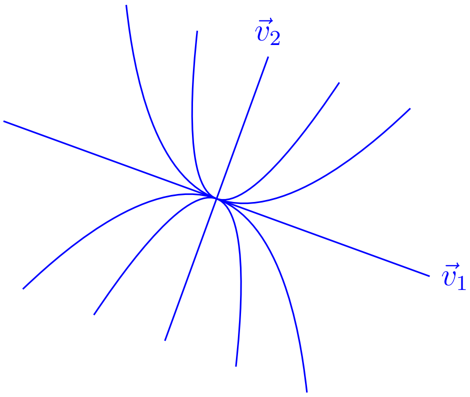
Thus, the solution of the initial value problem is then denoted $\vec{Y}(t) = \Psi(t)\vec{Y}_0$.

In general, there are basically three possible cases of $\dot{\vec{Y}} = M\vec{Y}$ corresponding to three different possible eigenvalues of M:

1. If both λ_1, λ_2 are real with opposite sign ($\lambda_1\lambda_2 < 0$). Without loss of generality assume $\lambda_1 > 0$. Then there is a saddle as above:

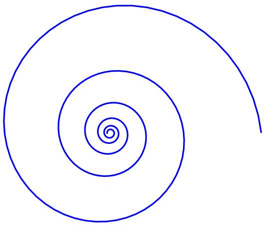


2. If λ_1, λ_2 are real with $\lambda_1\lambda_2 > 0$. Without loss of generality assume $|\lambda_1| \geq |\lambda_2|$. Then the phase portrait is:



If both $\lambda_1, \lambda_2 < 0$, then the arrows point towards the intersection and we say there is a stable node. If both are positive, they point outwards and there is an unstable node.

3. If λ_1, λ_2 are complex conjugates, then we get a spiral:



If $\Re(\lambda_{1,2})<0$, then it spirals inwards. If $\Re(\lambda_{1,2})>0$, then it spirals outwards. If $\Re(\lambda_{1,2})=0$, then we have ellipses with common centers instead of spirals. We can determine whether the spiral is positive (as shown above), or negative (mirror image of the spiral above) by considering the eigenvectors.

Coming back to:

$$\lambda_1+\lambda_2=\text{tr}(M),\lambda_1\lambda_2=\det(M),\lambda_{1,2}=\frac{\text{tr}(M)\pm\sqrt{\text{tr}(M)^2-4\det(M)}}{2}=\frac{\text{tr}(M)\pm\sqrt{\Delta}}{2} \tag{6.3.1018}$$

We then have as reminder:

- $\text{tr}(M)^2-4\det(M)>0$, two real roots (related to "overdamped systems" since the system leads to exponential decay). Then the solution is commonly written as ($\vec{v}_1$ and $\vec{v}_2$ are the eigenvectors):

$$\vec{Y}=A\vec{v}_1e^{\lambda_1 t}+B\vec{v}_2e^{\lambda_2 t} \tag{6.3.1019}$$

- $\text{tr}(M)^2-4\det(M)=0$, one (repeated) root (related to "critically damped systems" - there are no oscillations). Then the solution is commonly written as:

$$\vec{Y}=A\vec{v}_1e^{\lambda t}+B\vec{v}_2e^{\lambda t}(\vec{v}_2+t\vec{v}_1) \tag{6.3.1020}$$

- $\text{tr}(M)^2-4\det(M)<0$, two complex conjugated roots (related to "underdamped oscillating systems" consisting of decaying exponential times oscillations). Then the solution is commonly written as:

$$\vec{Y}=A\Re\left(e^{\alpha t}\vec{v}(\cos(\beta t)+\mathrm{i}\sin(\beta t)\right)+B\Im\left(e^{\alpha t}\vec{v}(\cos(\beta t)+\mathrm{i}\sin(\beta t)\right) \tag{6.3.1021}$$

But more in details:

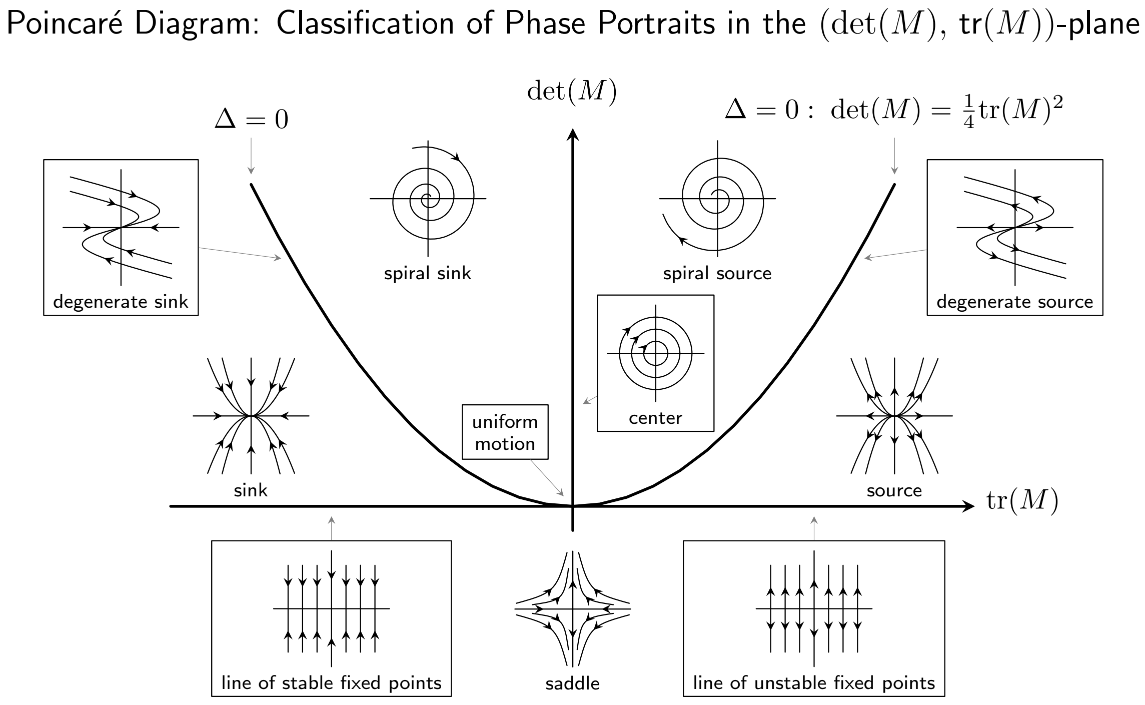
- If $\text{tr}(M)>0,\det(M)>0$, and $\text{tr}(M)^2-4\det(M)>0$, it is a source (unstable system!);
- If $\text{tr}(M)<0,\det(M)>0$, and $\text{tr}(M)^2-4\det(M)>0$, it is a sink (stable system!);
- If $\text{tr}(M)>0,\det(M)>0$, and $\text{tr}(M)^2-4\det(M)<0$, it is a spiral source (unstable system!);
- If $\text{tr}(M)<0,\det(M)>0$, and $\text{tr}(M)^2-4\det(M)<0$, it is a spiral sink (stable system!);
- If $\det(M)<0$, then it is a saddle (unstable system!). In this case, $\text{tr}(M)^2-4\det(M)>0$ always holds and it does not matter whether $\text{tr}(M)>0$ or $\text{tr}(M)<0$;
- If $\text{tr}(M)=0$ or $\det(M)=0$, it is degenerate (neutral system!)

If represented as a table:

Type	Eigenvalues	Stability
Node	Real λ, same signs	$\lambda < 0$, stable $\lambda > 0$, unstable
Saddle	Real λ opposite signs	Mostly Unstable
Center	λ pure imaginary	-
Focus/Spiral	Complex $\lambda, \Re(\lambda) \neq 0$	$\Re(\lambda) < 0$, stable $\Re(\lambda) > 0$, unstable
Degenerate Node	Repeated roots	$\lambda > 0$, stable
Lines of Equilibria	One zero eigenvalue	$\lambda < 0$, stable

Table 6.14: **List of typical behaviours in planar systems**

Here is a visual summary based on the matrix and the determinant (based on a manual drawing by Douglas R. Hundley):



Poincaré Diagram: Classification of Phase Portraits in the $(\det(M), \text{tr}(M))$-plane
$\Delta = 0$

Figure 6.64: **Poincaré Diagram - Classification of Phase Portraits for a 2×2 matrix (author: Gernot Salzer)**

In the trace-determinant plane above, the points with coordinates (T, D) (i.e. Trace/Determinant) correspond to systems with repeated eigenvalues. Furthermore, points above the parabola correspond to systems with two complex eigenvalues which are complex conjugates with each other. Lastly, points below the parabola correspond to planar systems with two distinct eigenvalues.

Caution! The above Poincaré diagram is really only for a 2×2 matrix A. For higher dimensions it can't be used anymore!

Remark

If the matrix M is symmetric we get another typical type of pattern ("star" pattern) that is not represented in the figure above.

6.3.3.6 Nonlinear dynamical systems

In mathematics and science, a nonlinear system is a system in which the change of the output is not proportional to the change of the input. Nonlinear problems are of interest to engineers, biologists, physicists, mathematicians, and many other scientists since most systems are inherently nonlinear in nature. Nonlinear dynamical systems, describing changes in variables over time, may appear chaotic, unpredictable, or counterintuitive, contrasting with much simpler linear systems. They are hard to solve or unsolvable in some situations. In most cases they cannot be solved by hand but by numerical simulations.

quote
6.3:1644.#55

> ❞ *Mathematics takes place at different timescales. If you can solve a problem in 5 minutes that others need an hour to solve, you can probably get a good job. If you can solve a problem in a month that others might need a year to solve, you will probably do well as a graduate student. But if you can solve a problem in 10 years that nobody else can solve in a lifetime, you could be a great mathematician.* ❞
>
> Robert Israel

A system of differential equations is said to be nonlinear if it is not a system of linear equations. Problems involving nonlinear differential equations are extremely diverse, and methods of solution or analysis are problem dependent. Examples of nonlinear differential equations treated in quite in details in this textbook are:

- The double pendulum (see page 3440)
- The Navier–Stokes equations in fluid dynamics (see page 3811)
- The Lotka–Volterra equations in biology (see page 7350)
- The Einstein's field equations in General Relativity (see page 5766)
- The Lorenz equation in meteorology (see page 8318)
- etc.

So the reader interested can pick up one of the subject above to get a quite detailed mathematical treatment of a special case of nonlinear dynamical systems.

6.3.3.7 Regular Methods of Perturbations

Very frequently in physics (high level physics) or financial engineering, a mathematical problem can not be solved exactly. Even if the solution is known sometimes there are such a dependency of parameters that the solution is difficult to use as such.

Sometimes, however, it happens that an identified parameter of the differential equation, which we denote by tradition with the Greek letter ε, is such that the solution is available and reasonably simple for $\varepsilon = 0$.

The problem then is to know how the solution is altered for a non-zero ε but still small. This study is the center of "perturbation theory" that we will use, for example in the section of General Relativity to calculate the precession of the perihelion of Mercury.

As the perturbation theory within the general framework is too complex for this textbook purpose, we propose an approach by example with first a simple algebraic equation and then with what interests us: a differential equation.

6.3.3.7.1 Perturbation theory for algebraic equations

Consider the following polynomial equation:

$$x^2 - 1 = \varepsilon x \qquad (6.3.1022)$$

We know from our study of the section Functional Analysis, that this polynomial equation has two roots that are trivially:

$$x_{1,2} = \frac{\varepsilon \pm \sqrt{\varepsilon^2 + 4}}{2} = \frac{\varepsilon}{2} \pm \sqrt{1 + \frac{\varepsilon^2}{4}} \qquad (6.3.1023)$$

For small ε, these roots can be approximated by the first term of the Taylor series expansion (see section Sequences and Series page 1696):

$$x_1 = 1 + \frac{\varepsilon}{2} + \frac{\varepsilon^2}{8} + \mathcal{O}(\varepsilon^3) \quad x_2 = -1 + \frac{\varepsilon}{2} - \frac{\varepsilon^2}{8} + \mathcal{O}(\varepsilon^3) \qquad (6.3.1024)$$

The question is whether we can get the two previous relation without a priori knowledge of the exact solution of the initial polynomial equation? The answer is obviously: YES with the help of perturbation theory.

The technique is based on four steps:

1. In the first step, we assume that the solution of the polynomial equation is an expression of the type Taylor series on ε. Then we have:

$$x = X_0 + \varepsilon X_1 + \varepsilon^2 X_2 + \mathcal{O}(\varepsilon^3) \qquad (6.3.1025)$$

   where X_1, X_2, X_3 are obviously to be determined.

2. In the second step, we inject the solution in our hypothetical polynomial equation:

$$\left(X_0+\varepsilon X_1+\varepsilon^2 X_2+\mathcal{O}(\varepsilon^3)\right)^2-1=\varepsilon\left(X_0+\varepsilon X_1+\varepsilon^2 X_2+\mathcal{O}(\varepsilon^3)\right) \tag{6.3.1026}$$

As:

$$\begin{aligned}
x^2 =&X_0^2+2\left(\varepsilon X_1+\varepsilon^2 X_2+\mathcal{O}(\varepsilon^3)\right)X_0+\left(\varepsilon X_1+\varepsilon^2 X_2+\mathcal{O}(\varepsilon^3)\right)^2\\
=&X_0^2+2\left(\varepsilon X_1+\varepsilon^2 X_2+\mathcal{O}(\varepsilon^3)\right)X_0+\left(\left(\varepsilon X_1+\varepsilon^2 X_2\right)^2+2\left(\varepsilon X_1+\varepsilon^2 X_2\right)\mathcal{O}(\varepsilon^3)\varepsilon^3\right)\\
\cong&X_0^2+2\left(\varepsilon X_1+\varepsilon^2 X_2\right)X_0+\left(\varepsilon X_1+\varepsilon^2 X_2\right)^2+\mathcal{O}(\varepsilon^3)\\
=&X_0^2+2\left(\varepsilon X_1+\varepsilon^2 X_2\right)X_0+\left(\varepsilon^2 X_1^2+2\varepsilon^3 X_1X_2+\varepsilon^4 X_2^2\right)+\mathcal{O}(\varepsilon^3)\\
\cong&X_0^2+2\left(\varepsilon X_1+\varepsilon^2 X_2\right)X_0+\left(\varepsilon^2 X_1^2\right)+\mathcal{O}(\varepsilon^3)\\
=&X_0^2+2\varepsilon X_0X_1+\varepsilon^2\left(X_1^2+2X_0X_2\right)+\mathcal{O}(\varepsilon^3)
\end{aligned} \tag{6.3.1027}$$

and:

$$\varepsilon x=\varepsilon X_0+\varepsilon^2 X_1+\mathcal{O}(\varepsilon^3) \tag{6.3.1028}$$

It finally comes that the polynomial equation can be written as:

$$X_0^2-1+\varepsilon(2X_0X_1-X_0)+\varepsilon^2\left(X_1^2+2X_0X_2-X_1\right)+\mathcal{O}(\varepsilon^3)=0 \tag{6.3.1029}$$

3. In the third step we successively equalize the terms with 0 such as:

$$\begin{aligned}
&\mathcal{O}(\varepsilon^0):X_0^2-1=0\\
&\mathcal{O}(\varepsilon^1):2X_0X_1-X_0=0\\
&\mathcal{O}(\varepsilon^2):X_1^2+2X_0X_2-X_1=0\\
&\mathcal{O}(\varepsilon^3):\ \ldots
\end{aligned} \tag{6.3.1030}$$

4. Fourth and last step, we solve successively the polynomial equations above to get:

$$X_0=\pm 1\Rightarrow X_1=\frac{1}{2}\Rightarrow X_2=\pm\frac{1}{8} \tag{6.3.1031}$$

By injecting these results in the hypothetical solution:

$$x=X_0+\varepsilon X_1+\varepsilon^2 X_2+\mathcal{O}(\varepsilon^3) \tag{6.3.1032}$$

it is obvious to observe that we fall back on the certain solution:

$$x_1=1+\frac{\varepsilon}{2}+\frac{\varepsilon^2}{8}+\mathcal{O}(\varepsilon^3)\qquad x_2=-1+\frac{\varepsilon}{2}-\frac{\varepsilon^2}{8}+\mathcal{O}(\varepsilon^3) \tag{6.3.1033}$$

6.3.3.7.2 Perturbation theory of differential equations

Perturbation theory is therefore also often used to resolve numerous differential equations. This is the case for example in fluid mechanics, in General Relativity or quantum physics.

Again, rather than doing a super abstract and general theory, we will see the concept with an example as previously.

Consider the following ordinary differential equation with second member and constant coefficients:

$$y''=-\varepsilon y'-1 \tag{6.3.1034}$$

Or written in another way:

$$y''+\varepsilon y'=-1 \tag{6.3.1035}$$

with the boundary conditions:

$$y(0)=0, y'(0)=1 \tag{6.3.1036}$$

The exact resolution is relatively easy to get!

First we start with the homogeneous equation:

$$y''+\varepsilon y'=0 \tag{6.3.1037}$$

So it is a linear differential equation of order 2 with constant coefficients, equation that it is relatively easy to solve in the general case. Given the equation:

$$y''+p\varepsilon y'+qy=0 \tag{6.3.1038}$$

Assume that the function y which satisfies this differential equation is the of the form $y=e^{Kx}$ where K may be a complex number. Then we have:

$$K^2e^{Kx}+pKe^{Kx}+qe^{Kx}=0 \quad \text{or} \quad K^2+pK+q=0 \tag{6.3.1039}$$

provided, of course, that $e^{Kx}\neq 0$. This last relation is the auxiliary quadratic equation of the differential equation (characteristic polynomial in other words). It has two solutions/roots (it's a simple resolution of a polynomial of the second degree) which we denote in the general case: K_1,K_2. Which means that:

$$K_1^2e^{K_1x}+pK_1e^{K_1x}+qK_1e^{K_1x}=0 \quad \text{and} \quad K_2^2e^{K_2x}+pK_2e^{K_2x}+qK_2e^{K_2x}=0 \tag{6.3.1040}$$

are satisfied for the two roots. If we do the sum, since both are equal to the same constant:

$$\left(K_1^2e^{K_1x}+K_2^2e^{K_2x}\right)+p\left(K_1e^{K_1x}+K_2e^{K_2x}\right)+q\left(e^{K_1x}+e^{K_2x}\right)=0 \tag{6.3.1041}$$

Thus, it is immediate that the general solution of the homogeneous equation is of the type:

$$y_h=Ae^{K_1x}+Be^{K_2x} \tag{6.3.1042}$$

where A, B are obviously constants to be determined. Now we solve the characteristic polynomial:

$$K^2+\varepsilon K=0 \tag{6.3.1043}$$

It comes immediately that:

$$K_{1,2}=\frac{-\varepsilon\pm\sqrt{\varepsilon^2}}{2}\Rightarrow\begin{cases}K_1=-\varepsilon\\K_2=0\end{cases} \tag{6.3.1044}$$

Therefore:

$$y_h=Ae^{-\varepsilon x} \tag{6.3.1045}$$

Now a particular solution to:

$$y''+\varepsilon y'=-1 \tag{6.3.1046}$$

is relatively trivially a solution of the type:

$$y_p=Bx \tag{6.3.1047}$$

where B is of course a constant to be determined and which is equal (once injected into the differential equation):

$$y''+\varepsilon y'=-1\Rightarrow 0+\varepsilon B=1\Rightarrow B=-\frac{1}{\varepsilon} \tag{6.3.1048}$$

Therefore:

$$y_p=-\frac{x}{\varepsilon}+c^{te} \tag{6.3.1049}$$

Hence finally the general solution:

$$y=y_p+y_h=Ae^{-ex}-\frac{x}{\varepsilon}+c^{te} \tag{6.3.1050}$$

Then, with the initial conditions that are a for reminder:

$$y(0)=0,y'(0)=1 \tag{6.3.1051}$$

it is very easy to find A:

$$y(0)=0\Rightarrow Ae^{-e0}-\frac{0}{\varepsilon}+c^{te}=A+c^{te}=0 \tag{6.3.1052}$$

$$\Rightarrow c^{te}=-A \tag{6.3.1053}$$

We also have:

$$y'(0)=1\Rightarrow-\varepsilon Ae^{-\varepsilon 0}-\frac{1}{\varepsilon}+c^{te}=-\varepsilon A-\frac{1}{\varepsilon}+c^{te}=1\Rightarrow A=-\frac{1}{\varepsilon}\left(1-c^{te}+\frac{1}{\varepsilon}\right)=-\left(\frac{\varepsilon-\varepsilon c^{te}+1}{\varepsilon^2}\right) \tag{6.3.1054}$$

We are free to choose that $c^{te}=0$ which gives us:

$$A=-\left(\frac{\varepsilon+1}{\varepsilon^2}\right) \tag{6.3.1055}$$

Then:

$$y=y_p+y_h=Ae^{-\varepsilon x}-\frac{x}{\varepsilon}+c^{te} \tag{6.3.1056}$$

becomes:

$$\begin{aligned} y&=-\frac{\varepsilon+1}{\varepsilon^2}e^{-\varepsilon x}-\frac{x}{\varepsilon}+c^{te}\\ &=-\frac{1+\varepsilon}{\varepsilon^2}e^{-\varepsilon x}-\frac{x}{\varepsilon}+\frac{1+\varepsilon}{\varepsilon^2}\\ &=\frac{1+\varepsilon}{\varepsilon^2}\left(1-e^{-\varepsilon x}\right)-\frac{x}{\varepsilon} \end{aligned} \tag{6.3.1057}$$

Now that we have the general solution if ε is small we can take the development of order 4 in Maclaurin series of the exponential (see section Sequences and Series page 1703). Such as:

$$e^{-\varepsilon x}=1-\varepsilon x+\frac{1}{2}\varepsilon^2x^2-\frac{1}{6}\varepsilon^3x^3+\mathcal{O}(\varepsilon^4x^4) \tag{6.3.1058}$$

Injected into y this gives (you will notice that we sometimes express explicitly... the term of order 5 by anticipation...):

$$\begin{aligned} y&=\frac{1+\varepsilon}{\varepsilon^2}\left(1-e^{-\varepsilon x}\right)-\frac{x}{\varepsilon}\\ &=\frac{1+\varepsilon}{\varepsilon^2}\left(\varepsilon x-\frac{1}{2}\varepsilon^2x^2+\frac{1}{6}\varepsilon^3x^3-\mathcal{O}(\varepsilon^4x^4)\right)-\frac{x}{\varepsilon}\\ &=\frac{1}{\varepsilon^2}\left(\varepsilon x-\frac{1}{2}\varepsilon^2x^2+\frac{1}{6}\varepsilon^3x^3-\mathcal{O}(\varepsilon^4x^4)\right)+\frac{1}{\varepsilon}\left(\varepsilon x-\frac{1}{2}\varepsilon^2x^2+\frac{1}{6}\varepsilon^3x^3-\mathcal{O}(\varepsilon^4x^4)\right)-\frac{x}{\varepsilon}\\ &=\frac{1}{\varepsilon}x-\frac{1}{2}x^2+\frac{1}{6}\varepsilon x^3-\frac{1}{24}\varepsilon^2x^4+x-\frac{1}{2}\varepsilon x^2+\frac{1}{6}\varepsilon^2x^3-\mathcal{O}(\varepsilon^3x^4)-\frac{x}{\varepsilon}\\ &=x-\frac{1}{2}x^2+\varepsilon\left(-\frac{1}{2}x^2+\frac{1}{6}x^3\right)+\varepsilon^2\left(\frac{1}{6}x^3-\frac{1}{24}x^4\right)-\mathcal{O}(\varepsilon^3x^4) \end{aligned} \tag{6.3.1059}$$

Now that we have this development, what we want to show is that from a perturbative expansion we can find the same result in series and this without any prior knowledge on the solution.

Again, the development is done in 4 steps:

1. In the first step, we assume that the solution of differential equation is an expression of the type Taylor series on ε. Then we have:

   $$y=y_0+\varepsilon y_1+\varepsilon^2y_2+\mathcal{O}(\varepsilon^3) \tag{6.3.1060}$$

   where y_0,y_1,y_2 are obviously to be determined.

2. In the second step, we inject the hypothetical solution of our differential equation in itself with the initial conditions and we develop the whole.

   First the differential equation:

$$\begin{aligned} y''+\varepsilon y'+1 &= \left(y_0''+\varepsilon y_1''+\varepsilon^2 y_2''+\mathcal{O}(\varepsilon^3)\right)+\varepsilon\left(y_0'+\varepsilon y_1'+\varepsilon^2 y_2'+\mathcal{O}(\varepsilon^3)\right)+1 \\ &= (y_0''+1)+\varepsilon(y_1''+y_0')+\varepsilon^2(y_2''+y_1')+\mathcal{O}(\varepsilon^3)=0 \end{aligned} \tag{6.3.1061}$$

   then the initial conditions:

$$\begin{aligned} y(0) &= y_0(0)+\varepsilon y_1(0)+\varepsilon^2 y_2(0)+\mathcal{O}(\varepsilon^3)=0 \\ y'(0) &= \left(y_0'(0)-1\right)+\varepsilon y_1'(0)+\varepsilon^2 y_2'(0)+\mathcal{O}(\varepsilon^3)=0 \end{aligned} \tag{6.3.1062}$$

3. In the third step we equalize successively the terms with 0 such as:

$$\begin{array}{llll} \mathcal{O}(\varepsilon^0): & y_0''+1=0 & y_0(0)=0 & y_0'(0)-1=0 \\ \mathcal{O}(\varepsilon^1): & y_1''+y_0'=0 & y_1(0)=0 & y_1'(0)=0 \\ \mathcal{O}(\varepsilon^2): & y_2''+y_1'=0 & y_2(0)=0 & y_2'(0)=0 \\ \mathcal{O}(\varepsilon^3): & \cdots & & \end{array} \tag{6.3.1063}$$

4. In the fourth step we solve the differential equations listed above (if you do not see how we solve them do not hesitate to contact us!):

$$\begin{aligned} y_0 &= x-\frac{1}{2}x^2 \\ y_1 &= -\frac{1}{2}x^2+\frac{1}{6}x^3 \\ y_2 &= \frac{1}{6}x^3-\frac{1}{24}x^4 \end{aligned} \tag{6.3.1064}$$

   By injecting relations in the supposed solution developed in Taylor series and injected into the differential equation:

$$y=y_0+\varepsilon y_1+\varepsilon^2 y_2+\mathcal{O}(\varepsilon^3) \tag{6.3.1065}$$

   We fall back on:

$$y=x-\frac{1}{2}x^2+\varepsilon\left(-\frac{1}{2}x^2+\frac{1}{6}x^3\right)+\varepsilon^2\left(\frac{1}{6}x^3-\frac{1}{24}x^4\right)-\mathcal{O}(\varepsilon^3x^4) \tag{6.3.1066}$$

6.4. Sequences and Series

SEQUENCES AND SERIES have a great importance in Applied Mathematics and that is why we devote to them a whole section. We will also see them often in various sections of the Mechanics chapters when we need to make some minor approximations (...) as well as in the sections of Economy and Quantitative Management Techniques. The reader should try to not confuse in what follows the concept of "sequences" with that of "series" which, while being similar in substance, are not always analyse mathematically in the same way.

We wanted to study in this section simple things without going to far within the topological concepts of sequences and series. However, those interested in more rigorous definitions can read the sections Fractals (see chapter of Theoretical Computing page 7038) and Topology (see chapter Topology page 2446) where many concepts about series are (supremum, infimum, subsequence, Bolzano-Weierstrass' theorem, etc.).

6.4.1 Sequences

Definition (#6.4.211): A "sequence" of a set is a family of elements indexed by the set of natural numbers (see section Numbers page 215) or by a part of it. In a vulgarized way we say that a sequence is a list of objects put in order, each with a order number. We typically write a sequence as:

$$(u_n) \quad \text{or} \quad (u_n)_{n\in\mathbb{N}} \tag{6.4.1}$$

where indexing is sometimes (by tradition...) without the 0.

For some sequences, we provide the first term u_1 (if indexing starts with 1 instead of 0), and a formula for any term u_{n+1} from the previous term u_n regardless $n\geq 1$. We name such a formulation a "recurring definition" and the sequence is defined "recursively" (and even if it is indexed from 0 instead of 1).

Before seeing some examples of sequences families that will be used in the various sections of the book (Population Dynamic, Economy, Nuclear Physics, etc.) let us see a small set of definitions as it is the tradition in mathematics...

Definitions (#6.4.212):

D1. Numbers (as sequence) are in "arithmetic progression" if the difference of two consecutive terms is equal to a constant r named the "reason".

D2. Numbers (as sequence) are in "geometric progression" if the ratio of two consecutive terms is equal to a constant r also named the "reason".

D3. Numbers (as sequence) are in "harmonic progression" if the inverse of two consecutive terms are in arithmetic progression.

Therefore, a number b is respectively the arithmetic mean, geometric, harmonic of a and c if the numbers a, b, c are respectively in an arithmetic, geometric or harmonic progression.

Remark

For the definitions of the averages listed above see the section Statistics.

Definitions (#6.4.213):

D1. A "majorated sequence" is a sequence such that there is a real number M such that: $\forall n \in \mathbb{N},\ u_n \leq M$

D2. A "minorated sequence" is a sequence such that there is a real number m such that: $\forall n \in \mathbb{N},\ u_n \geq m$

D3. A "bounded sequence" is a sequence that is both majorated and minorated.

D4. A sequence (u_n) is named "increasing sequence" if $\forall n \in \mathbb{N},\ u_{n+1} - u_n > 0$

D5. A sequence (u_n) is named "decreasing sequence" if $\forall n \in \mathbb{N},\ u_{n+1} - u_n < 0$

Remark

If a sequence is increasing or decreasing, we sometimes just say it is a "monotonous sequence" (without specifying if its increasing or decreasing).

D6. A sequence (u_n) is named "constant sequence" if $\forall n \in \mathbb{N},\ u_{n+1} = u_n$

We will now see some practical important arithmetic and geometric sequences that will be used later in other sections of this textbook.

But keep in mind during the lecture that we can express sequences most of time in two ways:

- A "closed formula" or "closed relation" for a sequence $(u_n)_{n\in\mathbb{N}}$ is a relation for u_n using a fixed finite number of operations on n only (and nothing else!). This is what we normally think of as a function of n only,
- A "recursive definition" for a sequence $(u_n)_{n\in\mathbb{N}}$ consists of a recurrence relation: a relation relating a term of the sequence to previous terms (terms with smaller index n) and an initial condition.

6.4.1.1 Arithmetic Sequences

Definition (#6.4.214): We say that numbers or "terms" are in an "arithmetic sequence" when the difference of their sequential value is equal to a constant r named the "reason" of the sequence so that (recursive relation):

$$u_{k+1}=u_k+r \tag{6.4.2}$$

where r is the "reason" of the progression. We then obviously have if the indexing starts from 0:

$$\boxed{u_k=u_0+k\cdot r} \tag{6.4.3}$$

✍**Examples:**

E1. The sequence:

$$n,n+1,n+2,n+3,\ldots,n+k \tag{6.4.4}$$

where n is a constant and the reason is equal 1.

E2. The sequence:

$$n+0\cdot x,n+1\cdot x,n+2\cdot x,n+3\cdot x,\ldots,n+k\cdot x \tag{6.4.5}$$

is an arithmetic sequence of reason x.

Thus, if we write u_n any term of the sequence (u_n) of reason r, we have:

$$u_0=\text{c}^{te},u_1=u_0+r,u_2=u_1+r=u_0+2\cdot r,\ldots,u_n=u_0+n\cdot r \tag{6.4.6}$$

We have the following properties for this type of sequences:

P1. A term whose rank is the average of the ranks of the other two terms is the arithmetic mean of these two terms.

Proof 6.17.2. Consider now (u_n) an arithmetic sequence of reason r given by the previous development:

$$u_n=u_0+n\cdot r \tag{6.4.7}$$

and $a,b,k\in\mathbb{N}$ such as $a+b=2k$, then we have:

$$\begin{aligned}u_a+u_b&=u_0+(a)r+u_0+(b)r=2u_0+2\left(\frac{a+b}{2}\right)r\\&=2\left(u_0+\left(\frac{a+b}{2}\right)r\right)=2u_{\frac{a+b}{2}}=2u_k\end{aligned} \tag{6.4.8}$$

and so:

$$u_k=\frac{u_a+u_b}{2} \tag{6.4.9}$$

with $k=\dfrac{a+b}{2}$.

■ Q.E.D.

P2. For three consecutive terms u_n, u_{n+1}, u_{n+2} in an arithmetic sequence of reason r, the second term is the arithmetic mean of the other two.

Proof 6.17.3. Let us write:

$$\frac{u_n+u_{n+2}}{2}=\frac{u_n+(u_n+2r)}{2}=2\frac{u_n+r}{2}=u_n+r=u_{n+1} \tag{6.4.10}$$

■ Q.E.D.

P3. If $u_1, u_2, u_3, \ldots, u_n, \ldots$ is an arithmetic sequence of ratio r, then the n-th partial sum S_n (that is to say, the sum of the first n terms to the power of 1) is given by:

$$S_n=\frac{n}{2}(2u_1+n\cdot r)=\frac{n}{2}(u_1+u_n) \tag{6.4.11}$$

when indexing is starts from 1.

Proof 6.17.4. We can write the sequence:

$$\begin{aligned}S_n&=u_1+u_2+u_3+u_4+\ldots+u_n\\&=u_1+(u_1+r)+(u_1+2r)+(u_1+3r)+\ldots+(u_1+(n-1)r)\end{aligned} \tag{6.4.12}$$

Playing with the second line, we get:

$$S_n=(u_1+u_1+u_1+u_1+\ldots+u_1)+(r+2r+3r+4r+\ldots+(n-1)r) \tag{6.4.13}$$

What can be simplified even more:

$$S_n=nu_1+r(1+2+3+4+\ldots+(n-1)) \tag{6.4.14}$$

Considering that we will prove a little bit later that the simple following Gauss series:

$$1+2+3+4+\ldots+n \tag{6.4.15}$$

is equal to:

$$S_1=\frac{n(n+1)}{2} \tag{6.4.16}$$

We then have for:

$$1+2+3+4+\ldots+(n-1) \tag{6.4.17}$$

the following relation:

$$S_1=\frac{(n-1)n}{2} \tag{6.4.18}$$

We thus get:

$$S_n=nu_1+r\frac{(n-1)n}{2}=\frac{n}{2\left[2u_1+r(n-1)\right]} \tag{6.4.19}$$

We see with the latter relation that if $u_1=r=1$ we fall back on the simple Gauss series.

As:

$$u_n=u_1+r(n-1) \tag{6.4.20}$$

when the indexation starts from 1 we thus get:

$$S_n=\frac{n}{2}\left[u_1+u_n\right] \tag{6.4.21}$$

■ Q.E.D.

We will see other types of summations a little bit further below during our study of series!

6.4.1.2 Harmonic Sequences

Definition (#6.4.215): We say that numbers $\frac{1}{a},\frac{1}{b},\frac{1}{c},\ldots$ generates an "harmonic sequence" when their inverses are in arithmetical progression (also with a "reason" r. We represent this progress by:

$$\boxed{h_{k+1}=\frac{1}{u_{k+1}}=\frac{1}{u_k+r}} \tag{6.4.22}$$

We then obviously if the indexing starts from 0:

$$\frac{1}{u_k}=\frac{1}{u_0+k\cdot r} \tag{6.4.23}$$

Moreover, we assume, in what follows, that there is no zero denominator.

By sharing this type of sequences successively in groups containing 2^n terms, we observe that each of the group is bigger than the next one. For example:

$$\frac{1}{1}>\frac{1}{2}+\frac{1}{3}>\frac{1}{4}+\frac{1}{5}+\frac{1}{6}+\frac{1}{7}>\ldots \tag{6.4.24}$$

We can also see that each term is the harmonic mean of the previous and consecutive one:

Proof 6.17.5.

$$\begin{aligned}\frac{1}{\frac{1}{h_{k-1}}+\frac{1}{h_{k+1}}}&=\frac{1}{\frac{1}{\frac{1}{u_0+(k-1)r}}+\frac{1}{\frac{1}{u_0+(k+1)r}}}=\frac{1}{(u_0+(k-1)r)+(u_0+(k+1)r)}\\&=\frac{1}{2u_0+2kr}=\frac{1}{2(u_0+kr)}=\frac{1}{2}\frac{1}{h_k}\end{aligned} \tag{6.4.25}$$

Thus:

$$\frac{1}{h_k}=\frac{2}{\frac{1}{h_{k-1}}+\frac{1}{h_{k+1}}} \tag{6.4.26}$$

So finally:

$$h_k=\frac{\frac{1}{h_{k-1}}+\frac{1}{h_{k+1}}}{2} \tag{6.4.27}$$

■ Q.E.D.

6.4.1.3 Geometric Sequences

Definition (#6.4.216): A "geometric sequence" is a sequence of numbers such that each of them is equal to the previous n multiplied by a constant number q that we also name the "reason" or "common ratio" of the sequence. What will denote by:

$$n, qn, q^2n, q^3n, \ldots \tag{6.4.28}$$

Thus, if we denote by u_n any term of the sequence (u_n), we have (trivial):

$$\boxed{u_k = u_0 q^k} \tag{6.4.29}$$

Here are some properties for such a type of sequence (without proof until now... except if some readers ask for them because most are really trivial):

P1. (trivial) The quotient of two terms of the same sequence is a power of the reason q whose exponent equals the difference in rank of the two terms chosen (simple ratio of two same bases with different powers).

P2. (trivial) If we multiply or divide term by term two geometric sequences, we get a third geometric sequence whose raison equal the product (respectively the quotient) of the reasons of the two chosen sequences (simple operation with the reasons of the two original sequences).

P3. In a geometric sequence, a term whose rank is the average of the ranks of the other two terms is the geometric mean (see section Statistics page 565) of these two terms (reread many times if needed...).

Let us prove the property P3:

Proof 6.17.6. Given a geometric sequence with real positive reason q, we have for recall:

$$u_n = u_0 q^n \tag{6.4.30}$$

Let a, b be the ranks of two terms of the geometric sequence, then we have:

$$u_a \cdot u_b = u_0^2 q^a q^b = \left(u_0 q^{\frac{a+b}{2}}\right)^2 = u_{\frac{a+b}{2}}^2 = u_k^2 \tag{6.4.31}$$

and thus:

$$u_k = \sqrt{u_a \cdot u_b} \tag{6.4.32}$$

■ Q.E.D.

Corollary 6.17.1. We have as corollary that for three consecutive terms $n, n+1, n+2$ in a geometric progression, the second term is the geometric mean of the other two.

Proof 6.17.7. We have:

$$u_n u_{n+2} = u_0^2 q^n q^{n+2} = u_0^2 q^{n+(n+2)} = u_0^2 q^{2n+2} \tag{6.4.33}$$

Thus:

$$\sqrt{u_n u_{n+2}} = \sqrt{u_0^2 q^{2n+2}} = u_0 q^{n+1} = u_{n+1} \tag{6.4.34}$$

■ Q.E.D.

However, there are some special sequences that have special properties that we find very frequently in mathematical or theoretical physics in this textbook. Without going into too much detail, here's a partial list of with the important proofs that we will have to use later:

6.4.1.4 Cauchy Sequence

It is often interesting for the mathematician, as much as for the physicist, to know the properties of a sequence with a given type of progression. The most important property is the limit to which it tends.

> **Remark**
>
> The reader who is not comfortable with topology can skip the text that follows... and whoever wants to know more about Cauchy sequences may read the section Topology or also particularly the section on Fractals at page 7038.

Definition (#6.4.217): Let (X,d) a metric space (see section Topology page 2447), we say that the sequence:

$$(x_n)_{n\in\mathbb{N}},\quad x_n\in X\quad \forall n\in\mathbb{N} \tag{6.4.35}$$

converges to $x\in X$ if (by definition!):

$$\forall\varepsilon>0,\exists N\in\mathbb{N}\quad\text{as}\quad n\geq N\Rightarrow d(x_n,x)<\varepsilon \tag{6.4.36}$$

In other words, more we go far in the sequence, the more points are close (in the sense of the metric d) to each other.

If we chose a particular metric (the Euclidean one for example) and a discrete sequence the above definition will look like this:

$$\forall\varepsilon>0,\exists N\in\mathbb{N}\quad\text{as}\quad n\geq N\Rightarrow|a_n-a|<\varepsilon \tag{6.4.37}$$

where the convergence point is therefore a and we have:

$$\lim_{n\rightarrow+\infty}a_n=a \tag{6.4.38}$$

In the example of the figure below where the sequence seems to converge to 1.13 we observe that for a given non-zero positive ε, there is a particular n which we denote N ($n=17$ in the figure below) from which the sequence converges:

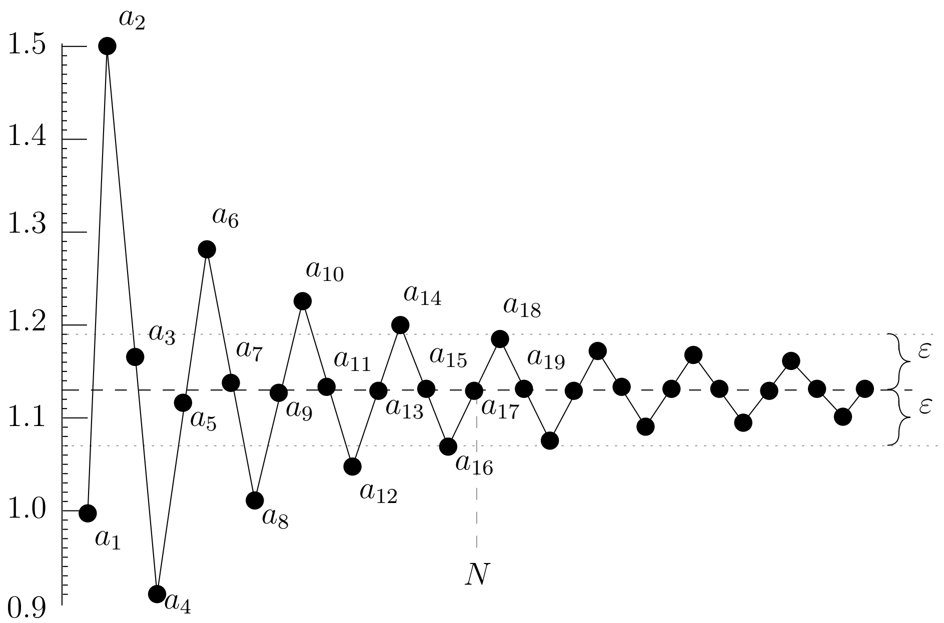

Figure 6.65: **Illustration of the principle of convergence of a sequence**

However, the above definition of the convergence makes problem because the number x should be known. In most cases of interest x is unfortunately not known. To break this deadlock, Cauchy had the idea to propose the following definition:

Definition (#6.4.218): We say by definition that a sequence $(x_n)_{n\in\mathbb{N}}$ of elements of X is a "Cauchy sequence" if:

$$\forall\varepsilon>0, \exists N\in\mathbb{N}\,\text{such that}\,\forall m,n\geq N\,\text{we have}\,d(x_n,x_m)\leq\varepsilon \qquad (6.4.39)$$

The reader must notice that it is not sufficient for each term to become arbitrarily close to the preceding term. This is why require that $|a_{N+1}-a_N|<\varepsilon$ is not sufficient!

It is almost obvious then that any convergent sequence is a Cauchy sequence (well there are some subtleties that we will not reference for now).

Remark

This criterion therefore facilitates some proofs because it helps to show the existence of a limit without involving its value, generally unknown.

Theorem 6.18. Let us now prove that theorem that asses that any convergent sequence is a Cauchy sequence.

Proof 6.18.1. Consider a sequence u_n converging to the value l (which is unknown to us) and $\varepsilon>0$ (randomly selected). Then there exists according to the definition of a convergent sequence, $n\in\mathbb{N}$ such that:

$$n\geq N\Rightarrow d(u_n,l)\leq\frac{\varepsilon}{2} \qquad (6.4.40)$$

The choice to write $\varepsilon/2$ is completely arbitrary but in fact we anticipate the final result of the demonstration so that it is more aesthetic...

Therefore for $p,q>N$ (in fact know the value of N is irrelevant, since it should work for any value... well don't forget that N depends on $\varepsilon/2$) we have using the triangle inequality (see section Vector Calculus page 1828):

$$d(u_p,u_q)\leq d(u_p,l)+d(l,u_q) \tag{6.4.41}$$

and because $d(u_n,l)\leq \dfrac{\varepsilon}{2}$ we can write:

$$d(u_p,u_q)\leq \frac{\varepsilon}{2}+\frac{\varepsilon}{2} \tag{6.4.42}$$

Therefore:

$$d(u_p,u_q)\leq \varepsilon \tag{6.4.43}$$

That may be a bit abstract so let's see an example with the harmonic sequence as an example to close the proof:

$$u_n=\sum_{k=1}^{n}\frac{1}{k} \tag{6.4.44}$$

First, nothing it is not forbidden to us to take $n\geq 2$ (otherwise it will be hard to make a difference between two terms...).

Therefore we take the Euclidean distance:

$$d(u_p,u_q)=d(u_{2n},u_n)=u_{2n}-u_n=\sum_{k=1}^{2n}\frac{1}{k}-\sum_{k=1}^{n}\frac{1}{k}=\sum_{k=n+1}^{2n}\frac{1}{k} \tag{6.4.45}$$

First, the reader will note that in all cases since $k\leq 2n$ is between $n+1$ and $2n$. Which brings us to write:

$$\frac{1}{k}\geq\frac{1}{2n}\qquad \forall\, n+1\leq k\leq 2n \tag{6.4.46}$$

So from this inequality it comes automatically that each term of the sum on the left below will be greater than each term of the sum on the right:

$$\sum_{k=n+1}^{2n}\frac{1}{k}\geq\sum_{k=n+1}^{2n}\frac{1}{2n} \tag{6.4.47}$$

With (just do a particular example):

$$\sum_{k=n+1}^{2n}\frac{1}{2n}=\frac{1}{2} \tag{6.4.48}$$

Therefore:

$$\sum_{k=n+1}^{2n}\frac{1}{k}\geq\frac{1}{2} \tag{6.4.49}$$

Now the idea is to see if the sum on the left is therefore greater than or equal to $\varepsilon=1/2$ and this for any n. Thus the suite is not convergent!

Thus, the idea is that we found an ε for which the Cauchy criterion is deficient.

■ Q.E.D.

So it is not because the points are always closer to each other that they converge to a given point, because this point may not exist.

The best example is probably the following (it is also a little bit stupid example but...):

✍**Example:**

Let us take $X=\mathbb{Q}$ and the absolute difference as distance:

$$d(p,q)=|p-q| \tag{6.4.50}$$

Given z an irrational number and $q_j\in\mathbb{Q}$ with $j\in\mathbb{N}^*$ such that:

$$|z-q_j|\leq\frac{1}{j} \tag{6.4.51}$$

The idea is that greater is j, more the rational number q_j is near the irrational z and we know we can find such a sequence. Let us show that the q_1,q_2 we could be able to build form a Cauchy sequence! Indeed using triangle inequality:

$$|q_m-q_n|\leq|z-q_m|-\leq|z-q_n|\leq\frac{1}{m}-\frac{1}{m} \tag{6.4.52}$$

and therefore is a Cauchy sequence if and only if $|q_m-q_n|\leq\varepsilon$ if:

$$m,n\geq\frac{1}{2\varepsilon} \tag{6.4.53}$$

We have thus found a N (equal to $\dfrac{1}{2\varepsilon}$) which satisfies our definition of a Cauchy sequence. But this sequence does not converge in $\mathbb{Q}$ otherwise z would be rational. You can check this with π and the sequence:

$$\begin{array}{ll}
q_1=\dfrac{3}{1}=3 & |\pi-q_1|\cong 0.141592\leq\dfrac{1}{1}\\
q_2=\dfrac{13}{4}=3.25 & |\pi-q_1|\cong 0.108407\leq\dfrac{1}{2}\\
q_3=\dfrac{19}{6}=3.1\bar{6} & |\pi-q_3|\cong 0.02507401\leq\dfrac{1}{3}\\
q_4=\dfrac{22}{7}=3.1428571428571428 & |\pi-q_4|\cong 0.001264489267\leq\dfrac{1}{4}\\
\ldots &
\end{array} \tag{6.4.54}$$

Remark

Mathematicians use such results to define the set of irrational and also by using some additional topological concepts.

We have just seen that a Cauchy sequence is not necessarily a convergent sequence in X. The inverse is however true: any convergent sequence is a Cauchy sequence!!

6.4.1.5 Fibonacci Sequence

If we calculate a sequence of numbers starting with 0 and 1, such that each term is equal to the sum of the two previous ones, we can form the following sequence:

$$0,1,1,2,3,5,8,13,21,34,55,89,144,\ldots \tag{6.4.55}$$

therefore, if we designate the different terms by:

$$u_0,u_1,u_2,\ldots \tag{6.4.56}$$

We build therefore the following sequence law:

$$u_{n+2}=u_n+u_{n+1} \tag{6.4.57}$$

More often written in the following form:

$$\boxed{F_{n+2}=F_n+F_{n+1}} \tag{6.4.58}$$

The Fibonacci sequence has many interesting strong properties, which will be developed later. However, it seems to be the first "recurring sequence" known in history (hence the fact that we are talking about it in this textbook).

The origin of this sequence seem to come from a rabbit problem asked to Fibonacci in 11202 (holocene calendar). Starting with a couple of rabbits, how much couples of rabbits will we get after a given number of months knowing that each pair produces a new pair every month (and no couples die...), which becomes productive only after two months. Therefore we have:

- Beginning: We have nothing (0)
- 1st month: We buy a couple of baby rabbits (1).
- 2nd month: The couple of rabbits are now adults (1).
- 3rd month: We have the couple of rabbits that make a new couple of baby rabbits. We have two couples (2).
- 4th month: We have two couple of adults with a new couple of babies. We have three couples (3).
- 5th month: We have three couples of adults rabbits and two new couples of baby rabbits. We have five couples (5)
- and so on...

Let us take now a "in real life" example (this is typically a biased scientific example because you will always finish to find in Nature what your are looking for to argue your theories with a least on particular example...): the heart of some flowers! The scales of a pineapple or pinecone form two families of spirals wound in opposite directions. On a pine cone, you will count 5 spiral in one direction and 8 in the other, on pineapples, 8 and 13, on sunflowers 21 and 34. Each time we get Fibonacci numbers!

A famous illustration of this is to do draw the following simple figure (named"Fibonacci Spiral") which reproduces the Fibonacci numbers on a grid plan with squares and corners connect with arc circles:

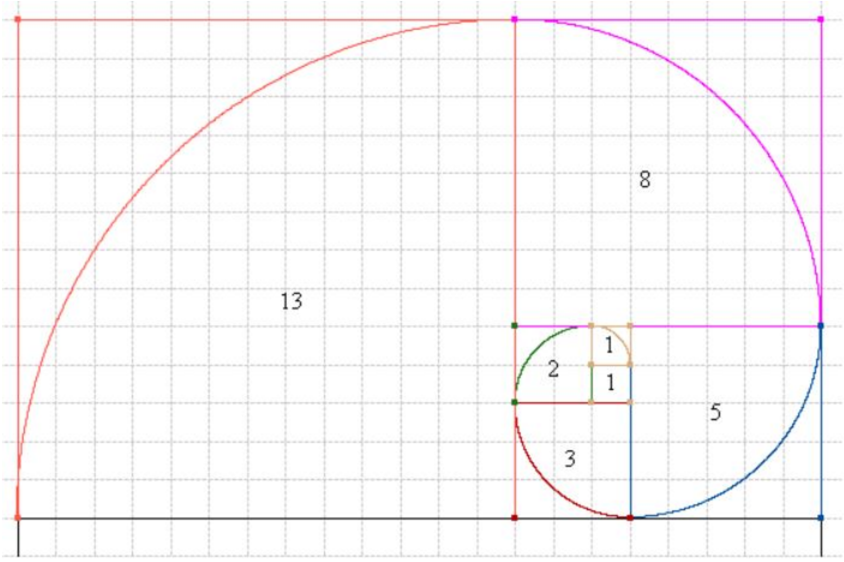

Figure 6.66: **Fibonacci spiral**

Remark

The Fibonacci spiral (quarter-circles tangent to the interior of each square) must not be confused with the "Golden Spiral" (a logarithmic spiral whose growth factor is the Golden ratio φ)!

Let us now consider the limit of the Fibonacci sequence, let:

$$\lim_{n\to+\infty}\frac{F_n}{F_{n-1}}=L \qquad (6.4.59)$$

by the properties of limits:

$$\lim_{n\to+\infty}\frac{F_n}{F_{n-1}}=\lim_{n\to+\infty}\frac{F_{n+1}}{F_n}=L \qquad (6.4.60)$$

As the construction of the Fibonacci sequence is given by:

$$F_{n+1}=F_n+F_{n-1} \qquad (6.4.61)$$

Using this equation to substitute, we get:

$$\lim_{n\to+\infty}\frac{F_{n+1}}{F_n}=\lim_{n\to+\infty}\frac{F_n+F_{n-1}}{F_n}=1+\frac{1}{L} \qquad (6.4.62)$$

and so we get the equivalent well known equation (see page 1389):

$$1+\frac{1}{L}=L\Leftrightarrow L^2-L-1=0 \tag{6.4.63}$$

and finally solving for L using the quadratic formula yields to (by keeping the only solution that makes sense):

$$\boxed{\lim_{n\rightarrow+\infty}\frac{F_n}{F_{n-1}}=L=\frac{1+\sqrt{5}}{2}=\varphi} \tag{6.4.64}$$

that is the "Golden ratio"!

We will come back later (see page 1783) on this sequence to prove another relation it has with the Golden ratio (see page 1389) through the direct determination of the n term value!

6.4.1.6 Logic Sequences/Psychologist Sequences

Definition (#6.4.219): Psychologists name "logical sequences", sequences that they write with an idea in mind, and they name "logical" people who find their idea, although there are other possibilities mathematically speaking (but psychologist don't know anything about real logic).

For example if you have to find the next number X to the logic sequence:

$$4,5,10,50,400,3500,X \tag{6.4.65}$$

In fact, you make the difference between the last and prior-previous number then you multiply by 10 therefore the next number is $X=(3500-400)\cdot 10=31000$.

From a mathematical point of view, any number is suitable to replace X, also exists for each value of X, a polynomial in n that takes the values $4,5,10,50,400,3500$ for $n=0,1,2\ldots,6$.

For the example above we can take for example:

$$P(n)=-\frac{1}{120}(x-6)(2646x^5-25735x^4+88490x^3-124945x^2+59584x+80) \tag{6.4.66}$$

and is such that $P(0)=4,P(1)=5,P(2)=10,\ldots,P(6)=0$.

6.4.2 Series

The physicists often needs to simply and formally solve problems, to approximate some given "terms" of their equations. For this purpose, they will use the properties of some given series. Also statisticians and financial analysts often face to series they need to simplify.

Definition (#6.4.220): Let be given an infinite number sequence:

$$u_1, u_2, u_3, \ldots, u_n, \ldots \tag{6.4.67}$$

The expression:

$$u_1 + u_2 + u_3 + \ldots + u_n + \ldots \tag{6.4.68}$$

is named a "numeric series".

Definition (#6.4.221): The partial sum of the first n terms of the series is named "partial sum" and denoted by:

$$\boxed{S_n = u_1 + u_2 + u_3 + \ldots + u_n} \tag{6.4.69}$$

If the following limit denoted S exists and is finite:

$$S = \lim_{n \to +\infty} S_n \tag{6.4.70}$$

we name it "sum of the series" and we say that then that the series is a "convergent series" (it is therefore a Cauchy series!). However, if the limit does not exist, we say that the series is a "divergent series" and has no sum (for details see further below when we will deal with some empirical convergence criteria).

Theorem 6.19. Also let us prove for fun (because it is almost trivial) that if $\sum\limits_{k \geq 0} u_k$ is a convergent numerical series then:

$$\lim_{k \to +\infty} u_k = 0 \tag{6.4.71}$$

But the opposite is not necessarily true!! In fact remember the example during our study above of Cauchy sequences with the harmonic series $\sum_{k=1}^{n} \dfrac{1}{k}$ that is not convergent even if the terms tends to zero when $k \to +\infty$.

Proof 6.19.1. We assume first that $\sum\limits_{k \geq 0} u_k$ is a convergent series and denote its limit by S. Let:

$$S_n = \sum_{k=0}^{n} u_k \qquad S_{n-1} = \sum_{k=0}^{n-1} u_k \tag{6.4.72}$$

Therefore:

$$S_n - S_{n-1} = u_n \tag{6.4.73}$$

However, if the series is really convergent:

$$\lim_{n \to +\infty} S_n = \lim_{n \to +\infty} S_{n-1} = S \tag{6.4.74}$$

So finally:

$$\lim_{n \to +\infty} S_n - \lim_{n \to +\infty} S_{n-1} = \lim_{n \to +\infty} (S_n - S_{n-1}) = \lim_{n \to +\infty} u_n = S - S = 0 \tag{6.4.75}$$

■ Q.E.D.

Following a reader request, let us prove in detail (not only assuming that it is intuitive) that the harmonic series:

$$H=\sum_{n=1}^{+\infty}\frac{1}{n}=1+\frac{1}{2}+\frac{1}{3}+\frac{1}{4}+\frac{1}{5}+\frac{1}{6}+\frac{1}{7}+\frac{1}{8}+\ldots \tag{6.4.76}$$

diverges.

Proof 6.19.2. Suppose the series converges to H, i.e.:

$$H=1+\frac{1}{2}+\frac{1}{3}+\frac{1}{4}+\frac{1}{5}+\frac{1}{6}+\frac{1}{7}+\frac{1}{8}+\ldots \tag{6.4.77}$$

Then:

$$H\geq 1+\frac{1}{2}+\underbrace{\frac{1}{4}+\frac{1}{4}}+\underbrace{\frac{1}{6}+\frac{1}{6}}+\underbrace{\frac{1}{8}+\frac{1}{8}}+\ldots \tag{6.4.78}$$

Calculating the underbraces, we get:

$$H\geq 1+\frac{1}{2}+\frac{1}{2}+\frac{1}{3}+\frac{1}{4}+\ldots=\frac{1}{2}+1+\frac{1}{2}+\frac{1}{3}+\frac{1}{4}+\ldots=\frac{1}{2}+H \tag{6.4.79}$$

This contradiction concludes the proof.

■ Q.E.D.

Remark

Many people are struggling understanding intuitively why the harmonic series diverges but the p-harmonic series converges. For sure there are methods and applications to prove convergence and divergence, but many people have trouble understanding intuitively why it is. We know we must never trust too much or intuition, but this is hard for many to grasp. In both cases, the terms of the series are getting smaller, hence are approaching zero, but they both result in different answers!

$$\begin{aligned}\sum_{n=1}^{+\infty}\frac{1}{n}&=1+\frac{1}{2}+\frac{1}{3}+\frac{1}{4}+\cdots=\text{diverges}\\ \sum_{n=1}^{+\infty}\frac{1}{n^2}&=1+\frac{1}{2^2}+\frac{1}{3^2}+\frac{1}{4^2}+\cdots=\text{converges}\end{aligned} \tag{6.4.80}$$

Perhaps a convincing way is to make an analytical prolongation to change the sum into an integral (see section Differential and Integral Calculus page 1534):

$$\int_1^{+\infty}\frac{1}{x^2}\mathrm{d}x=-\frac{1}{x}\bigg|_1^{+\infty}=-\frac{1}{+\infty}+1=1 \tag{6.4.81}$$

converges but:

$$\int_{1}^{+\infty} \frac{1}{x}\mathrm{d}x = \ln(x)\Big|_{1}^{+\infty} = +\infty \qquad (6.4.82)$$

In the next subsection we will see how to calculate the partial sum of some classic series that are important in physics, statistics and finance. We will start with Gauss arithmetic series that are an expression of the sum of the n first non-zero integers raised to a given power k in a condensed form. The application of this condensed form of a series has an important practical use in physics, statistics and finance when we wish to simplify the expression of certain results.

6.4.2.1 Gauss Series

Gauss arithmetic series are an expression of the sum of the n first non-zero integers raised to a given power k in a condensed form S_k. The application of this condensed form of a series has an important practical use in physics, statistics and finance when we wish to simplify the expression of certain results.

It is said that Gauss have found an attractive method in 11786 (holocene calendar) to determine the arithmetic sum of the first n integers at the power of 1 when he was nine years old (...):

$$\begin{array}{rl} S_1 = & 1+2+3+\ldots+(n-1)+n \\ +S_1 = & n+(n-1)+(n-2)+\ldots+2+1 \\ \hline 2S_1 = & (n+1)+(n+1)+(n+1)+\ldots+(n+1)+(n+1) \end{array} \qquad (6.4.83)$$

After simplifying we find easily the following closed formula (notice that this is not a recursive relation!):

$$\boxed{S_n = \frac{n(n+1)}{2}} \qquad (6.4.84)$$

for $n \geq 0$. Let us indicate that each intermediate sum of the series (1, 3, 6, 10, 15, etc.) is named "triangular number" since it is possible to represent it in the following way:

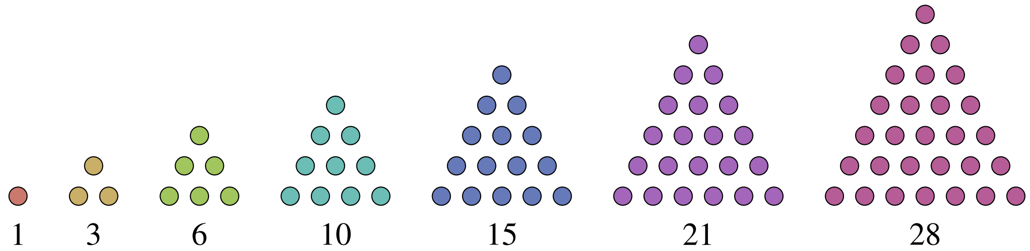

Figure 6.67: **Triangular numbers (author: Lauren K. Williams)**

We can continue with higher powers but not as exercises because these relations are very useful!

Now let us calculate the very important case that we find ourselves in a number of other sections (Economy, Quantum Wave Physics, Industrial Engineering, etc.) and that is the sum of the first n square integer numbers (still non-zero!).

Let us write for this:

$$\begin{aligned}S_1&=1+2+3+\ldots+n\\S_2&=1^2+2^2+3^2+\ldots+n^2\end{aligned}\qquad(6.4.85)$$

We know from Newton's binomial theorem (see section Calculus page 1364):

$$(k+1)^3-k^3=3k^2+3k+1\qquad(6.4.86)$$

So we can write and add member to member the n following equalities:

$$\begin{array}{r}2^3-1^3=3\cdot 1^2+3\cdot 1+1\\3^3-2^3=3\cdot 2^2+3\cdot 2+1\\4^3-3^3=3\cdot 3^2+3\cdot 3+1\\\ldots\qquad\qquad\\(n+1)^3-n^3=3n^3+3n+1\\\hline(n+1)^3-1=3(1^2+2^2+\ldots+n^2)+3(1+2+\ldots+n)+n\end{array}\qquad(6.4.87)$$

And the sum can be simplified as:

$$(n+1)^3-1=3S_2+3S_1+1n\qquad(6.4.88)$$

After some elementary algebra manipulations we get:

$$\begin{aligned}3S_2&=(n+1)^3-1-3S_1-n=(n+1)^3-1-3\frac{n(n+1)}{2}-n\\&=(n+1)^3-(n+1)-3\frac{n(n+1)}{2}=\frac{n(n+1)}{2}\left[2(n+1)^2-2-3n\right]\end{aligned}\qquad(6.4.89)$$

Therefore:

$$S_2=\frac{n(n+1)}{6}\left[2n^2+4n+2-2-3n\right]=\frac{n+1}{6}(2n^2+n)\qquad(6.4.90)$$

Finally:

$$\boxed{S_2=\frac{n(n+1)(2n+1)}{6}}\qquad(6.4.91)$$

We continue with the sum of the first n cubes (non-zero) integers. The principle is the same as before, we write:

$$\begin{aligned}S_1&=1+2+\ldots+n\\S_2&=1^2+2^2+\ldots+n^2\\S_3&=1^3+2^3+\ldots+n^3\end{aligned}\qquad(6.4.92)$$

We know from Newton's binomial theorem (see section Calculus page 1364):

$$(k+1)^4-k^4=4k^3+6k^2+4k+1\qquad(6.4.93)$$

We get by varying k from 1 to n, n relations that we can add a member to member:

$$\begin{array}{l} 2^4-1^4=4\cdot 1^3+6\cdot 1^2+4\cdot 1+1 \\ 3^4-2^4=4\cdot 2^3+6\cdot 2^2+4\cdot 2+1 \\ \quad\ldots \\ \underline{(n+1)^4-n^4=4n^3+6n^2+4n+1 \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad} \\ (n+1)^4-1=4(1^3+2^3+\ldots+n^3)+6(1^2+2^2+\ldots+n^2)+4(1+2+\ldots+n)+n \end{array} \tag{6.4.94}$$

And the sum can be simplified as:

$$(n+1)^4-1^4=4S_3+6S_2+4S_1+n \tag{6.4.95}$$

Giving after development:

$$(n+1)^4-1^4=4S_3+6\frac{n(n+1)(2n+1)}{6}+4\frac{n(n+1)}{2}+n \tag{6.4.96}$$

And after a first simplification:

$$(n+1)^4-1^4=4S_3+n(n+1)(2n+1)+2n(n+1)+n \tag{6.4.97}$$

And a second simplification:

$$\begin{aligned} 4S_3&=-n(n+1)(2n+1)-2n(n+1)-n+(n+1)^4-1\\ &=-\left((n^2+n)(2n+1)\right)-(2n^2+2n)-n+(n^4+4n^3+6n^2+4n+1)-1\\ &=-(2n^3+n^2+2n^2+n)+n^4+4n^3+4n^2+n\\ &=n^4+2n^3+n^2=n^2(n^2+2n+1)=n^2(n+1)^2 \end{aligned} \tag{6.4.98}$$

The result is therefore:

$$S_3=\left(\frac{n(n+1)}{2}\right)^2 \tag{6.4.99}$$

or written differently:

$$\boxed{S_3=\frac{n^2(n+1)^2}{4}} \tag{6.4.100}$$

For sure, we can continue like this during a long time, but from a certain value of the power things get a bit more complicated (furthermore the method is a little bit boring). Thus, one of the members of the Bernoulli family (it was a family of very talented mathematicians... as you can see int the Biographies chapter) founded a general relation working for any power by defining what we name the "Bernoulli polynomial" (see further below).

Let us conclude with a last case that we will need during our study of Fourier series. We put:

$$S_n=x+x^3+x^5+\ldots+x^{2n-1} \tag{6.4.101}$$

We want express this expression (series) as rational fraction. To do this, we multiply all by x^2. So we have two expressions:

$$\begin{aligned} S_n&=x+x^3+x^5+\ldots+x^{2n-1}\\ x^2S_n&=x^3+x^5+x^7+\ldots+x^{2n+1} \end{aligned} \tag{6.4.102}$$

We subtract the first from the second:

$$S_n(x^2-1)=x^{2n+1}-x \tag{6.4.103}$$

Finally:

$$\boxed{S_n=\frac{x^{2n+1}-x}{x^2-1}} \tag{6.4.104}$$

Most of times, to indicate that this is for odd powers we prefer to write:

$$S_{2n+1}=\frac{x^{2n+1}-x}{x^2-1} \tag{6.4.105}$$

Similarly, for the needs of the section of Economy, we have:

$$\begin{aligned}S_n&=1+x^2+x^4+\ldots+x^{2n}\\ x^2S_n&=x^2+x^4+x^6+\ldots+x^{2n+2}\end{aligned} \tag{6.4.106}$$

Therefore:

$$S_n(1-x^2)=1-x^{2n+2} \tag{6.4.107}$$

Finally:

$$\boxed{S_n=\frac{1-x^{2n+2}}{1-x^2}} \tag{6.4.108}$$

Most of times, to indicate that this is for even powers we prefer to write:

$$S_{2n}=\frac{1-x^{2n+2}}{1-x^2} \tag{6.4.109}$$

6.4.2.1.1 Bernoulli's Numbers and Polynomials

As we have seen above, it is possible to express the sum of the first n non-zero integers to a given power (the first four have been proved previously) following the below relations where we put now $n:=n+1$ as we want now n to be the number of terms for which we want the sum including 0 (hence the negative sign in the relations below that we did not have earlier):

$$\begin{aligned}&S_0=n\\ &S_1=\frac{1}{2}n^2-\frac{1}{2}n=\frac{n(n-1)}{2}\\ &S_2=\frac{1}{3}n^3-\frac{1}{2}n^2+\frac{1}{6}n=\frac{n(n-1)(2n-2)}{6}\\ &S_3=\frac{1}{4}n^4-\frac{1}{2}n^3+\frac{1}{4}n^2=\frac{n^2(n-1)^2}{4}\\ &S_4=\frac{1}{5}n^5-\frac{1}{2}n^4+\frac{1}{3}n^3-\frac{1}{30}n=\frac{n(n-1)(2n-1)(3n^2-3n-1)}{30}\\ &S_5=\frac{1}{6}n^6-\frac{1}{2}n^5+\frac{5}{12}n^4-\frac{1}{12}n^2=\frac{n^2(2n^2-2n-1)(n-1)^2}{12}\\ &\quad\ldots\end{aligned} \tag{6.4.110}$$

It is said that Jacob Bernoulli then noticed that the polynomials S_p had the form:

$$S_p=\frac{1}{p+1}n^{p+1}-\frac{1}{2}n^p+\frac{p}{12}n^{p-1}+0\cdot n^{p-2}+\ldots \tag{6.4.111}$$

In this expression, the numbers $(1,-1/2,1/12,0,\ldots)$ seem not to depend on p. More generally, after trial and error we see that the polynomial can be written as:

$$\begin{aligned}S_p(n)&=\sum_{k=0}^{p}\frac{B_k}{k!}\frac{p!}{(p+1-k)!}n^{p+1-k}=\frac{1}{p+1}\sum_{k=0}^{p}C_k^{p+1}n^{p+1-k}\\&=\frac{B_0}{0!}\frac{n^{p+1}}{p+1}+\frac{B_1}{1!}n^p+\frac{B_2}{2!}pn^{p-1}+\frac{B_3}{3!}p(p-1)n^{p-2}+\ldots+\frac{B_p}{1!}n\end{aligned} \tag{6.4.112}$$

Giving by identification the "Bernoulli's numbers":

$$B_0=1,B_1=-\frac{1}{2},B_2=\frac{1}{6},B_3=0,\ldots \tag{6.4.113}$$

Theorem 6.20. Thereafter, it seems that mathematicians in their research fell randomly (???) on the fact that the Bernoulli numbers could be expressed by the series:

$$G(z)=\frac{z}{e^z-1}=\sum_{k=0}^{+\infty}B_k\frac{z^k}{k!} \tag{6.4.114}$$

with $|z|<2\pi$. In other words, the generating function of Bernoulli numbers would be $G(z)$. If we expand the first terms of this series:

$$G(z)=\left(\frac{e^z-1}{z}\right)^{-1}=\left(1+\frac{z}{2!}+\frac{z^2}{3!}+\frac{z^3}{4!}+\ldots\right)^{-1}=1-\frac{z}{2}+\frac{z^2}{12}-\frac{z^4}{720}+\frac{z^6}{30240}-\frac{z^8}{1209600}+\ldots \tag{6.4.115}$$

Proof 6.20.1. We have seen during our study of complex numbers (see section Numbers page 251) that:

$$e^z=1+\frac{z}{1!}+\frac{z^2}{2!}+\ldots \tag{6.4.116}$$

Therefore:

$$G(z)=\left(\frac{z+\dfrac{z^2}{2!}+\dfrac{z^3}{3!}+\ldots}{z}\right)^{-1}=\left(1+\frac{z}{2!}+\frac{z^2}{3!}+\ldots\right)^{-1} \tag{6.4.117}$$

Let us write now:

$$G(z):=a_0+a_1z+a_2z^2+\ldots \tag{6.4.118}$$

Then we must have:

$$\begin{aligned}G(z)\frac{1}{G(z)}&=(a_0+a_1z+a_2z^2+\ldots)\frac{1}{\left(1+\dfrac{z}{2!}+\dfrac{z^2}{3!}+\ldots\right)^{-1}}\\&=(a_0+a_1z+a_2z^2+\ldots)\left(1+\frac{z}{2!}+\frac{z^2}{3!}+\ldots\right)=1\end{aligned} \tag{6.4.119}$$

We see (by distributing) that:

$$(a_0+a_1z+a_2z^2+\ldots)\left(1+\frac{z}{2!}+\frac{z^2}{3!}+\ldots\right)=a_0+\left(a_1+\frac{a_0}{2!}\right)z+\left(a_2+\frac{a_1}{2!}+\frac{a_0}{3!}\right)z^2+\ldots \tag{6.4.120}$$

for all this to be equal to unity we must have:

$$\begin{aligned} a_0&=1\\ a_1+\frac{a_0}{2!}&=0\\ a_2+\frac{a_1}{2!}+\frac{a_0}{3!}&=0\\ &\ldots \end{aligned} \tag{6.4.121}$$

From the second equation we get:

$$a_1=-\frac{1}{2} \tag{6.4.122}$$

and from the third equation we get:

$$a_2=-\frac{1}{6}+\frac{1}{4}=\frac{1}{12} \tag{6.4.123}$$

etc. Continuing this way we show that:

$$a_3=0,\, a_4=-\frac{1}{720},\ldots \tag{6.4.124}$$

It is obvious that this method allows us to calculate by hand only the first terms of this series.

Thus, based on (as we will see later, this is the expression of an "ordinary generating function"):

$$G(z)=\frac{z}{e^z-1}=\sum_{k=0}^{+\infty}B_k\frac{z^k}{k!} \tag{6.4.125}$$

we find that the first Bernoulli numbers are:

k	B_k
0	1
1	-1/2
2	1/6
3	0
4	-1/30
5	0
6	1/42
7	0
8	-1/30
9	0
10	5/66
11	0
12	-691/2730
13	0
14	7/6
...	...

Table 6.15: **Bernoulli numbers**

The reader will have noticed that $B_k = 0$ when k is odd and different from 1. That's why sometimes the above relation is given by (remember that 0 is an even number!):

$$G(z) = \frac{z}{e^z - 1} = \sum_{k \geq 0\,(\text{even})} B_k \frac{z^k}{k!} \tag{6.4.126}$$

■ Q.E.D.

We see easily that the values of the Bernoulli numbers can not be described in a simple way. In fact, they are essentially values of the zeta Riemann function (see below page 1682) for negative integer values of the variable, and these numbers are associated with profound theoretical properties that go beyond the study of this textbook. Furthermore, the Bernoulli numbers also appear in the Taylor series expansion of circular and hyperbolic trigonometric tangent functions in the Euler-Maclaurin formula (see below).

With a small modification it is possible to define the "Bernoulli polynomials" $B_k(x)$ by:

$$G(z,x) = \frac{ze^{zx}}{e^z - 1} = \sum_{k=0}^{+\infty} B_k(x) \frac{z^k}{k!} \tag{6.4.127}$$

with:

$$G(z,0) = G(z) \tag{6.4.128}$$

Theorem 6.21. Furthermore, it is normally easy to observe that:

$$\frac{\partial G(z,x)}{\partial x} = z\frac{ze^{zx}}{e^z - 1} = zG(z,x) = \sum_{k=0}^{+\infty} \frac{\mathrm{d}B_k(x)}{\mathrm{d}x} \frac{z^k}{k!} \tag{6.4.129}$$

and therefore it normally easy to deduce that:

$$\sum_{k=0}^{+\infty} \frac{\mathrm{d}B_k(x)}{\mathrm{d}x} \frac{z^k}{k!} = \sum_{k=1}^{+\infty} B_{k-1}(x) \frac{z^k}{(k-1)!} \tag{6.4.130}$$

Proof 6.21.1. On one side we have:

$$zG(z,x) = z\sum_{k=0}^{+\infty} B_k(x) \frac{z^k}{k!} = \sum_{k=0}^{+\infty} B_k(x) \frac{z^{k+1}}{k!} = \sum_{k=1}^{+\infty} B_{k-1}(x) \frac{z^k}{(k-1)!} \tag{6.4.131}$$

and another we have:

$$zG(z,x) = \sum_{k=0}^{+\infty} \frac{\mathrm{d}B_k(x)}{\mathrm{d}x} \frac{z^k}{k!} \tag{6.4.132}$$

So:

$$\sum_{k=0}^{+\infty} \frac{\mathrm{d}B_k(x)}{\mathrm{d}x} \frac{z^k}{k!} = \sum_{k=1}^{+\infty} B_{k-1}(x) \frac{z^k}{(k-1)!} \tag{6.4.133}$$

■ Q.E.D.

And by identification of the coefficients we deduce:

$$\frac{\mathrm{d}B_0(x)}{\mathrm{d}x}=0 \tag{6.4.134}$$

and for $k\geq 1$:

$$\frac{\mathrm{d}B_k(x)}{\mathrm{d}x}=kB_{k-1}(x) \tag{6.4.135}$$

It is then easy to deduce that the polynomials $B_k(x)$ are of degree k:

$$\begin{aligned}
&B_0(x)=1\\
&B_1(x)=x-\frac{1}{2}\\
&B_2(x)=x^2-x+\frac{1}{6}\\
&B_3(x)=x^3-\frac{3}{2}x^2+\frac{1}{2}x\\
&B_4(x)=x^4-2x^3+x^2-\frac{1}{30}\\
&B_5(x)=x^5-\frac{5}{2}x^4+\frac{5}{3}x^3-\frac{1}{6}x\\
&\ldots
\end{aligned} \tag{6.4.136}$$

Here is a plot of these polynomials:

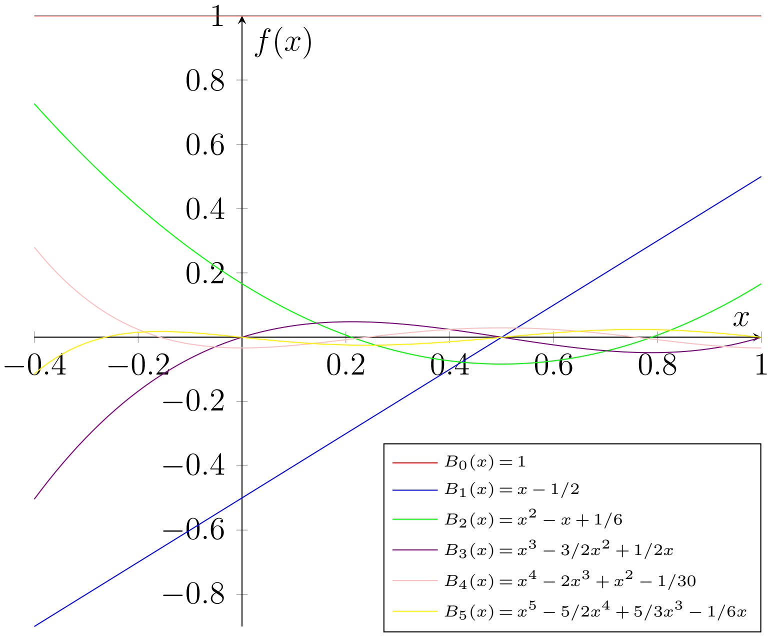

Figure 6.68: Some Bernoulli polynomials

What is remarkable is that using the Bernoulli polynomials, we see that it is possible to write the S_p as follows after some trials:

$$\boxed{S_p(n)=\sum_{k=0}^{n-1}k^p=\frac{1}{p+1}\big(B_{p+1}(n)-B_{p+1}(0)\big)} \qquad (6.4.137)$$

Some write this relations even otherwise. Indeed, from previous relation, we can write:

$$(p+1)\sum_{k=0}^{n-1}k^p=B_{p+1}(n)-B_{p+1}(0) \qquad (6.4.138)$$

using:

$$\frac{\mathrm{d}B_k(x)}{\mathrm{d}x}=kB_{k-1}(x) \qquad (6.4.139)$$

We have:

$$\begin{aligned}&\frac{\mathrm{d}B_{p+1}(x)}{\mathrm{d}x}=(p+1)B_p(x)\\ \Rightarrow &B_p(x)=\frac{1}{p+1}B'_{p+1}(x)\\ \Rightarrow &\int\limits_0^k B_p(x)\mathrm{d}x=\frac{1}{p+1}\int\limits_0^k B'_{p+1}(x)\mathrm{d}x=\frac{1}{p+1}B_{p+1}(x)\Big|_0^k=\frac{1}{p+1}\left[B_{p+1}(x)-B_{p+1}(0)\right]\end{aligned} \qquad (6.4.140)$$

So we just demonstrated in an engineer way that:

$$\boxed{S_p(n)=\sum_{k=0}^{n-1}k^p=\int\limits_0^k B_p(x)\mathrm{d}x} \qquad (6.4.141)$$

However, we can now ask ourselves what happens to the partial sum of arithmetic and geometric sequences as presented earlier in this section.

6.4.2.1.2 Euler-Maclaurin formula

The Euler–Maclaurin formula is a relation for the difference between an integral and a closely related sum. It can be used to approximate integrals by finite sums, or conversely to evaluate finite sums and infinite series using integrals and the machinery of calculus. For example, many asymptotic expansions are derived from the formula[10].

If m and n are natural numbers and $f(x)$ is a real or complex valued continuous function for real numbers x in the interval $[m,n]$, then the integral:

$$I(n)=\int\limits_m^n f(x)\mathrm{d}x \qquad (6.4.142)$$

---

[10] It will be useful to us during our study of the electromagnetic effect in the section of Wave Quantum Physics.

can be approximated by the sum (or vice versa):

$$S(n) = f(m+1) + \cdots + f(n-1) + f(n) \tag{6.4.143}$$

(see rectangle method page 6623). The Euler-Maclaurin formula provides expressions for the difference between the sum and the integral in terms of the higher derivatives $f^{(k)}(x)$ evaluated at the endpoints of the interval, that is to say when $x = m$ and $x = n$.

Explicitly, for p a positive integer and a function $f(x)$ that is p times continuously differentiable on the interval $[m,n]$, we have:

$$S(n) - I(n) = \sum_{k=1}^{p} \frac{B_k}{k!}\left(f^{(k-1)}(n) - f^{(k-1)}(m)\right) + R_p \tag{6.4.144}$$

where B_k is the k th Bernoulli number (with $B_1 = 1/2$) and R_p, is an error term which depends on n, m, p, and f and is usually small for suitable values of p. The formula is often written with the subscript taking only even values, since the odd Bernoulli numbers are zero except for B_1. In this case we have:

$$\sum_{i=m}^{n} f(i) - \int\limits_{m}^{n} f(x)\mathrm{d}x = \frac{f(n)+f(m)}{2} + \sum_{k=1}^{\lfloor p/2 \rfloor} \frac{B_{2k}}{(2k)!}\left(f^{(2k-1)}(n) - f^{(2k-1)}(m)\right) + R_p \tag{6.4.145}$$

or alternatively:

$$\sum_{i=m+1}^{n} f(i) - \int\limits_{m}^{n} f(x)\mathrm{d}x = \frac{f(n)-f(m)}{2} + \sum_{k=1}^{\lfloor p/2 \rfloor} \frac{B_{2k}}{(2k)!}\left(f^{(2k-1)}(n) - f^{(2k-1)}(m)\right) + R_p \tag{6.4.146}$$

Proof 6.21.2. One of the fundamental concepts of calculus is the correspondence between sums and integrals. Given any sufficiently well-behaved continuous function $f(x)$, consider the sum the integral defined by:

$$S(n) = \sum_{k=0}^{n} f(k) \qquad I(n) = \int\limits_{x=0}^{n} f(x)\mathrm{d}x \tag{6.4.147}$$

These two functions obviously have some similarities, but they also have significant differences. For example, the summation is taken over the values of $f(k)$ at discrete integer arguments $k = 0, 1, 2, \ldots, n$, whereas the integral is taken over the values of $f(x)$ for arguments x varying continuously from 0 to n. Strictly speaking, the function $S(n)$ is defined only for integer arguments, while $I(m)$ is defined for any non-negative real value of n. Nevertheless, we can derive an interesting and useful relation between these two functions.

First, notice that $I(n)$ can be written in the form:

$$I(n) = \int\limits_{x=0}^{1} [f(0+x) + f(1+x) + f(2+x) + \ldots + f(n-1+x)]\mathrm{d}x \tag{6.4.148}$$

The Taylor series expansion of each of the individual terms of the integrand is of the form:

$$f(k+x)=\frac{f^{(0)}(k)}{0!}+\frac{f^{(1)}(k)}{1!}x+\frac{f^{(2)}(k)}{2!}x^2+\frac{f^{(3)}(k)}{3!}x^3+\ldots \tag{6.4.149}$$

where $f^{(j)}$ denotes the jth derivative of f. The integral of this term from $x=0$ to 1 is:

$$\int\limits_{x=0}^{1} f(k+x)\mathrm{d}x=\frac{f^{(0)}(k)}{1!}+\frac{f^{(1)}(k)}{2!}+\frac{f^{(2)}(k)}{3!}+\frac{f^{(3)}(k)}{4!}+\ldots \tag{6.4.150}$$

Inserting all these expressions into the original integral, we get:

$$I(n)=\frac{S(0)}{1!}+\frac{S(1)}{2!}+\frac{S(2)}{3!}+\frac{S(3)}{4!}+\ldots \tag{6.4.151}$$

where:

$$S(j)=\sum_{k=0}^{n-1} f^{(j)}(k) \tag{6.4.152}$$

Now, if we had started with the derivative of $I(n)$ in place of simply $I(n)$ itself, we would have arrived at the same expression:

$$I(n)=\frac{S(0)}{1!}+\frac{S(1)}{2!}+\frac{S(2)}{3!}+\frac{S(3)}{4!}+\ldots \tag{6.4.153}$$

except that each $f^{(j)}$ would be replaced with $f^{(j+1)}$, and hence each $S(j)$ would be replaced with $S(j+1)$, and $I(n)$ would be replaced with $I^{(1)}(n)$ where:

$$I^{(j)}(n)=\int\limits_{x=0}^{n} f^{j}(x)\mathrm{d}x=f^{(j-1)}(n)-f^{(j-1)}(0) \tag{6.4.154}$$

Thus beginning with successively higher derivatives of f, we get the infinite sequence of relations:

$$\begin{aligned}
I^{(0)}(n)&=\frac{S(1)}{1!}+\frac{S(2)}{2!}+\frac{S(3)}{3!}+\frac{S(4)}{4!}+\ldots\\
I^{(1)}(n)&=\frac{S(2)}{1!}+\frac{S(3)}{2!}+\frac{S(4)}{3!}+\frac{S(5)}{4!}+\ldots\\
I^{(2)}(n)&=\frac{S(3)}{1!}+\frac{S(4)}{2!}+\frac{S(5)}{3!}+\frac{S(6)}{4!}+\ldots\\
&\text{etc.}
\end{aligned} \tag{6.4.155}$$

Each of these equations has (in general) infinitely many terms, but we can solve the system of equations for any finite numbers of terms by taking just a restricted portion of these equations. For example, taking just the terms up to $S(6)$ from the first four equations, we have (in matrix form):

$$\begin{bmatrix}
\frac{1}{1!} & \frac{1}{2!} & \frac{1}{3!} & \frac{1}{4!} & \frac{1}{5!} & \frac{1}{6!}\\
0 & \frac{1}{1!} & \frac{1}{2!} & \frac{1}{3!} & \frac{1}{4!} & \frac{1}{5!}\\
0 & 0 & \frac{1}{1!} & \frac{1}{2!} & \frac{1}{3!} & \frac{1}{4!}\\
0 & 0 & 0 & \frac{1}{1!} & \frac{1}{2!} & \frac{1}{3!}\\
0 & 0 & 0 & 0 & \frac{1}{1!} & \frac{1}{2!}\\
0 & 0 & 0 & 0 & 0 & \frac{1}{1!}
\end{bmatrix}
\begin{bmatrix} S(0)\\ S(1)\\ S(2)\\ S(3)\\ S(4)\\ S(5)\\ S(6) \end{bmatrix}
=
\begin{bmatrix} I^{(0)}\\ I^{(1)}\\ I^{(2)}\\ I^{(3)}\\ I^{(4)}\\ I^{(5)}\\ I^{(6)} \end{bmatrix} \tag{6.4.156}$$

Solving this system of equations gives:

$$\begin{bmatrix} S(1) \\ S(2) \\ S(3) \\ S(4) \\ S(5) \\ S(6) \end{bmatrix} = \begin{bmatrix} \frac{B_0}{0!} & \frac{B_1}{1!} & \frac{B_2}{2!} & \frac{B_3}{3!} & \frac{B_4}{4!} & \frac{B_5}{5!} \\ 0 & \frac{B_0}{0!} & \frac{B_1}{1!} & \frac{B_2}{2!} & \frac{B_3}{3!} & \frac{B_4}{4!} \\ 0 & 0 & \frac{B_0}{0!} & \frac{B_1}{1!} & \frac{B_2}{2!} & \frac{B_3}{3!} \\ 0 & 0 & 0 & \frac{B_0}{0!} & \frac{B_1}{1!} & \frac{B_2}{2!} \\ 0 & 0 & 0 & 0 & \frac{B_0}{0!} & \frac{B_1}{1!} \\ 0 & 0 & 0 & 0 & 0 & \frac{B_0}{0!} \end{bmatrix} \tag{6.4.157}$$

where:

$$B_0 = 1 \quad B_1 = -\frac{1}{2} \quad B_2 = \frac{1}{6} \quad B_3 = 0 \quad B_4 = -\frac{1}{30} \quad B_5 = 0 \quad B_6 = \frac{1}{42} \tag{6.4.158}$$

and so on are the Bernoulli numbers. Thus we have:

$$\mathrm{S}(1) = \frac{B_0}{0!}I(0) + \frac{B_1}{1!}I(1) + \frac{B_2}{2!}I(2) + \frac{B_3}{3!}I(3) + \ldots \tag{6.4.159}$$

Inserting the expressions for each $I^{(j)}$ from relation:

$$I^{(j)}(n) = \int\limits_{x=0}^{n} f^{(j)}(x)\mathrm{d}x = f^{(j-1)}(n) - f^{(j-1)}(0) \tag{6.4.160}$$

this gives:

$$S(0) = \frac{B_0}{0!}\int\limits_{x=0}^{n} f(x)\mathrm{d}x + \frac{B_1}{1!}[f(n) - f(0)] + \frac{B_2}{2!}\left[f^{(1)}(n) - f^{(1)}(0)\right] + \ldots \tag{6.4.161}$$

Recall that $S(0)$ is defined as the sum of $f(k)$ for $k = 0, 1, 2, \ldots, n-1$. Therefore, if we wish to express this in terms of a summation from $k = 0$ to n, we must add $f(n)$ to both sides. Noting that $B_1 = -1/2$, this leads to the result:

$$\boxed{\sum_{x=0}^{n} f(x) = \int\limits_{x=0}^{n} f(x)\mathrm{d}x + \frac{1}{2}[f(n) + f(0)] + \frac{B_2}{2!}[f(1)(n) - f(1)(0)] + \ldots} \tag{6.4.162}$$

This is named the "Euler-Maclaurin formula", a generalization of Bernoulli's formula for the sum of powers of the first n integers. Often used in the following form:

$$\sum_{x=0}^{n} f(x) - \int\limits_{x=0}^{n} f(x)\mathrm{d}x = \frac{1}{2}[f(n) + f(0)] + \frac{B_2}{2!}[f(1)(n) - f(1)(0)] + \ldots \tag{6.4.163}$$

or using a condensed notation:

$$S - I = \sum_{k=1}^{p} \frac{B_k}{k!}\left(f^{(k-1)}(n) - f^{(k-1)}(m)\right) + R_p \tag{6.4.164}$$

We should note that this series is divergent for most applications, but the error is less than the first neglected term, so the Euler-Maclaurin formula is often a useful method of approximation, relating the series summation to the continuous integral of a function.

■ Q.E.D.

✍**Example:**

The Bernoulli numbers from B_1 to B_7 are $1/2, 1/6, 0, -1/30, 0, 1/42, 0$. Therefore the low-order cases of the Euler-Maclaurin formula are:

$$\begin{aligned}
\sum_{i=m}^{n} f(i) - \int\limits_{m}^{n} f(x)\mathrm{d}x &= \frac{f(m)+f(n)}{2} + \int\limits_{m}^{n} f'(x)P_1(x)\mathrm{d}x \\
&= \frac{f(m)+f(n)}{2} + \frac{1}{6}\frac{f'(n)-f'(m)}{2!} - \int\limits_{m}^{n} f''(x)\frac{P_2(x)}{2!}\mathrm{d}x \\
&= \frac{f(m)+f(n)}{2} + \frac{1}{6}\frac{f'(n)-f'(m)}{2!} + \int\limits_{m}^{n} f'''(x)\frac{P_3(x)}{3!}\mathrm{d}x \\
&= \frac{f(m)+f(n)}{2} + \frac{1}{6}\frac{f'(n)-f'(m)}{2!} - \frac{1}{30}\frac{f'''(n)-f'''(m)}{4!} \\
&- \int\limits_{m}^{n} f^{(4)}(x)\frac{P_4(x)}{4!}\mathrm{d}x \\
&= \frac{f(m)!f(n)}{2} + \frac{1}{6}\frac{f'(n)-f'(m)}{2!} - \frac{1}{30}\frac{f'''(n)-f'''(m)}{4!} \\
&+ \int\limits_{m}^{n} f^{(5)}(x)\frac{P_5(x)}{5!}\mathrm{d}x \\
&= \frac{f(m)+f(n)}{2} + \frac{1}{6}\frac{f'(n)-f'(m)}{2!} - \frac{1}{30}\frac{f'''(n)-f'''(m)}{4!} \\
&+ \frac{1}{42}\frac{f^{(5)}(n)-f^{(5)}(m)}{6!} - \int\limits_{m}^{n} f^{(6)}(x)\frac{P_6(x)}{6!}\mathrm{d}x \\
&= \frac{f(m)+f(n)}{2} + \frac{1}{6}\frac{f'(n)-f'(m)}{2!} - \frac{1}{30}\frac{f'''(n)-f'''(m)}{4!} \\
&+ \frac{1}{42}\frac{f^{(5)}(n)-f^{(5)}(m)}{6!} + \int\limits_{m}^{n} f^{(7)}(x)\frac{P_7(x)}{7!}\mathrm{d}x
\end{aligned} \tag{6.4.165}$$

6.4.2.2 Arithmetic Series

We have shown above that the partial sum of a Gauss series (analogous to the sum of the terms of an arithmetic progression of reason $r = 1$) was given by:

$$S_1 = \frac{n(n+1)}{2} \tag{6.4.166}$$

If we not denote the value of the n-th term by u_n instead of n, the development that we made for the series of Gauss then brings us to:

$$S_n = \frac{n(u_n+1)}{2} \tag{6.4.167}$$

And if we denote the first term 1 of the Gauss series u_0 then we have:

$$\boxed{S_n = \frac{n(u_n+u_0)}{2}} \tag{6.4.168}$$

Which gives us simple the partial sum of the n-terms of an arithmetic sequence of reason r.

✍**Examples:**

E1. A simple Gauss series of reason 1 starting at 4, finishing at 6:

$$S_3 = 4+5+6 = \frac{n(u_n+u_0)}{2} = \frac{3(6+4)}{2} = 15 \tag{6.4.169}$$

E2. Now an arithmetic partial sum series of reason 2 starting at 4, finishing at 8:

$$4+6+8 = \frac{n(u_n+u_0)}{2} = \frac{3(8+4)}{2} = 18 \tag{6.4.170}$$

Remark

The reader will have observed that the reason r does not appear in the latter relation. Indeed, by taking (always) the same development that for the Gauss series, the term r is simplified and vanish!

6.4.2.3 Geometric Series

Similarly, with a geometrical sum where we have for recall:

$$u_n = u_0 q^n \tag{6.4.171}$$

we have therefore:

$$\begin{array}{rr} & S_n = u_0 + u_1 + \cdots + u_{n-1} + u_n \\ & qS_n = u_1 + u_2 + \cdots + u_n + u_{n+1} \\ - & \overline{s_n - qS_n = u_0 + u_1 - u_1 + u_2 - u_2 + \cdots + u_n - u_n - u_{n+1}} \end{array} \tag{6.4.172}$$

The last relation is written (after simplification):

$$S_n - qS_n = (1-q)S_n = u_0 - u_{n+1} \tag{6.4.173}$$

and if $q \neq 1$ we get:

$$S_n = \frac{u_0 - u_{n+1}}{(1-q)} \tag{6.4.174}$$

which can be written by factoring u_0:

$$\boxed{S_n = u_0 \frac{(1-q^{n+1})}{(1-q)}} \tag{6.4.175}$$

If q is positive and less than 1, as n approaches infinity we have the result that will be used extensively in the section Economy:

$$S_{n \to +\infty} \underset{q<1}{=} u_0 \frac{1}{(1-q)} \tag{6.4.176}$$

That we found often in the following form (special case):

$$S_{n \to +\infty} \underset{x<1}{=} = 1 + x + x^2 + x^3 + \ldots + x^n = \frac{1}{1-x} \tag{6.4.177}$$

✍**Examples:**

E1. Consider the following geometric series of reason $q = 2$:

$$1 \cdot 2^0 + 1 \cdot 2^1 + 1 \cdot 2^2 + 1 \cdot 2^3 + \cdots + 1 \cdot 2^n = 1 + 2 + 4 + 8 + \cdots + 2^n \tag{6.4.178}$$

to calculate the sum of the first four terms $\{1, 2, 3, 4\}$, we take the power of 2 equivalent of $n = 2$ (zero is not taken into account). We then get well: $S_3 = 15$.

E2. Consider the quite famous geometric series of reason $q = 1/2$. We then have:

$$S_n = \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \ldots = \frac{1}{2} \frac{1 - \left(\frac{1}{2}\right)^{n+1}}{1 - \frac{1}{2}} = 1 - \frac{1}{2^{n+1}} \tag{6.4.179}$$

On the request of a reader let deal with the famous case $1 = 0.99999\ldots$ whose rigorous derivation use geometric series! First let use see three naive proof of this equality.

First way that doesn't involve geometric series, we start from:

$$\frac{1}{3} = 0.33333\ldots \tag{6.4.180}$$

We multiply by 3 on both sides. That gives the obvious result (as there is no room for a number between 1 and $1 = 0.99999\ldots$):

$$1 = 0.99999\ldots \tag{6.4.181}$$

Second way that also don't involve geometric series, we start from:

$$a=0.99999\ldots \tag{6.4.182}$$

We multiply by 10 on both sides:

$$10\cdot a=9.99999\ldots \tag{6.4.183}$$

We subtract a from both sides:

$$\underbrace{10\cdot a-a}_{9a}=\underbrace{9.99999\ldots-0.99999\ldots}_{9} \tag{6.4.184}$$

Therefore:

$$\begin{gathered}9\cdot a=9\Longrightarrow a=1\\0.99999\ldots=1\end{gathered} \tag{6.4.185}$$

Finally the last naive proof still not using geometric series is a very short argument deduced from the following fact (so-named "Archimedean property of the set of real numbers"):

If two real numbers are different, then there is at least a third number between them, different from the other two. This third number can be the average between the two. Now, as we cannot insert a number between $0.99999...$ and 1; they are therefore necessarily equal.

Now that we have seen the three common naive proof, let us see the rigorous one using geometric series properties!

We know that:

$$0.99999\ldots=0.9+0.09+0.009+\ldots \tag{6.4.186}$$

We define $0.9999...$ as a geometric series, that is to say a sum in which each term is equal to the previous one multiplied by a constant, here $1/10$.

We say that it is a geometric series with a ratio of $1/10$, and we write:

$$0.99999\ldots=0.9+0.09+0.009+\ldots=\frac{9}{10}+\frac{9}{10^2}+\frac{9}{10^3}+\cdots=\sum_{k=1}^{+\infty}\frac{9}{10^k} \tag{6.4.187}$$

But using the proof of the sum of the first n terms of a geometric series, we get:

$$S_n=u_0\frac{(1-q^{n+1})}{(1-q)}=0.9\cdot\frac{1-\frac{1}{10^n}}{1-\frac{1}{10}} \tag{6.4.188}$$

Hence:

$$S_n=1-\frac{1}{10^n} \tag{6.4.189}$$

But:

$$0.9999\ldots=\lim_{n\to+\infty}S_n=\lim_{n\to+\infty}1-\frac{1}{10^n}=1 \tag{6.4.190}$$

Therefore:

$$0.99999\ldots=1 \tag{6.4.191}$$

6.4.2.3.1 Zeta function and Euler's product formula

The German mathematician Riemann named "zeta" a function already studied before him, but that he examined when the value is a complex number (see section Numbers page 243). This function is represented as a series of inverse powers of integers. This how typically the series looks like for a special case:

$$\zeta(5)=\frac{1}{1}+\frac{1}{2^5}+\frac{1}{3^5}+\cdots=\sum_{n=1}^{+\infty}\frac{1}{n^5} \tag{6.4.192}$$

This may seems to the reader as pure abstract mathematics. However as we will see in the next chapters of this textbook, this function will appear for example during our study of the Black body (Stefan-Boltzmann law), or during our study of the Casimir force in Quantum Physics, but also during our study of the recombination of the Cosmological Microwave Background.

Remarks

R1. It is traditional to denote by s the variable upon which this series depends.

R2. The Riemann zeta function is a special case of the "zeta function" defined by:

$$\zeta_A(s)=\sum_{n=1}^{+\infty}\frac{1}{a_n^s} \tag{6.4.193}$$

where $s=\Re(s)+\mathrm{i}\Im(s)=\sigma+\mathrm{i}t$ but when $a_n=n$.

This series has an interesting property but if we remain within the framework of positive integer powers here is how we can introduce its origin:

$$\frac{1}{x^0}+\frac{1}{x^1}+\cdots+\frac{1}{x^n}+\cdots=u_0\frac{(1-q^{n+1})}{(1-q)}=1\frac{1-\left(\dfrac{1}{x^{n+1}}\right)}{1-\dfrac{1}{x}} \tag{6.4.194}$$

when $n\longrightarrow+\infty$ then we have:

$$\sum_{n=0}^{+\infty}=\frac{1}{x^n}=\frac{1}{x^0}+\frac{1}{x^1}+\cdots+\frac{1}{x^n}+\cdots=\frac{1}{1-\dfrac{1}{x}} \tag{6.4.195}$$

If we put $x=2^s$, we get the sum of the inverse of powers of 2 and similarity with $x=3^s$ such that:

$$\begin{gathered}1+\frac{1}{2^s}+\frac{1}{4^5}+\frac{1}{8^5}+\cdots+\frac{1}{2^{a5}}+\cdots=\frac{1}{1-\dfrac{1}{2^5}}\\ 1+\frac{1}{3^5}+\frac{1}{9^5}+\frac{1}{27^5}+\cdots+\frac{1}{3^{b5}}+\cdots=\frac{1}{1-\dfrac{1}{3^5}}\end{gathered} \tag{6.4.196}$$

If we do the product of these two expressions, we get the sum of the powers of all fractions whose denominator is a product of 2 and 3:

$$\frac{1}{1-\dfrac{1}{2^s}}\cdot\frac{1}{1-\dfrac{1}{3^s}}=1+\frac{1}{2^s}+\frac{1}{3^s}+\frac{1}{4^s}+\frac{1}{5^s}+\frac{1}{6^s}+\cdots+\frac{1}{(2^a3^b)^s}+\cdots \tag{6.4.197}$$

If we take all primes left, we'll get on the right all integers, since every integer is the product of prime numbers according to the fundamental theorem of arithmetic (see section Number Theory page 352), and this is Euler fundamental identity: what we now name "Riemann zeta function" is both a finished product involving prime numbers and an infinite sum of inverse powers of all integers:

$$\zeta(s)=\frac{1}{1-\dfrac{1}{2^s}}\cdot\frac{1}{1-\dfrac{1}{3^s}}\cdot\frac{1}{1-\dfrac{1}{5^s}}=1+\frac{1}{2^s}+\frac{1}{3^s}+\frac{1}{4^s}+\frac{1}{5^s}+\frac{1}{6^s}+\cdots+\frac{1}{(2^a3^b5^c)^s} \tag{6.4.198}$$

In condensed notation, the "Euler's product formula" of the Riemann zeta function is given by:

$$\boxed{\zeta(s)=\sum_{n=1}^{+\infty}\frac{1}{n^s}=\prod_{p\,(\text{prime})}\frac{1}{1-\dfrac{1}{p^s}}} \tag{6.4.199}$$

where p as indicated below the product symbol are the prime numbers.

Remark

The zeta Riemann function is a special case of "Dirichlet series" that are defined by:

$$\mathfrak{D}(s)=\sum_{n=1}^{+\infty}\frac{a_n}{n^s} \tag{6.4.200}$$

When the real part of s is greater than 1, the Dirichlet series converges. On the other hand, the Dirichlet series diverges when the real part of s is less than or equal to 1, so, in particular, the series $1+2+3+4+\ldots$ that results from setting $s=-1$ does not converge!

We now recommend most readers to skip what follows on the Riemann zeta function and return back here once the Fourier series and the Gamma-Euler function presented later in this section are mastered and understood...

We assume in what follows that the Fourier series and Gamma-Euler function are known and mastered and that the Parseval's equality (see below page 1756) was studied (since it is also proved further below).

We will seek to determine first the Riemann zeta function for two positive values (s respectively having values 2 and 4) that will be useful in the valuation of integrals in some sections of the chapter about Mechanics. As the two values are positive the series converge and there won't be too many issues evaluating the Riemann zeta function[11].

Once done we will determine the value of the Riemann zeta function for any negative integer value! And here obviously the series seems to be divergent. In mathematics and theoretical physics for that kind of situation, we use the "zeta function regularization" that is a type of regularization or summability method that assigns finite values to divergent sums or products, and that in particular can be used to define determinants and traces of some self-adjoint operators. The technique is now commonly applied to problems in physics, but has its origins in attempts to give precise meanings to ill-conditioned sums appearing in Number Theory. As we will see just below and during our study of Grandi's series (see page 1691) there are several different summation methods named "zeta function regularization" for defining the sum of a possibly divergent series!

---

[11] For the section of Cosmology we should need also the value of the Riemann zeta function for $s=3$ but however the result give an irrational constant (i.e. the result cannot be written as a fraction p/q where p and q are integers) named the "Apéry's constant". There is a theorem that proves that $\zeta(3)$ is irrational named the "Apéry's theorem".

So let's start!

- To determine the value of $\zeta(2)$, we will express the function:

  $$f(x) \qquad \forall x \in [-\pi, \pi] \tag{6.4.201}$$

  in Fourier series form (see a little further below in this section at page 1727). During our study of Fourier series we will see that there are two traditional ways to define a Fourier series and we have done here the choice of the definition of the most commonly used among physicists and engineers:

  $$f(x) = \frac{a_0}{2} + \sum_{n=1}^{+\infty} (a_n \cos(nx) + b_n \sin(nx)) \tag{6.4.202}$$

  As we prove it in our study of Fourier series, Fourier coefficients a_0, a_n, b_n are obtained by solving:

  $$a_n = \frac{2}{T} \int\limits_{-T/2}^{T/2} f(x) \cos(nx) \mathrm{d}x \qquad b_n = \frac{2}{T} \int\limits_{-T/2}^{T/2} f(x) \sin(nx) \mathrm{d}x \tag{6.4.203}$$

  and using the integration by parts (see section Differential and Integral Calculus page 1532) we have:

  $$\begin{aligned}
  a_0 &= \frac{2}{T} \int\limits_{-T/2}^{+T/2} f(x) \mathrm{d}x = \frac{2}{2\pi} \int\limits_{-\pi}^{\pi} x \mathrm{d}x = \frac{1}{\pi} \int\limits_{-\pi}^{\pi} x \mathrm{d}x = \frac{1}{2\pi} \left(x^2 \big|_{-\pi}^{\pi} \right) = 0 \\
  a_n &= \frac{2}{T} \int\limits_{-T/2}^{+T/2} f(x) \cos(nx) \mathrm{d}x = \frac{2}{2\pi} \int\limits_{-\pi}^{\pi} x \cos(nx) \mathrm{d}x = \frac{1}{\pi} \left(\frac{x \sin(nx)}{n} \bigg|_{-\pi}^{\pi} - \int\limits_{-\pi}^{\pi} \frac{\sin(nx)}{n} \mathrm{d}x \right) \\
  &= \frac{1}{\pi} \left(\frac{\cos(nx)}{n^2} \bigg|_{-\pi}^{\pi} \right) \\
  b_n &= \frac{2}{T} \int\limits_{-T/2}^{+T/2} f(x) \sin(nx) \mathrm{d}x = \frac{2}{2\pi} \int\limits_{-\pi}^{\pi} x \sin(nx) \mathrm{d}x = \frac{1}{\pi} \int\limits_{-\pi}^{\pi} x \sin(nx) \mathrm{d}x \\
  &= \frac{1}{\pi} \left(-\frac{x \cos(nx)}{n} \bigg|_{-\pi}^{\pi} - \int\limits_{-\pi}^{\pi} \frac{\cos(nx)}{n} \mathrm{d}x \right) = \frac{1}{\pi} \left(-\frac{x \cos(nx)}{n} \bigg|_{-\pi}^{\pi} - \frac{\sin(nx)}{n} \bigg|_{-\pi}^{\pi} \right) \\
  &= \frac{1}{\pi} \left(-\frac{x \cos(nx)}{n} \bigg|_{-\pi}^{\pi} \right) = (-1)^{n+1} \frac{2}{n}
  \end{aligned} \tag{6.4.204}$$

It comes then:

$$f(x)=x=\frac{a_0}{2}+\sum_{n=1}^{+\infty}(a_n\cos(nx)+b_n\sin(nx))=\sum_{n=1}^{+\infty}b_n\sin(nx)=\sum_{n=1}^{+\infty}(-1)^{n+1}\frac{2}{n}\sin(nx) \tag{6.4.205}$$

But the Parseval's theorem that we will prove in our study of Fourier series a little bit further below gives us too (depending on the choice of the definition of the Fourier series and associated coefficients, the Parseval's theorem is expressed a little bit differently!):

$$f(x)=x=\sum_{n=1}^{+\infty}(-1)^{n+1}\frac{2}{n}\sin(nx)=\frac{a_0^2}{4}+\frac{1}{2}\sum_{n=1}^{+\infty}(a_n^2+b_n^2) \tag{6.4.206}$$

Therefore we get immediately:

$$f(x)=x=\sum_{n=1}^{+\infty}(-1)^{n+1}\frac{2}{n}\sin(nx)=\frac{1}{2}\sum_{n=1}^{+\infty}b_n^2=\frac{1}{2}\sum_{n=1}^{+\infty}\left((-1)^{n+1}\frac{2}{n}\right)^2=\frac{1}{2}\sum_{n=1}^{+\infty}\frac{4}{n^2}=2\sum_{n=1}^{+\infty}\frac{1}{n^2} \tag{6.4.207}$$

But we will also see during our proof of Parseval's theorem that:

$$\frac{1}{T}\int\limits_{-T/2}^{T/2}f(t)\bar{f}(t)\mathrm{d}t=\frac{a_0^2}{4}+\frac{1}{2}\sum_{n=1}^{+\infty}(a_n^2+b_n^2) \tag{6.4.208}$$

Therefore it comes in our case:

$$\frac{1}{2\pi}\int\limits_{-\pi}^{\pi}x^2\mathrm{d}x=2\sum_{n=1}^{+\infty}\frac{1}{n^2} \tag{6.4.209}$$

Therefore:

$$\frac{1}{2\pi}\frac{x^3}{3}\bigg|_{-\pi}^{\pi}=2\sum_{n=1}^{+\infty}\frac{1}{n^2}\Rightarrow\frac{1}{2\pi}\left[\frac{\pi^3}{3}-\frac{(-\pi)^3}{3}\right]=2\sum_{n=1}^{+\infty}\frac{1}{n^2}\Rightarrow\frac{\pi^3}{3\pi}=2\sum_{n=1}^{+\infty}\frac{1}{n^2} \tag{6.4.210}$$

and finally:

$$\zeta(2)=\sum_{n=1}^{+\infty}\frac{1}{n^2}=\frac{\pi^2}{6} \tag{6.4.211}$$

The problem of finding the value this series converges to is known as the "Basel problem". Leonhard Euler found the solution in 11735 (holocene calendar)...

- To determine the value of $\zeta(4)$, we will do the same, but with the function:

$$f(x)=x^2 \qquad \forall x\in[-\pi,+\pi] \tag{6.4.212}$$

in the form of Fourier series:

$$f(x)=x^2=\frac{a_0}{2}+\sum_{n=1}^{+\infty}(a_n\cos(nx)+b_n\sin(nx)) \tag{6.4.213}$$

For this purpose, we will calculate Fourier coefficients using the integration by parts (see section Differential and Integral Calculus page 1532).

Then we have:

$$\begin{aligned}
a_0&=\frac{2}{T}\int\limits_{-T/2}^{+T/2} f(x)\mathrm{d}x=\frac{2}{2\pi}\int\limits_{-\pi}^{\pi}x^2\mathrm{d}x=\frac{1}{3\pi}\left(x^3|_{-\pi}^{\pi}\right)=\frac{2\pi^2}{3}\\
a_n&=\frac{2}{T}\int\limits_{-T/2}^{+T/2} f(x)\cos(nx)\mathrm{d}x=\frac{2}{2\pi}\int\limits_{-\pi}^{\pi}x^2\cos(nx)\mathrm{d}x=\frac{1}{\pi}\left(\frac{x^2\sin(nx)}{n}\Bigg|_{-\pi}^{\pi}-\int\limits_{-\pi}^{\pi}-2x\frac{\sin(nx)}{n}\mathrm{d}x\right)\\
&=-\frac{2}{\pi n}\left(-x\frac{\cos(nx)}{n}\Bigg|_{-\pi}^{\pi}+\frac{\sin(nx)}{n^2}\Bigg|_{-\pi}^{\pi}\right)=\frac{2}{\pi n}x\frac{\cos(nx)}{n}\Bigg|_{-\pi}^{\pi}=(-1)^{n+1}\frac{4}{n^2}\\
b_n&=\frac{2}{T}\int\limits_{-T/2}^{+T/2} f(x)\sin(nx)\mathrm{d}x=\frac{2}{2\pi}\int\limits_{-\pi}^{\pi}x^2\sin(nx)\mathrm{d}x=\frac{1}{\pi}\int\limits_{-\pi}^{\pi}x^2\sin(nx)\mathrm{d}x\\
&=\frac{1}{\pi}\left(-x^2\frac{\cos(nx)}{n}\Bigg|_{-\pi}^{\pi}+\int\limits_{-\pi}^{\pi}2x\frac{\cos(nx)}{n}\mathrm{d}x\right)=\frac{2}{\pi n}\left(x\frac{\sin(nx)}{n}\Bigg|_{-\pi}^{\pi}+\int\limits_{-T/2}^{+T/2}\frac{\sin(nx)}{x}\mathrm{d}x\right)\\
&=-\frac{2}{\pi n}\left(\int\limits_{-T/2}^{+T/2}\frac{\sin(nx)}{x}\mathrm{d}x\right)=-\frac{2}{\pi n^2}\left(\frac{-\cos(nx)}{n}\Bigg|_{-\pi}^{\pi}\right)=0
\end{aligned}\tag{6.4.214}$$

Therefore we have:

$$f(x)=x^2=\frac{a_0}{2}+\sum_{n=1}^{+\infty}a_n\cos(nx)=\frac{\pi^2}{3}+\sum_{n=1}^{+\infty}(-1)^{n+1}\frac{4}{n^2}\cos(nx)\tag{6.4.215}$$

But the Parseval's theorem that we will prove below gives us also:

$$f(x)=x^2=\frac{\pi^2}{3}+\sum_{n=1}^{+\infty}(-1)^{n+1}\frac{4}{n^2}\cos(nx)=\frac{a_0^2}{4}+\frac{1}{2}\sum_{n=1}^{+\infty}(a_n^2+b_n^2)\tag{6.4.216}$$

It then comes immediately:

$$f(x)=x^2=\frac{\pi^2}{3}+\sum_{n=1}^{+\infty}(-1)^{n+1}\frac{4}{n^2}\cos(nx)=\frac{\pi^2}{9}+8\sum_{n=1}^{+\infty}\frac{1}{n^4}=\frac{\pi^4}{9}+8\zeta(4)\tag{6.4.217}$$

But we will see also see later below during our Parseval's theorem proof that:

$$\frac{1}{T}\int\limits_{-T/2}^{+T/2}f(t)\bar{f}(t)\mathrm{d}t=\frac{a_0^2}{4}+\frac{1}{2}\sum_{n=1}^{+\infty}(a_n^2+b_n^2)\tag{6.4.218}$$

Then it comes in our case:

$$\frac{1}{2\pi}\int\limits_{-\pi}^{+\pi}x^4\mathrm{d}x=\frac{\pi^4}{9}+8\zeta(4)\tag{6.4.219}$$

Therefore:

$$\frac{1}{2\pi}\frac{x^5}{5}\bigg|_{-\pi}^{\pi}=\frac{\pi^4}{9}+8\zeta(4)\Rightarrow\frac{1}{2\pi}\left[\frac{\pi^5}{5}-\frac{(-\pi)^5}{5}\right]=\frac{\pi^4}{9}+8\zeta(4) \tag{6.4.220}$$

That is to say:

$$\frac{\pi^4}{5}-\frac{\pi^4}{9}=8\zeta(4)\Rightarrow\frac{9\pi^4}{45}-\frac{5\pi^4}{45}=8\zeta(4)\Rightarrow\frac{4\pi^4}{45}=8\zeta(4) \tag{6.4.221}$$

Finally:

$$\zeta(4)=\sum_{n=1}^{+\infty}\frac{1}{n^4}=\frac{\pi^4}{90} \tag{6.4.222}$$

- Now let us focus on the first divergent case $\zeta(-1)$.

  There are a few ways to prove that:

$$\zeta(s=-1)=\sum_{n=1}^{+\infty}\frac{1}{n^{-1}}=\sum_{n=1}^{+\infty}n=1+2+3+\ldots=-\frac{1}{12} \tag{6.4.223}$$

  One method, along the lines of Euler's reasoning, uses the relationship between the Riemann zeta function and what we define as the "Dirichlet eta function" or "alternating zeta function[12]":

$$\eta(s)=\sum_{n=1}^{+\infty}\frac{(-1)^{n-1}}{n^s}=\frac{1}{1^s}-\frac{1}{2^s}+\frac{1}{3^s}-\frac{1}{4^s}+\cdots \tag{6.4.224}$$

  This Dirichlet series is the alternating sum corresponding to the Dirichlet series expansion of the Riemann zeta function, $\zeta(s)$.

  Where both Dirichlet series converge, one has the identities:

$$\begin{aligned}\zeta(s)&=1^{-s}+2^{-s}+3^{-s}+4^{-s}+5^{-s}+6^{-s}+\cdots\\ 2\cdot2^{-s}\zeta(s)&=\phantom{1^{-s}+{}}2\cdot2^{-s}\phantom{+3^{-s}}+2\cdot4^{-s}\phantom{+5^{-s}}+2\cdot6^{-s}+\cdots\\ \left(1-2^{1-s}\right)\zeta(s)&=1^{-s}-2^{-s}+3^{-s}-4^{-s}+5^{-s}-6^{-s}+\cdots=\eta(s)\end{aligned} \tag{6.4.225}$$

  The identity$(1-2^{1-s})\zeta(s)=\eta(s)$ continues to hold when both functions are extended by analytic continuation to include values of s for which the above series diverge. Substituting $s=-1$, one gets $-3\zeta(-1)=\eta(-1)$. Now, computing $\eta(-1)$ is an easier task, as the eta function is equal to the Abel sum of its defining series, which is a one-sided limit:

$$-3\zeta(-1)=\eta(-1)=\lim_{x\to1^-}\left(1-2x+3x^2-4x^3+\cdots\right)=\lim_{x\to1^-}\frac{1}{(1+x)^2}=\frac{1}{4} \tag{6.4.226}$$

  Dividing both sides by -3, one gets:

$$\zeta(-1)=-\frac{1}{12} \tag{6.4.227}$$

---

[12] Yes there are a lot of different kind (variations) of the zeta function. You can find a list of the 34 most important of them on Wikipedia.

The first example in which zeta function regularization is available appears in the Casimir effect (see section page Wave Quantum Physics page 4825), which is in a flat space the bulk contributions of the quantum field in three space dimensions. In this case we must calculate the value of Riemann zeta function at -3:

$$\zeta(s=-3)=\sum_{n=1}^{+\infty}\frac{1}{n^s}=\sum_{n=1}^{+\infty}n^3=\zeta(-3)=1+8+27+64+\ldots \qquad (6.4.228)$$

which diverges explicitly. However, it can be analytically continued to $s=-3$ where hopefully there is no pole (see section Complex Analysis page 2440), thus giving a finite value to the expression.

Remark

The reason why we see $\zeta(-1)$ in many YouTube videos and physics textbook, rather than $\zeta(-3)$ is that when you imagine the Casimir effect as happening in one dimension (along a line rather than in 3D), the energy density you calculate is $\zeta(-1)$ rather than $\zeta(-3)$.

Let us see another and more rigorous way to prove that $\zeta(-1)=-\dfrac{1}{12}$.

We need a result first:

$$\begin{aligned}\int_0^{+\infty}\frac{xt^{x-1}}{e^t+1}\mathrm{d}t&=\int_0^{+\infty}\frac{xt^{x-1}}{1+e^{-t}}e^{-t}\mathrm{d}t=x\sum_{k=1}^{+\infty}(-1)^{k-1}\int_0^{+\infty}t^{x-1}e^{-kt}\mathrm{d}t\\&=x\sum_{k=1}^{+\infty}(-1)^{k-1}k^{-x}\int_0^{+\infty}t^{x-1}e^{-t}\,\mathrm{d}t=x\eta(x)\Gamma(x)=(1-2^{1-x})\zeta(x)\Gamma(x+1)\end{aligned} \qquad (6.4.229)$$

Let us now multiply the above result by $x+1$, then integrate by parts twice, to we get:

$$\begin{aligned}(1-2^{1-x})\zeta(x)\Gamma(x+2)&=\int_0^{+\infty}\frac{(x+1)xt^{x-1}}{e^t+1}\mathrm{d}t=\int_0^{+\infty}\frac{(x+1)t^xe^t}{(e^t+1)^2}\mathrm{d}t\\&=\int_0^{+\infty}\frac{t^{x+1}(e^{2t}-e^t)}{(e^t+1)^3}\mathrm{d}t\end{aligned} \qquad (6.4.230)$$

Now we can plug in $x=-1$ into the above result to get:

$$\begin{aligned}(1-2^2)\zeta(-1)\Gamma(1)&=\int_0^{+\infty}\frac{e^{2t}-e^t}{(e^t+1)^3}\mathrm{d}t=\int_1^{+\infty}\frac{u-1}{(u+1)^3}\mathrm{d}u\\&=\int_1^{+\infty}\left(\frac{1}{(u+1)^2}-\frac{2}{(u+1)^3}\right)\mathrm{d}u=\frac{1}{4}\end{aligned} \qquad (6.4.231)$$

Since $(1-2^2)\Gamma(1)=-3$ the above result can be rearrange to:

$$\zeta(-1)=-\frac{1}{12} \qquad (6.4.232)$$

We will see a third method just below to get that same result and even a fourth one during our study later of Grandi's series (see page 1691).

- Let us prove now an elegant and fast way to determine the value of the zeta function for all negative integers (there are other methods but involving heavy and boring mathematics for most engineers).

  For that purpose we will first need to prove the following lemma:

  Lemma 6.21.1. The Riemann zeta function in the critical strip is given by:

  $$\zeta(s)=\frac{1}{s-1}+1-s\int_1^{+\infty}\frac{x-[x]}{x^{s+1}}\mathrm{d}x \tag{6.4.233}$$

  where $[x]$ denotes the integer part of x.

  For the proof we need first for $\Re(s)>1$:

  $$\begin{aligned}\zeta(s)&=\sum_{n=1}^{+\infty}\frac{1}{n^s}=\sum_{n=1}^{1}\frac{n}{n^s}+\sum_{n=2}^{\infty}\frac{1}{n^s}=\sum_{n=1}^{1}\frac{n}{n^s}+\sum_{n=2}^{+\infty}\frac{n-(n-1)}{n^s}\\&=\sum_{n=1}^{1}\frac{n}{n^s}+\sum_{n=2}^{+\infty}\frac{n}{n^s}-\sum_{n=2}^{+\infty}\frac{n-1}{n^s}=\sum_{n=1}^{+\infty}\frac{n}{n^s}-\sum_{n=2}^{+\infty}\frac{n-1}{n^s}\\&=\sum_{n=1}^{+\infty}\frac{n}{n^s}-\sum_{n=1}^{+\infty}\frac{n}{(n+1)^s}=\sum_{n=1}^{+\infty}n\left[\frac{1}{n^s}-\frac{1}{(n+1)^s}\right]\\&=s\sum_{n=1}^{+\infty}n\int_n^{n+1}x^{-s-1}\mathrm{d}x\end{aligned} \tag{6.4.234}$$

  Since $[x]=n$ for any x in the interval $[n,n+1]$, we have:

  $$\begin{aligned}&=s\sum_{n=1}^{+\infty}\int_n^{n+1}[x]x^{-s-1}\mathrm{d}x=s\int_1^{+\infty}[x]x^{-s-1}\mathrm{d}x\\&=s\left[\int_1^{+\infty}x^{-s}\mathrm{d}x\right]-s\int_1^{+\infty}\{x\}x^{-s-1}\mathrm{d}x\quad\text{(because by definition:}[x]=x-\{x\})\\&=s\left[\left.\frac{x^{-s+1}}{-s+1}\right|_1^{+\infty}\right]-s\int_1^{+\infty}\{x\}x^{-s-1}\mathrm{d}x\end{aligned} \tag{6.4.235}$$

  allowing the following simplification:

  $$\zeta(s)=\frac{s}{s-1}-s\int_1^{+\infty}\frac{\{x\}}{x^{s+1}}\mathrm{d}x\quad\Re(s)>1 \tag{6.4.236}$$

Because $0 \leq \{x\} < 1$, the last integral converges and is holomorphic (see section Complex Analysis page 2399) on $\Re(s) > 0$. But that means the full equation is meromorphic (see section Complex Analysis page 2402) on $\Re(s) > 0$, and thus provides an analytic continuation of $\zeta(s)$ on the half plane $\Re(s) > 0$. The $s/(s-1)$ term gives a simple pole at $s = 1$ with residue 1 (see section Complex Analysis page 2440).

Injecting again back $[x] = x - \{x\} \Leftrightarrow \{x\} = x - [x]$, we get:

$$\zeta(s) = \frac{s}{s-1} - s\int\limits_1^{+\infty} \frac{x-[x]}{x^{s+1}}\mathrm{d}x = \frac{1}{s-1} + 1 - s\int\limits_1^{+\infty} \frac{x-[x]}{x^{s+1}}\mathrm{d}x \quad \Re(s) > 1 \tag{6.4.237}$$

That finish the proof of the lemma.

Now remember that we have proved just earlier above that:

$$\zeta(s) = s\int\limits_1^{+\infty} \frac{[x]}{x^{s+1}}\mathrm{d}x = \frac{s}{s-1} - s\int\limits_1^{+\infty} \frac{\{x\}}{x^{s+1}}\mathrm{d}x \tag{6.4.238}$$

where $\{x\}$ denotes the fractional part of x. This gives the analytic continuation of $\zeta(s)$ for $\Re(s) > 0$. We can now proceed inductively. Writing:

$$\int\limits_1^{+\infty} \frac{\{x\}}{x^{s+1}}\mathrm{d}x = \sum_{n=1}^{\infty} \int\limits_n^{n-1} \frac{x-n}{x^{s+1}}\mathrm{d}x = \sum_{n=1}^{+\infty} \int\limits_0^1 \frac{u\mathrm{d}u}{(u+n)^{n+1}} \tag{6.4.239}$$

and integrating the last integral by parts, we get:

$$\sum_{n=1}^{+\infty} \int\limits_0^1 \frac{u\mathrm{d}u}{(u+n)^{s+1}} = \frac{1}{2}\sum_{n=1}^{+\infty} \frac{1}{(n+1)^{s+1}} + \frac{(s+1)}{2}\int\limits_1^{+\infty} \frac{\{x\}^2}{x^{s+2}}\mathrm{d}x = \frac{1}{2}(\zeta(s+1)-1) + \frac{(s+1)}{2}\int\limits_1^{+\infty} \frac{\{x\}^2}{x^{s+2}}\mathrm{d}x \tag{6.4.240}$$

and the latter integral converges for $\Re(s) > -1$. That is:

$$\zeta(s) = \frac{s}{s-1} - \frac{s}{2}(\zeta(s+1)-1) - \frac{s(s+1)}{2}\int_1^x \frac{\{x\}^2}{x^{s+2}}\mathrm{d}x \tag{6.4.241}$$

Thus, inductively, we deduce:

$$\begin{aligned}\zeta(s) = 1 + \frac{1}{s-1} - \sum_{r=1}^{m} \frac{s(s+1)\cdots(s+r-1)}{(r+1)!}(\zeta(s+r)-1) \\ - \frac{s(s+1)\cdots(s+m)}{(m+1)!}\sum_{n=1}^{\infty}\int_0^1 \frac{u^{m+1}\mathrm{d}u}{(u+n)^{s+m+1}}\end{aligned} \tag{6.4.242}$$

and the infinite sum on the right hand side converges for $\Re(s) > -m$.

If in the relation above we put $s = 1-m$, and note that for $r = m$ that $\zeta(s+m)$ has a simple pole at $s = 1-m$, we get the recurrence:

$$\zeta(1-m) = 1 - \frac{1}{m} + \frac{(-1)^m}{m(m+1)} - \sum_{r=1}^{m-1}(-1)^r \begin{pmatrix} m-1 \\ r \end{pmatrix} \frac{1}{r+1}(\zeta(1-m+r)-1) \tag{6.4.243}$$

The first few values at non positive integers are immediate and given by:

$$\zeta(0) = -\frac{1}{2}, \zeta(-1) = -\frac{1}{12}, \zeta(-2) = 0, \zeta(-3) = \frac{1}{120} \tag{6.4.244}$$

And that's it!

6.4.2.4 Telescoping Series

A "telescoping series" is a series in which most of terms cancel in each of the partial sums, leaving only some of the first terms and some of the last terms.

For example, the series:

$$\sum_{n=1}^{+\infty}\frac{1}{n(n+1)} \tag{6.4.245}$$

simplifies as:

$$\begin{aligned}\sum_{n=1}^{+\infty}\frac{1}{n(n+1)}&=\sum_{n=1}^{+\infty}\left(\frac{1}{n}-\frac{1}{n+1}\right)\\&=\lim_{N\rightarrow+\infty}\sum_{n=1}^{N}\left(\frac{1}{n}-\frac{1}{n+1}\right)\\&=\lim_{N\rightarrow+\infty}\left[\left(1-\frac{1}{2}\right)+\left(\frac{1}{2}-\frac{1}{3}\right)+\cdots+\left(\frac{1}{N}-\frac{1}{N+1}\right)\right]\\&=\lim_{N\rightarrow+\infty}\left[1+\left(-\frac{1}{2}+\frac{1}{2}\right)+\left(-\frac{1}{3}+\frac{1}{3}\right)+\cdots+\left(-\frac{1}{N}+\frac{1}{N}\right)-\frac{1}{N+1}\right]\\&=\lim_{N\rightarrow+\infty}\left[1-\frac{1}{N+1}\right]=1.\end{aligned} \tag{6.4.246}$$

We will encounter such a series for business purposes (management) in our study of Queuing Theory in the section of Quantitative Management!!!

6.4.2.5 Grandi's Series

The "Grandi's series" (after Italian mathematician, philosopher, and priest Guido Grandi, who gave a memorable treatment of the series in 11703 according to holocene calendar) is defined as the following arithmetic series:

$$\sum_{n=0}^{+\infty}(-1)^n=1-1+1-1+\cdots \tag{6.4.247}$$

It is a very famous series in mathematics and physics because:

- It highlights in a very simple way the fact (see below) that it is dangerous to manipulate infinite series
- Its result seems completes non-intuitive but in fact it opens the door to a more general definition of what is a "sum"
- It is a beautiful example of a series that seems useless and purely mathematics but that has in fact important application in quantum physics (Casimir Effect as seen in the section of Wave Quantum Physics at page 4825) and String Theory (number of dimensions as seen in the section of String Theory).

and this is why we dedicate to it a special subsection in this textbook!

It seems quite obvious at a first glance that it is a divergent series, meaning that it lacks a sum in the usual sense (the sequence of partial sums of Grandi's series clearly does not approach any number). But the other hand, its Cesàro sum is $1/2$!!?? So what the hell is a Cesàro sum?

Definition (#6.4.222): In mathematical analysis a "Cesàro sum assigns values to some infinite sums that are not convergent in the usual sense. The Cesàro sum is defined as the limit of the arithmetic mean of the partial sums of the series.

Let $\{a_n\}$ be a sequence, and let:

$$s_k = a_1 + \cdots + a_k = \sum_{n=1}^{k} a_n \tag{6.4.248}$$

be the kth partial sum of the series:

$$\sum_{n=1}^{+\infty} a_n \tag{6.4.249}$$

The series $\sum_{n=1}^{+\infty} a_n$ is say to be "Cesàro summable", with Cesàro sum $S \in \mathbb{R}$, if the average value of its partial sums s_k tends to S:

$$\lim_{n\rightarrow\infty} \frac{1}{n}\sum_{k=1}^{n} s_k = S \tag{6.4.250}$$

In other words, the Cesàro sum of an infinite series is the limit of the arithmetic mean (average) of the first n partial sums of the series, as n goes to infinity. If a series is convergent, then it is Cesàro summable and its Cesàro sum is the usual sum. For any convergent sequence, the corresponding series is Cesàro summable and the limit of the sequence coincides with the Cesàro sum.

One obvious method to attack the Grandi's series:

$$\sum_{n=0}^{+\infty} (-1)^n = 1-1+1-1+1-1+1-1+\ldots \tag{6.4.251}$$

is to treat it like a telescoping series and perform the subtractions in place:

$$\sum_{n=0}^{+\infty} (-1)^n = (1-1)+(1-1)+(1-1)+\ldots = 0+0+0+\ldots = 0 \tag{6.4.252}$$

On the other hand, a similar bracketing procedure leads to the apparently contradictory result:

$$\sum_{n=0}^{+\infty} (-1)^n = 1+(-1+1)+(-1+1)+(-1+1)+\ldots = 1+0+0+0+\ldots = 1 \tag{6.4.253}$$

Thus, by applying parentheses to Grandi's series in different ways, one can get either 0 or 1 as a "value". It can be shown that it is not valid to perform many seemingly innocuous operations on a series, such as reordering individual terms, unless the series is absolutely convergent. Otherwise these operations can alter the result of summation.

Treating Grandi's series as a divergent geometric series we may use the same algebraic methods that evaluate convergent geometric series to get a third value:

$$S = 1 - 1 + 1 - 1 + \ldots \tag{6.4.254}$$

so:

$$1 - S = 1 - (1 - 1 + 1 - 1 + \ldots) = 1 - 1 + 1 - 1 + \ldots = S \tag{6.4.255}$$

Therefore:

$$1 - S = S \tag{6.4.256}$$

Finally:

$$S = \sum_{n=0}^{+\infty} (-1)^n = \frac{1}{2} \tag{6.4.257}$$

The same conclusion results from calculating $-S$, subtracting the result from S, and solving $2S = 1$.

The above manipulations do not consider what the sum of a series actually means. Still, to the extent that it is important to be able to bracket series at will, and that it is more important to be able to perform arithmetic with them, one can arrive at two conclusions:

- The series $1 - 1 + 1 - 1 + \ldots$ has no sum
- ...but its sum should be $1/2$ (see further below)

In fact, both of these statements can be made precise and formally proven, but only using well-defined mathematical concepts that arise in the 119th century (holocene calendar). After the late 117th century introduction of calculus in Europe, but before the advent of modern rigour, the tension between these answers fuelled what has been characterized as an "endless" and "violent" dispute between mathematicians. The funniest is that the violent discussions still continue today... a YouTube video on this subject has more than $5,000$ comments... and a blog post more than 200 comments and a forum thread more than 600... (and by the way the comments show the worst of what the human behaviour and respect can be...). So this remains quite a hot topic!

Let us also recall that at the beginning of our study of geometric series we have proved that:

$$S_n = u_0 q^0 + u_0 q^1 + u_0 q^2 + u_0 q^3 + \ldots = u_0 \frac{1 - q^{n+1}}{1 - q} \tag{6.4.258}$$

Therefore if $u_0 = 1$ this reduce to:

$$S_n = 1 + q^1 + q^2 + q^3 + \ldots = \frac{1 - q^{n+1}}{1 - q} \tag{6.4.259}$$

where as n goes to infinity, the absolute value of $|q|$ must be less than one for the series to converge!

Now notice that if $q=-1$ we fall back on Grandi's series and therefore that latter is a special case of the geometric series $1+q^1+q^2+q^3+\ldots$ and then we would perhaps write a bit too quick:

$$S_n=1+(-1)^1+(-1)^2+(-1)^3+\ldots=1-1+1-1+\ldots=\frac{1-(-1)^{n+1}}{1-(-1)} \tag{6.4.260}$$

But as we have just mention it, we are not authorized to write the latter fraction if $q=\pm 1$ otherwise the series diverge excepted... if we work in a special axiomatic framework. This is almost as chocking as when imaginary numbers were introduced in the 116th century (holocene calendar), as well as negative numbers that were poorly understood and regarded by some as fictitious or useless, much as zero once was...

Remark

There have been very interesting studies about the reaction of high-school level students to Grandi's series presentation. The reactions and analysis are very interesting and I can personally only recommend every teacher to introduce this series in classes but without giving the result in a first time!

But there is a "one more thing"... We will now calculate a sum, thinking it really gives infinity as a result:

$$B=\sum_{n=1}^{+\infty} n=1+2+3+4+5+\ldots \tag{6.4.261}$$

To do this, let's do another trick of mathematical magician:

$$B=1+2+3+4+\ldots \tag{6.4.262}$$

Therefore:

$$4B=4+8+\ldots \tag{6.4.263}$$

So we can compute:

$$-3B=B-4B=1-2+3-4+\ldots=\sum_{n=1}^{+\infty}(-1)^{n+1}n=C \tag{6.4.264}$$

Our first concrete result, squared, can be rewritten as follows:

$$S^2=(-1+1-1+1-1+\ldots)^2 \tag{6.4.265}$$

Or well:

$$S^2=S\cdot S \tag{6.4.266}$$

Explicitly:

$$(-1+1-1+1-1+\ldots)$$

$$
\begin{array}{r}
\underline{\times(-1+1-1+1-1+\ldots)} \\
=1-1+1-1+1-1+1-1+\cdots \\
-1+1-1+1-1+1-1+\cdots \\
+1-1+1-1+1-1+\cdots \\
\ldots
\end{array}
$$

Summing each column we see that we fall back on:

$$1-2+3-4+5-6+\ldots=C \tag{6.4.267}$$

Therefore:

$$S^2=C \tag{6.4.268}$$

But as $S=1/2$, then:

$$S^2=C=(1/2)^2=\frac{1}{4} \tag{6.4.269}$$

Therefore:

$$B=-\frac{C}{3}=\frac{1}{12} \tag{6.4.270}$$

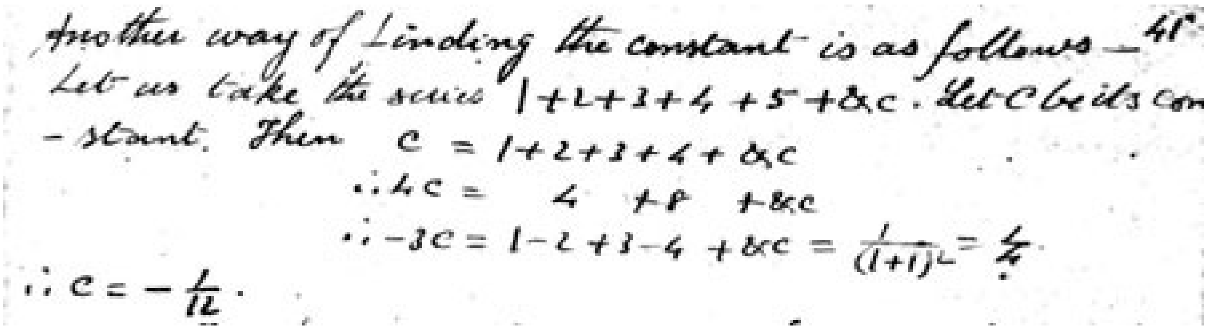
That is (to freak out a last time), we have shown that:

$$\boxed{\sum_{n=1}^{+\infty} n=1+2+3+4+5+\ldots=-\frac{1}{12}} \tag{6.4.271}$$

Quite interesting! But don't forget that we get this result in a special framework that we have build and that generalize the conventional sum that we learn at high-school. It seems that all generalizations of the conventional sum (as mathematicians do definitions with coffee as we know...) lead to the same result of $-1/12$...

It is also quite chocking that as the set of natural numbers $\mathbb{N}$ is closed under addition that the sum of all naturals is $-1/12$...

Furthermore, all this stuff is not new! It was known by many people long time before (few hundred years) and it was especially Srinivasa Ramanujan and later Godfrey Harold Hardy in a book titled *Divergent Series* that formalized the subject in a more elegant and technical way than the one you have here above.



Another way of finding the constant is as follows — 41
Let us take the series $1+2+3+4+5+\&c$. Let C be its con
-stant. Then $C = 1+2+3+4+\&c$

$\therefore 4C = \quad 4 \quad +8 \quad +\&c$

$\therefore -3C = 1-2+3-4+\&c = \frac{1}{(1+1)^2} = \frac{1}{4}$

$\therefore C = -\frac{1}{12}$.

Figure 6.69: Piece of Ramanujan's first notebook about $-1/12$

6.4.2.6 Taylor and Maclaurin Series

Taylor and Maclaurin series provide a convenient and powerful tool to simplify theoretical models and computer calculations (fluid modelling or fields in space). They are used heavily in all fields of physics but they are also found in the industry including engineering (design of experiments, numerical methods, quality management), statistics (integral approximations), finance (stochastic processes), complex analysis... We strongly advise the reader to consult carefully the developments that follow. There is also a serious funny quote on the subject:

quote
6.4:1696.#57

> ❝ *Everything is just some form of first order Taylor Expansion!* ❞

To start, consider a polynomial (with one variable/univariate):

$$P_n(x)=\sum_{k=0}^{n} a_k x^k \qquad (6.4.272)$$

We trivially have for this latter:

$$P(0)=a_0 \qquad (6.4.273)$$

Given now the derivative of the polynomial $P(x)$:

$$P(x)=\sum_{k=1}^{n} k a_k x^{k-1} \qquad (6.4.274)$$

Therefore:

$$P'(0)=1\cdot a_1 \qquad (6.4.275)$$

and so on with $P''(x), P'''(x), \ldots$ such that:

$$\begin{aligned} P''(x)&=\sum_{k=2}^{n} k(k-1)a_k x^{k-2} \Rightarrow P''(0)=1\cdot 2\cdot a_2\\ P'''(x)&=\sum_{k=3}^{n} k(k-1)(k-2)a_k x^{k-3} \Rightarrow P''(0)=1\cdot 2\cdot 3\cdot a_3\\ &\ldots\\ \frac{\mathrm{d}^n P(x)}{\mathrm{d}x^n}&=\sum_{k=n}^{n} k(k-1)\cdots(k-(n-1))a_k x^{k-n} \Rightarrow P''(0)=n!\cdot a_n \end{aligned} \qquad (6.4.276)$$

Then:

$$a_0=P(0), a_1=\frac{1}{1!}\frac{\mathrm{d}P(0)}{\mathrm{d}x}, a_2=\frac{1}{2!}\frac{\mathrm{d}^2P(0)}{\mathrm{d}x^2}, a3=\frac{1}{3!}\frac{\mathrm{d}^3P(0)}{\mathrm{d}x^3}, \cdots, a_n=\frac{1}{n!}\frac{\mathrm{d}^nP(0)}{\mathrm{d}x^n} \qquad (6.4.277)$$

Therefore:

$$\boxed{P_n(x)=\sum_{k=0}^{n}\frac{1}{k!}\frac{\mathrm{d}^kP(0)}{\mathrm{d}x^k}x^k} \qquad (6.4.278)$$

relation that we name "limited Maclaurin series" or simply "Maclaurin series" of order $k+1$.

Remark

In practice, as we will see in many other sections of this textbook, we often use limited developments of order 1 (also named "affine approximations", or "affine tangent approximations"), which can facilitate the calculations, when we do not expect too much precision in the final result.

Now by applying the same reasoning but by centring the value of the polynomial on $x = x_0$, we have:

$$P_n(x) = \sum_{k=0}^{n} a_k (x - x_0)^k \tag{6.4.279}$$

and so the previous development becomes more general:

$$\boxed{P_n(x) = \sum_{k=0}^{n} \frac{1}{k!} \frac{\mathrm{d}^k P(x_0)}{\mathrm{d}x^k} (x - x_0)^k} \tag{6.4.280}$$

which is no other than the general expression of a polynomial expression in a form named "limited Taylor series" of order $k+1$. This function can be assimilate to a polynomial as n is finite. But if n is infinite, as we shall see later, this series converges to the function we are seeking the representation in the form of a sum of terms.

Thus, some functions $f(x)$ of class $\mathcal{C}^n$ that can be approximated by a polynomial $P(x)$ (a sum of powers in other words...) centered on the value x_0 can be expressed as:

$$f(x) = \sum_{k=0}^{n} \frac{1}{k!} \frac{\mathrm{d}^k f(x_0)}{\mathrm{d}x^k} (x - x_0)^k = \sum_{k=0}^{n} \frac{\mathrm{d}^{(k)} f(x_0)}{k!} (x - x_0)^k \tag{6.4.281}$$

Result often referred to as "Taylor's theorem".

But this last relation is not correct for all functions that can not be expressed as a polynomial. Therefore we say that the series is not convergent for them. We will see an example later below.

The latter relation is sometimes also written ... more conventionally:

$$f(x) = \sum_{k=0}^{n} \frac{\mathrm{D}^k f(x_0)}{k!} (x - x_0)^k \tag{6.4.282}$$

In finance (and not only!), we will often use the following rearrangement:

$$\boxed{\begin{gathered} f(x) = f(x_0) + \sum_{k=1}^{n} \frac{\mathrm{D}^k f(x_0)}{k!} (x - x_0)^k \\ \Rightarrow f(x) - f(x_0) = \sum_{k=1}^{n} \frac{\mathrm{D}^k f(x_0)}{k!} (x - x_0)^k \\ \lim_{x - x_0 \to \mathrm{d}x} \mathrm{d}x = \sum_{k=1}^{n} \frac{\mathrm{D}^k f(x_0)}{k!} \mathrm{d}x^k \end{gathered}} \tag{6.4.283}$$

Let us return briefly to the approximation of $f(x)$ near and centered in x_0:

$$f(x)=\sum_{k=0}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(x_0)}{\mathrm{d}x^k}(x-x_0)^k=\sum_{k=0}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(x_0)}{\mathrm{d}x^k}(\Delta x)^k \tag{6.4.284}$$

Another very common notation in physics and financial engineering of the above relation is:

$$\widetilde{f}(x)=f(x_0)+\sum_{k=1}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(x_0)}{\mathrm{d}x^k}(\Delta x)^k \Leftrightarrow \mathrm{d}f(x)=\sum_{k=1}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(x_0)}{\mathrm{d}x^k}(\Delta x)^k \tag{6.4.285}$$

Some people do not like using this formulation because we have the risk to forget that the approximation for a few terms is only good as long as we are not too far from x_0 with x. This is why it often happens that we write:

$$x=x_0+\Delta h=x_0+h \tag{6.4.286}$$

with x_0 fixed and a h variable but small (!) and so it then comes a common form of notation of Taylor series(!):

$$f(x_0+h)=\sum_{k=0}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(x_0)}{\mathrm{d}x^k}(x_0+h-x_0)^k=\sum_{k=0}^{n}\frac{h^k}{k!}\frac{\mathrm{d}^k f}{\mathrm{d}x^k}(x_0) \tag{6.4.287}$$

Let's see an application example with Maclaurin series (with x_0 being zero) of the function $\sin(x)$ and Maple™ 4.00b:

```
>p[n](x) = sum((D@@i)(f)(a)/i!*(x-a)^i,i=0..n);
>p11:= taylor(sin(x),x=0,12);
>p11:= convert(p11,polynom);
>with(plots):
>tays:= plots[display](sinplot):
for i from 1 by 2 to 11 do
tpl:= convert(taylor(sin(x), x=0,i),polynom):
tays:= tays,plots[display]([sinplot,plot(tpl,x=-Pi..2*Pi,y=-2..2,
color=black,title=convert(tpl,string))]) od:
>plots[display]([tays],view=[-Pi..2*Pi,-2..2]);
```

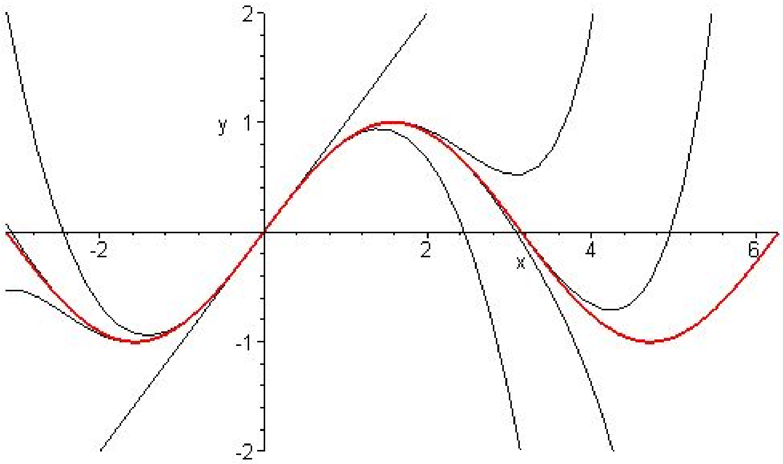


Figure 6.70: **Approximation of the sine function by a Maclaurin development in Maple™ 4.00b**

Or in better quality with TikZ:

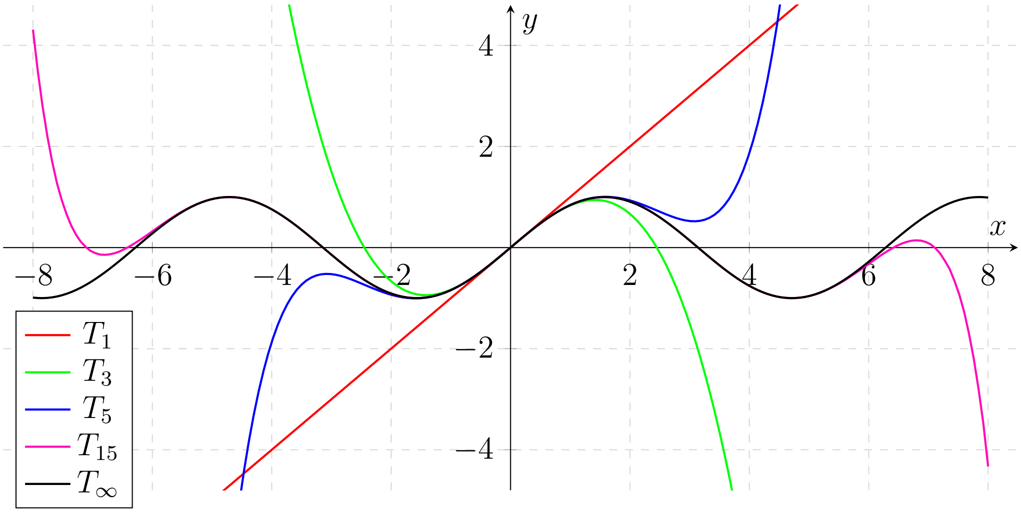

Figure 6.71: **Approximation of the sine function by a Maclaurin development with TikZ**

We see well in this example that the Maclaurin series only allows to approach a function at a point with a limited number of points. But more terms we take (put 100 terms in the Maple™ code above) more the validity is big on the whole domain of definition of the function. In fact it is possible to prove that the function $sin(x)$ is exactly expressible in Maclaurin series when the number of terms is infinite. We say then that its "rest" is zero.

But this is not true for all functions! For example the function:

$$f(x) = \frac{1}{1-x^2} \tag{6.4.288}$$

```
>p[n](x) = sum((D@@i)(f)(a)/i!*(x-a)^i,i=0..n);
>p10:= taylor(1/(1-x^2),x=0,10);
>p10:= convert(p10,polynom);
>with(plots):
>tays:= plots[display](xplot):
for i from 1 by 2 to 10 do
tpl:= convert(taylor(1/(1-x^2), x=0,i),polynom):
tays:= tays,plots[display]([xplot,plot(tpl,x=-2..2,y=-2..2,
color=black,title=convert(tpl,string))]) od:
>plots[display]([tays],view=[-2..2,-2..2]);
```

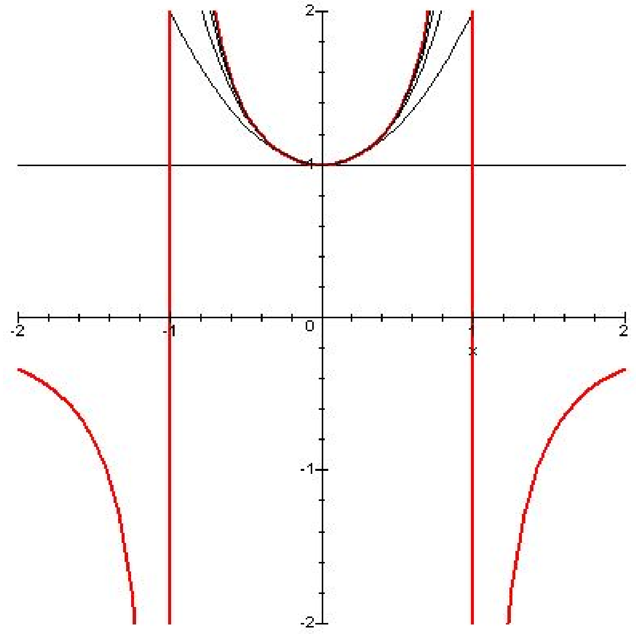

Figure 6.72: **Example of non-convergent Maclaurin series in Maple™ 4.00b**

We see above that regardless of the number of terms that we take the Maclaurin series converges only in one area of definition between $]-1,1[$. This interval is named the "radius of convergence" and it determination (the singularity) is crucial in many areas of engineering, physics and analysis. We will return in more detail on this example in the section of Complex Analysis.

But we can shift the Maclaurin series of the previous function to approximate the function with a Taylor series in other non-singular point such as in x_0 having for value 2:

```
>p[n](x) = sum((D@@i)(f)(a)/i!*(x-a)^i,i=0..n);
>p10:= taylor(1/(1-x^2),x=2,10);
>p10:= convert(p10,polynom);
>with(plots):
>tays:= plots[display](xplot):
for i from 1 by 2 to 10 do
tpl:= convert(taylor(1/(1-x^2), x=2,i),polynom):
tays:= tays,plots[display]([xplot,plot(tpl,x=0..5,y=-2..2,
color=black,title=convert(tpl,string))]) od:
>plots[display]([tays],view=[-0..5,-2..2]);
```

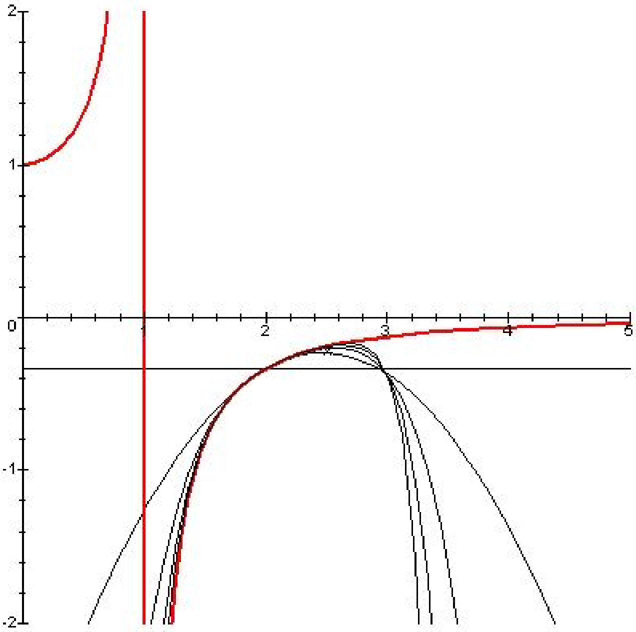

Figure 6.73: **Shift possibility of Maclaurin series in Maple™ 4.00b**

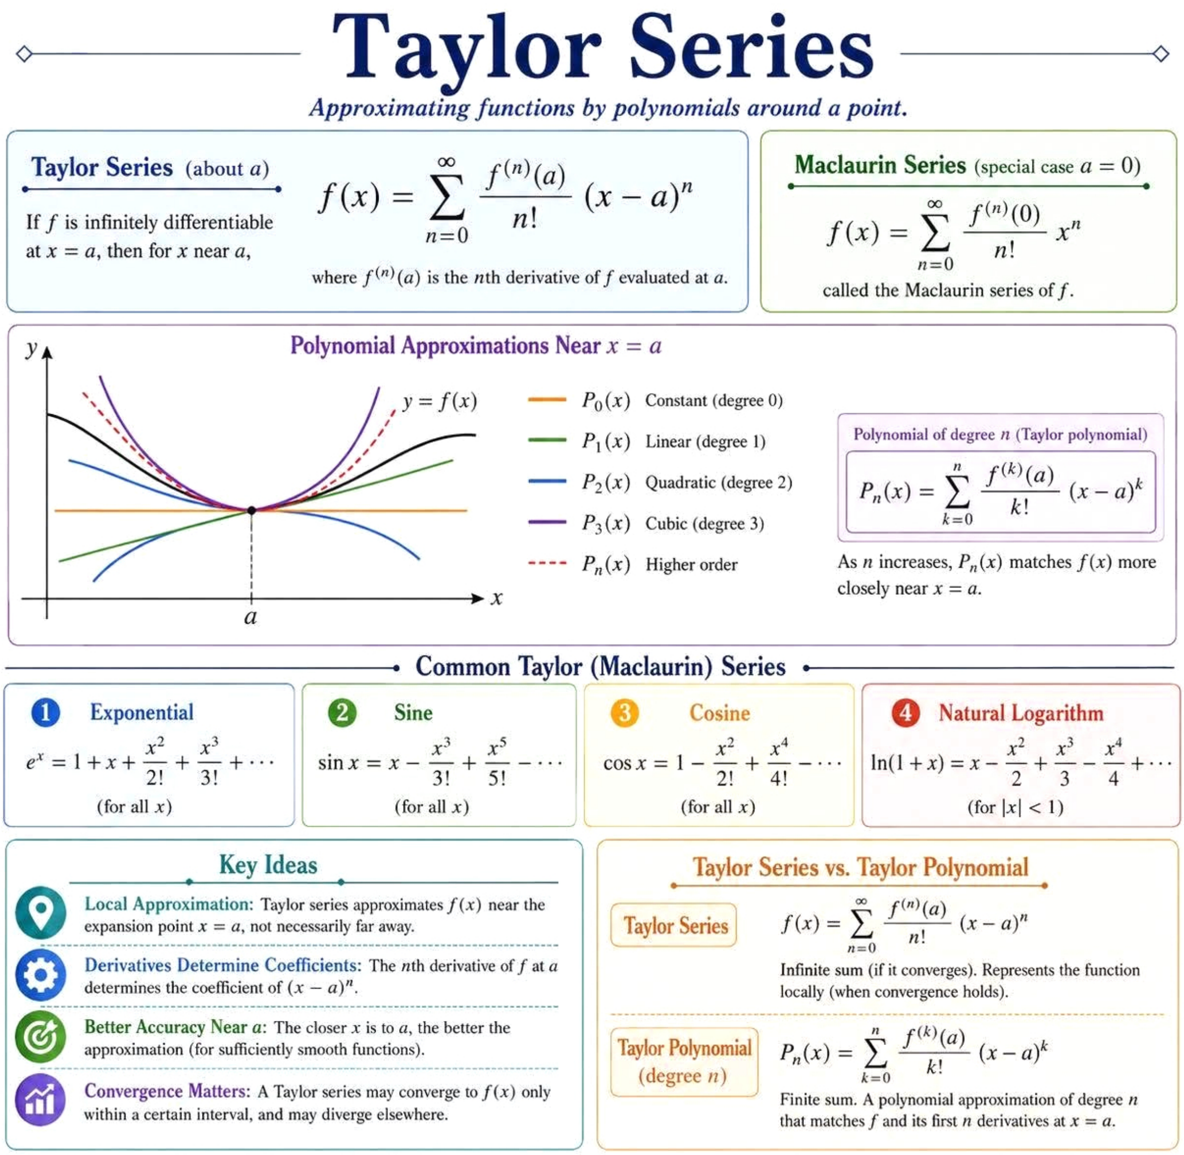
We will study a generalization to the complex plane of Taylor series in the section of Complex Analysis to get a veeeeery powerful result for physicists to calculate complicated curvilinear integrals.



Taylor Series

Approximating functions by polynomials around a point.

Taylor Series (about a)

If f is infinitely differentiable at $x = a$, then for x near a,

$$f(x) = \sum_{n=0}^{\infty} \frac{f^{(n)}(a)}{n!}(x-a)^n$$

where $f^{(n)}(a)$ is the nth derivative of f evaluated at a.

Maclaurin Series (special case $a = 0$)

$$f(x) = \sum_{n=0}^{\infty} \frac{f^{(n)}(0)}{n!}x^n$$

called the Maclaurin series of f.

Polynomial Approximations Near $x = a$

—	$P_0(x)$	Constant (degree 0)
—	$P_1(x)$	Linear (degree 1)
—	$P_2(x)$	Quadratic (degree 2)
—	$P_3(x)$	Cubic (degree 3)
----	$P_n(x)$	Higher order

Polynomial of degree n (Taylor polynomial)

$$P_n(x) = \sum_{k=0}^{n} \frac{f^{(k)}(a)}{k!}(x-a)^k$$

As n increases, $P_n(x)$ matches $f(x)$ more closely near $x = a$.

Common Taylor (Maclaurin) Series

① **Exponential**

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots$$

(for all x)

② **Sine**

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \cdots$$

(for all x)

③ **Cosine**

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \cdots$$

(for all x)

④ **Natural Logarithm**

$$\ln(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \cdots$$

(for $|x| < 1$)

Key Ideas

Local Approximation: Taylor series approximates $f(x)$ near the expansion point $x = a$, not necessarily far away.

Derivatives Determine Coefficients: The nth derivative of f at a determines the coefficient of $(x-a)^n$.

Better Accuracy Near a: The closer x is to a, the better the approximation (for sufficiently smooth functions).

Convergence Matters: A Taylor series may converge to $f(x)$ only within a certain interval, and may diverge elsewhere.

Taylor Series vs. Taylor Polynomial

Taylor Series

$$f(x) = \sum_{n=0}^{\infty} \frac{f^{(n)}(a)}{n!}(x-a)^n$$

Infinite sum (if it converges). Represents the function locally (when convergence holds).

Taylor Polynomial (degree n)

$$P_n(x) = \sum_{k=0}^{n} \frac{f^{(k)}(a)}{k!}(x-a)^k$$

Finite sum. A polynomial approximation of degree n that matches f and its first n derivatives at $x = a$.

6.4.2.6.1 Usual Maclaurin developments

We will prove here the most frequent Maclaurin developments (about ten) to the second order that we can meet in theoretical and mathematical physics (in fact we have developed here only use almost everywhere in the book). The list is not exhaustive for the time being but as the proof below are generalized, they can be applied to many other cases (that we will apply/meet throughout this textbook).

> **Remark**
>
> The Taylor expansions (that is to say elsewhere than on zero) are very rare (there are one or two in this entire book but they are detailed in their respective sections), we will omit them.

1. Taylor-Maclaurin development of $f(x)=e^x$:

   First remember that we have proved in the section of Differential and Integral Calculus that:

$$\begin{aligned}f'(x)&=\frac{\mathrm{d}e^x}{\mathrm{d}x}=e^x\\ f''(x)&=\frac{\mathrm{d}^2e^x}{\mathrm{d}x^2}=e^x\\ f'''(x)&=\frac{\mathrm{d}^3e^x}{\mathrm{d}x^3}=e^x\end{aligned} \tag{6.4.289}$$

   Therefore we have:

$$\begin{aligned}&f_3(x)\cong e^x\\ &\cong\sum_{k=0}^{3}\frac{1}{k!}\frac{\mathrm{d}^kP(0)}{\mathrm{d}x^k}x^k=\frac{1}{0!}\frac{\mathrm{d}^0P(0)}{\mathrm{d}x^0}x^0+\frac{1}{1!}\frac{\mathrm{d}^1P(0)}{\mathrm{d}x^1}x^1+\frac{1}{2!}\frac{\mathrm{d}^2P(0)}{\mathrm{d}x^2}x^2+\frac{1}{3!}\frac{\mathrm{d}^3P(0)}{\mathrm{d}x^3}x^3\\ &=\frac{1}{0!}e^x|_{x=0}+\frac{1}{1!}\frac{\mathrm{d}e^x}{\mathrm{d}x}\bigg|_{x=0}x^1+\frac{1}{2!}\frac{\mathrm{d}^2e^x}{\mathrm{d}x^2}\bigg|_{x=0}x^2+\frac{1}{3!}\frac{\mathrm{d}^3e^x}{\mathrm{d}x^3}\bigg|_{x=0}x^3\\ &=\frac{1}{0!}e^x|_{x=0}+\frac{1}{1!}e^x|_{x=0}x+\frac{1}{2!}e^x|_{x=0}x^2+\frac{1}{3!}e^x|_{x=0}x^3\\ &=1+\frac{1}{1!}e^0x+\frac{1}{2!}e^0x^2+\frac{1}{3!}e^0x^3\\ &=1+\frac{1}{1!}x+\frac{1}{2!}x^2+\frac{1}{3!}x^3=1+x+\frac{x^2}{2!}+\frac{x^3}{3!}\end{aligned} \tag{6.4.290}$$

   More generally:

$$e^x=1+\sum_{i=1}^{+\infty}\frac{1}{i!}x^i=\sum_{i=0}^{+\infty}\frac{1}{i!}x^i \tag{6.4.291}$$

   And therefore we have the famous result for $x=1$:

$$e=\sum_{n=0}^{+\infty}\frac{1}{n!} \tag{6.4.292}$$

   that is sometimes named the "exponential sequence".

2. Taylor-Maclaurin development of $f(x)=\sin(x)$:

   First remember that we have proved in the section of Differential and Integral Calculus that:

$$\begin{aligned}f'(x)&=\frac{\mathrm{d}\sin(x)}{\mathrm{d}x}=\cos(x)\\ f''(x)&=\frac{\mathrm{d}^2\sin(x)}{\mathrm{d}x^2}=\frac{\mathrm{d}\cos(x)}{\mathrm{d}x}=-\sin(x)\\ f'''(x)&=\frac{\mathrm{d}^3\sin(x)}{\mathrm{d}x^3}=\frac{\mathrm{d}(-\sin(x))}{\mathrm{d}x}=-\cos(x)\end{aligned}\tag{6.4.293}$$

   Therefore we have:

$$\begin{aligned}f_3(x)&\cong\sin(x)\\ &\cong\sum_{k=0}^{3}\frac{1}{k!}\frac{\mathrm{d}^kP(0)}{\mathrm{d}x^k}x^k=\frac{1}{0!}\frac{\mathrm{d}^0P(0)}{\mathrm{d}x^0}x^0+\frac{1}{1!}\frac{\mathrm{d}^1P(0)}{\mathrm{d}x^1}x^1+\frac{1}{2!}\frac{\mathrm{d}^2P(0)}{\mathrm{d}x^2}x^2+\frac{1}{3!}\frac{\mathrm{d}^3P(0)}{\mathrm{d}x^3}x^3\\ &=\frac{1}{0!}\sin(x)|_{x=0}+\frac{1}{1!}\left.\frac{\mathrm{d}\sin(x)}{\mathrm{d}x}\right|_{x=0}x^1+\frac{1}{2!}\left.\frac{\mathrm{d}^2\sin(x)}{\mathrm{d}x^2}\right|_{x=0}x^2+\frac{1}{3!}\left.\frac{\mathrm{d}^3\sin(x)}{\mathrm{d}x^3}\right|_{x=0}x^3\\ &=\frac{1}{0!}\sin(x)|_{x=0}+\frac{1}{1!}\cos(x)|_{x=0}x-\frac{1}{2!}\sin(x)|_{x=0}x^2-\frac{1}{3!}\cos(x)|_{x=0}x^3\\ &=\frac{1}{1!}x-\frac{1}{3!}x^3=x-\frac{x^3}{3!}\end{aligned}\tag{6.4.294}$$

3. Taylor-Maclaurin development of $f(x)=\cos(x)$:

   First remember that we have proved in the section of Differential and Integral Calculus that:

$$\begin{aligned}f'(x)&=\frac{\mathrm{d}\cos(x)}{\mathrm{d}x}=-\sin(x)\\ f''(x)&=\frac{\mathrm{d}^2\cos(x)}{\mathrm{d}x^2}=\frac{\mathrm{d}(-\sin(x))}{\mathrm{d}x}=-\cos(x)\\ f'''(x)&=\frac{\mathrm{d}^3\cos(x)}{\mathrm{d}x^3}=\frac{\mathrm{d}(-\cos(x))}{\mathrm{d}x}=\sin(x)\end{aligned}\tag{6.4.295}$$

   Therefore we have:

$$\begin{aligned}f_3(x)&\cong\cos(x)\\ &\cong\sum_{k=0}^{3}\frac{1}{k!}\frac{\mathrm{d}^kP(0)}{\mathrm{d}x^k}x^k=\frac{1}{0!}\frac{\mathrm{d}^0P(0)}{\mathrm{d}x^0}x^0+\frac{1}{1!}\frac{\mathrm{d}^1P(0)}{\mathrm{d}x^1}x^1+\frac{1}{2!}\frac{\mathrm{d}^2P(0)}{\mathrm{d}x^2}x^2+\frac{1}{3!}\frac{\mathrm{d}^3P(0)}{\mathrm{d}x^3}x^3\\ &=\frac{1}{0!}\cos(x)|_{x=0}+\frac{1}{1!}\left.\frac{\mathrm{d}\cos(x)}{\mathrm{d}x}\right|_{x=0}x^1+\frac{1}{2!}\left.\frac{\mathrm{d}^2\cos(x)}{\mathrm{d}x^2}\right|_{x=0}x^2+\frac{1}{3!}\left.\frac{\mathrm{d}^3\cos(x)}{\mathrm{d}x^3}\right|_{x=0}x^3\\ &=\frac{1}{0!}\cos(x)|_{x=0}-\frac{1}{1!}\sin(x)|_{x=0}x-\frac{1}{2!}\cos(x)|_{x=0}x^2+\frac{1}{3!}\sin(x)|_{x=0}x^3\\ &=\frac{1}{0!}-\frac{1}{2!}x^2=1-\frac{x^2}{2!}\end{aligned}\tag{6.4.296}$$

4. Taylor-Maclaurin development of $f(x)=\tan(x)$:

   First remember that we have proved in the section of Differential and Integral Calculus that:

$$\begin{aligned}
f'(x)&=\frac{\mathrm{d}\tan(x)}{\mathrm{d}x}=\frac{1}{\cos^2(x)}=1+\tan^2(x)\\
f''(x)&=\frac{\mathrm{d}^2\tan(x)}{\mathrm{d}x^2}=\frac{\mathrm{d}}{\mathrm{d}x}\frac{1}{\cos^2(x)}=2\frac{\sin(x)}{\cos^3(x)}\\
f'''(x)&=\frac{\mathrm{d}^3\tan(x)}{\mathrm{d}x^3}=2\frac{\mathrm{d}\left(\dfrac{\sin(x)}{\cos^3(x)}\right)}{\mathrm{d}x}=2\frac{\mathrm{d}\left(\sin(x)\dfrac{1}{\cos^3(x)}\right)}{\mathrm{d}x}\\
&=\frac{2}{\cos^2(x)}+2\sin(x)3\frac{\sin(x)}{\cos^4(x)}=\frac{2}{\cos^2(x)}+6\frac{\sin^2(x)}{\cos^4(x)}
\end{aligned}\tag{6.4.297}$$

   Therefore we have:

$$\begin{aligned}
&f_3(x)\cong\tan(x)\\
&\cong\sum_{k=0}^{3}\frac{1}{k!}\frac{\mathrm{d}^kP(0)}{\mathrm{d}x^k}x^k=\frac{1}{0!}\frac{\mathrm{d}^0P(0)}{\mathrm{d}x^0}x^0+\frac{1}{1!}\frac{\mathrm{d}^1P(0)}{\mathrm{d}x^1}x^1+\frac{1}{2!}\frac{\mathrm{d}^2P(0)}{\mathrm{d}x^2}x^2+\frac{1}{3!}\frac{\mathrm{d}^3P(0)}{\mathrm{d}x^3}x^3\\
&=\frac{1}{0!}\tan(x)|_{x=0}+\frac{1}{1!}\frac{\mathrm{d}\tan(x)}{\mathrm{d}x}\bigg|_{x=0}x^1+\frac{1}{2!}\frac{\mathrm{d}^2\tan(x)}{\mathrm{d}x^2}\bigg|_{x=0}x^2+\frac{1}{3!}\frac{\mathrm{d}^3\tan(x)}{\mathrm{d}x^3}\bigg|_{x=0}x^3\\
&=\frac{1}{0!}\tan(0)x^0+\frac{1}{1!}\left(1+\frac{\sin^2(x)}{\cos^2(x)}\right)\bigg|_{x=0}x^1+\frac{1}{2!}\left(2\frac{\sin(x)}{\cos(x)}+2\frac{\sin^3(x)}{\cos^3(x)}\right)\bigg|_{x=0}x^2\\
&+\frac{1}{3!}\left(2+8\frac{\sin^2(x)}{\cos^2(x)}+6\frac{\sin^4(x)}{\cos^4(x)}\right)\bigg|_{x=0}x^3\\
&=\frac{1}{1!}x-\frac{2}{3!}x^3=x+\frac{x^3}{3}
\end{aligned}\tag{6.4.298}$$

Remark

The reader must remember that for physicists and engineers the three following approximations are very useful and famous for small θ:

$$\sin(\theta)\cong\theta\qquad\cos(\theta)\cong 1\qquad\tan(\theta)\cong\theta$$

5. Taylor-Maclaurin development of $f(x)=\arctan(x)$:

   First remember that we have proved in the section of Differential and Integral Calculus that:

$$\begin{aligned}
f'(x)&=\frac{\mathrm{d}\arctan(x)}{\mathrm{d}x}=\frac{1}{1+x^2}\\
f''(x)&=\frac{\mathrm{d}^2\arctan(x)}{\mathrm{d}x^2}=\frac{\mathrm{d}}{\mathrm{d}x}\frac{1}{1+x^2}=-2\frac{x}{(1+x^2)^2}\\
f'''(x)&=\frac{\mathrm{d}^3\arctan(x)}{\mathrm{d}x^3}=\frac{\mathrm{d}\left(-2\dfrac{x}{(1+x^2)^2}\right)}{\mathrm{d}x}=-2\frac{\mathrm{d}\left(x\dfrac{1}{(1+x^2)^2}\right)}{\mathrm{d}x}\\
&=\frac{-2}{(1+x^2)^2}+(-2)x\frac{(-2)2x}{(1+x^2)^3}=\frac{-2}{(1+x^2)^2}+\frac{8x^2}{(1+x^2)^3}
\end{aligned}\tag{6.4.299}$$

Therefore we have:

$$\begin{aligned}
&f_3(x) \cong \arctan(x)\\
&\cong \sum_{k=0}^{3} \frac{1}{k!}\frac{\mathrm{d}^k P(0)}{\mathrm{d}x^k}x^k = \frac{1}{0!}\frac{\mathrm{d}^0 P(0)}{\mathrm{d}x^0}x^0 + \frac{1}{1!}\frac{\mathrm{d}^1 P(0)}{\mathrm{d}x^1}x^1 + \frac{1}{2!}\frac{\mathrm{d}^2 P(0)}{\mathrm{d}x^2}x^2 + \frac{1}{3!}\frac{\mathrm{d}^3 P(0)}{\mathrm{d}x^3}x^3\\
&= \frac{1}{0!}\arctan(x)|_{x=0} + \frac{1}{1!}\frac{\mathrm{d}\arctan(x)}{\mathrm{d}x}\bigg|_{x=0} x^1 + \frac{1}{2!}\frac{\mathrm{d}^2\arctan(x)}{\mathrm{d}x^2}\bigg|_{x=0} x^2 + \frac{1}{3!}\frac{\mathrm{d}^3\arctan(x)}{\mathrm{d}x^3}\bigg|_{x=0} x^3\\
&= \frac{1}{0!}\arctan(0)x^0 + \frac{1}{1!}\frac{1}{1+x^2}\bigg|_{x=0} x^1 + \frac{1}{2!}\frac{-2x}{(1+x^2)^2}\bigg|_{x=0} x^2\\
&+ \frac{1}{3!}\left(\frac{-2}{(1+x^2)^2} + \frac{8x^2}{(1+x^2)^3}\right)\bigg|_{x=0} x^3\\
&= \frac{1}{1!}x - \frac{2}{3!}x^3 = x - \frac{x^3}{3}
\end{aligned} \tag{6.4.300}$$

6. Taylor-Maclaurin development of $f(x) = \dfrac{1}{1+x}$:

First remember that we have proved in the section of Differential and Integral Calculus that:

$$\begin{aligned}
f'(x) &= \frac{\mathrm{d}\frac{1}{1+x}}{\mathrm{d}x} = -\frac{1}{1+x}^{2}\\
f''(x) &= \frac{\mathrm{d}^2\frac{1}{1+x}}{\mathrm{d}x^2} = \frac{\mathrm{d}}{\mathrm{d}x} - \frac{1}{1+x}^{2} = \frac{2}{(1+x)^3}\\
f'''(x) &= \frac{\mathrm{d}^3\frac{1}{1+x}}{\mathrm{d}x^3} = \frac{\mathrm{d}\left(\dfrac{2}{(1+x)^3}\right)}{\mathrm{d}x} = -\frac{6}{(1+x)^4}
\end{aligned} \tag{6.4.301}$$

Therefore we have:

$$\begin{aligned}
&f_3(x) \cong \frac{1}{1+x}\\
&\cong \sum_{k=0}^{3} \frac{1}{k!}\frac{\mathrm{d}^k P(0)}{\mathrm{d}x^k}x^k = \frac{1}{0!}\frac{\mathrm{d}^0 P(0)}{\mathrm{d}x^0}x^0 + \frac{1}{1!}\frac{\mathrm{d}^1 P(0)}{\mathrm{d}x^1}x^1 + \frac{1}{2!}\frac{\mathrm{d}^2 P(0)}{\mathrm{d}x^2}x^2 + \frac{1}{3!}\frac{\mathrm{d}^3 P(0)}{\mathrm{d}x^3}x^3\\
&= \frac{1}{0!}\frac{1}{1+x}|_{x=0} + \frac{1}{1!}\frac{\mathrm{d}\frac{1}{1+x}}{\mathrm{d}x}\bigg|_{x=0} x^1 + \frac{1}{2!}\frac{\mathrm{d}^2\frac{1}{1+x}}{\mathrm{d}x^2}\bigg|_{x=0} x^2 + \frac{1}{3!}\frac{\mathrm{d}^3\frac{1}{1+x}}{\mathrm{d}x^3}\bigg|_{x=0} x^3\\
&= \frac{1}{0!}1x^0 - \frac{1}{1!}\frac{1}{(1+x)^2}\bigg|_{x=0} x^1 + \frac{1}{2!}\frac{2}{(1+x)^3}\bigg|_{x=0} x^2 - \frac{1}{3!}\left(\frac{6}{(1+x)^4}\right)\bigg|_{x=0} x^3\\
&= 1 - \frac{1}{1!}x - \frac{2}{2!}x^2 - \frac{6}{3!}x^3 = 1 - x + x^2 - x^3
\end{aligned} \tag{6.4.302}$$

It then follows immediately another Taylor series we will also meet again many number of times:

$$f_2(x) \cong \frac{1}{(1+x)^2} = -\frac{\mathrm{d}}{x}\frac{1}{(1+x)} \cong -\frac{\mathrm{d}}{x}\left(1 - x + x^2 - x^3\right) = 1 - x^2 + 3x^2 \tag{6.4.303}$$

For our study of the Cosmological Microwave Background in the section of Cosmology (especially recombination era), we will need a result related to the two series above named the "Binomial theorem for negative integer exponents". Given the binomial coefficient given for recall by:

$$\begin{pmatrix} \alpha \\ k \end{pmatrix}=\frac{\alpha!}{k!(\alpha-k)!} \tag{6.4.304}$$

Let n be a positive integer, then (without proof but using "engineer intuition") we have:

$$\boxed{\frac{1}{(1+x)^n}=1-nx+\frac{(-n)(-n-1)}{2}x^2+\cdots=\sum_{k=0}^{+\infty}\begin{pmatrix} n+k-1 \\ k \end{pmatrix}(-1)^k x^k} \tag{6.4.305}$$

for $|x|<1$.

7. Taylor-Maclaurin development of $f(x)=\sqrt{1+x}$:

   First remember that we have proved in the section of Differential and Integral Calculus that:

$$\begin{aligned}
f'(x)&=\frac{\mathrm{d}\sqrt{1+x}}{\mathrm{d}x}=\frac{1}{2}\frac{1}{\sqrt{1+x}}\\
f''(x)&=\frac{\mathrm{d}^2\sqrt{1+x}}{\mathrm{d}x^2}=\frac{\mathrm{d}}{\mathrm{d}x}\frac{1}{2}\frac{1}{\sqrt{1+x}}=-\frac{1}{4}\frac{1}{(1+x)^{3/2}}\\
f'''(x)&=\frac{\mathrm{d}^3\sqrt{1+x}}{\mathrm{d}x^3}=\frac{\mathrm{d}\left(-\frac{1}{4}\frac{1}{(1+x)^{3/2}}\right)}{\mathrm{d}x}=\frac{3}{8}\frac{1}{(1+x)^{5/2}}
\end{aligned} \tag{6.4.306}$$

   Therefore we have:

$$\begin{aligned}
f_3(x)&\cong\sqrt{1+x}\\
&\cong\sum_{k=0}^{3}\frac{1}{k!}\frac{\mathrm{d}^kP(0)}{\mathrm{d}x^k}x^k=\frac{1}{0!}\frac{\mathrm{d}^0P(0)}{\mathrm{d}x^0}x^0+\frac{1}{1!}\frac{\mathrm{d}^1P(0)}{\mathrm{d}x^1}x^1+\frac{1}{2!}\frac{\mathrm{d}^2P(0)}{\mathrm{d}x^2}x^2+\frac{1}{3!}\frac{\mathrm{d}^3P(0)}{\mathrm{d}x^3}x^3\\
&=\frac{1}{0!}\sqrt{1+x}|_{x=0}+\frac{1}{1!}\left.\frac{\mathrm{d}\sqrt{1+x}}{\mathrm{d}x}\right|_{x=0}x^1+\frac{1}{2!}\left.\frac{\mathrm{d}^2\sqrt{1+x}}{\mathrm{d}x^2}\right|_{x=0}x^2+\frac{1}{3!}\left.\frac{\mathrm{d}^3\sqrt{1+x}}{\mathrm{d}x^3}\right|_{x=0}x^3\\
&=\frac{1}{0!}\sqrt{1+x}\Big|_{x=0}x^0+\frac{1}{1!}\frac{1}{2}\frac{1}{\sqrt{1+x}}\Big|_{x=0}x^1-\frac{1}{2!}\frac{1}{4}\frac{1}{(1+x)^{3/2}}\Big|_{x=0}x^2+\frac{1}{3!}\left(\frac{3}{8}\frac{1}{(1+x)^{5/2}}\right)\Big|_{x=0}x^3\\
&=\frac{1}{0!}+\frac{1}{1!}\frac{1}{2}x-\frac{1}{2!}\frac{1}{4}x^2+\frac{1}{3!}\frac{3}{8}x^3=1+\frac{1}{2}x-\frac{1}{2\cdot 4}x^2+\frac{1\cdot 3}{2\cdot 4\cdot 6}x^3
\end{aligned} \tag{6.4.307}$$

   It then also follows immediately another Taylor series we will also meet again many number of times:

$$\begin{aligned}
f_2(x)&\cong\frac{1}{\sqrt{1+x}}=2\frac{\mathrm{d}}{\mathrm{d}x}\sqrt{1+x}\cong 2\frac{\mathrm{d}}{\mathrm{d}x}\left(1+\frac{1}{2}x-\frac{1}{2\cdot 4}x^2+\frac{1\cdot 3}{2\cdot 4\cdot 6}x^3\right)\\
&=1-\frac{1}{2}x+\frac{1\cdot 3}{2\cdot 4}x^2
\end{aligned} \tag{6.4.308}$$

8. Taylor-Maclaurin development of $f(x)=\sqrt{1-x^2}$ (that will be useful to us in the section of Astronomy):

Using the usual derivatives we have proved in the section of Differential and Integral Calculus we have:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}x}\left[\sqrt{1-x^2}\right]&=\frac{1}{2}\left(1-x^2\right)^{\frac{1}{2}-1}\cdot\frac{\mathrm{d}}{\mathrm{d}x}\left[1-x^2\right]=\frac{\frac{\mathrm{d}}{\mathrm{d}x}[1]-\frac{\mathrm{d}}{\mathrm{d}x}\left[x^2\right]}{2\sqrt{1-x^2}}\\&=\frac{0-2x}{2\sqrt{1-x^2}}=-\frac{x}{\sqrt{1-x^2}}\end{aligned}\tag{6.4.309}$$

And for the second derivative:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}x}\left[-\frac{x}{\sqrt{1-x^2}}\right]&=-\frac{\mathrm{d}}{\mathrm{d}x}\left[\frac{x}{\sqrt{1-x^2}}\right]=-\frac{\frac{\mathrm{d}}{\mathrm{d}x}[x]\cdot\sqrt{1-x^2}-x\cdot\frac{\mathrm{d}}{\mathrm{d}x}\left[\sqrt{1-x^2}\right]}{\left(\sqrt{1-x^2}\right)^2}\\&=-\frac{1\sqrt{1-x^2}-x\cdot\frac{1}{2}\left(1-x^2\right)^{\frac{1}{2}-1}\cdot\frac{\mathrm{d}}{\mathrm{d}x}\left[1-x^2\right]}{1-x^2}\\&=-\frac{\sqrt{1-x^2}-\frac{x\left(\frac{\mathrm{d}}{\mathrm{d}x}[1]-\frac{\mathrm{d}}{\mathrm{d}x}\left[x^2\right]\right)}{2\sqrt{1-x^2}}}{1-x^2}=-\frac{\sqrt{1-x^2}-\frac{x(0-2x)}{2\sqrt{1-x^2}}}{1-x^2}\\&=-\frac{\sqrt{1-x^2}+\frac{x^2}{\sqrt{1-x^2}}}{1-x^2}=-\frac{1}{\sqrt{1-x^2}}-\frac{x^2}{\left(1-x^2\right)^{\frac{3}{2}}}=-\frac{1}{\left(1-x^2\right)^{\frac{3}{2}}}\end{aligned}\tag{6.4.310}$$

and for the third derivative:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}x}\left[-\frac{1}{\left(1-x^2\right)^{\frac{3}{2}}}\right]&=-\left(-\frac{3}{2}\right)\left(1-x^2\right)^{-\frac{3}{2}-1}\cdot\frac{\mathrm{d}}{\mathrm{d}x}\left[1-x^2\right]\\&=\frac{3\left(\frac{\mathrm{d}}{\mathrm{d}x}[1]-\frac{\mathrm{d}}{\mathrm{d}x}\left[x^2\right]\right)}{2\left(1-x^2\right)^{\frac{5}{2}}}=\frac{3(0-2x)}{2\left(1-x^2\right)^{\frac{5}{2}}}=-\frac{3x}{\left(1-x^2\right)^{\frac{5}{2}}}\end{aligned}\tag{6.4.311}$$

and for the fourth and last derivative:

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}x}\left[-\frac{3x}{(1-x^2)^{\frac{5}{2}}}\right] &= -3\cdot\frac{\mathrm{d}}{\mathrm{d}x}\left[\frac{x}{(1-x^2)^{\frac{5}{2}}}\right] \\
&= -3\cdot\frac{\frac{\mathrm{d}}{\mathrm{d}x}[x]\cdot(1-x^2)^{\frac{5}{2}}-x\cdot\frac{\mathrm{d}}{\mathrm{d}x}\left[(1-x^2)^{\frac{5}{2}}\right]}{\left((1-x^2)^{\frac{5}{2}}\right)^2} \\
&= -\frac{3\left(1\,(1-x^2)^{\frac{5}{2}}-\frac{5}{2}\,(1-x^2)^{\frac{5}{2}-1}\cdot\frac{\mathrm{d}}{\mathrm{d}x}\,[1-x^2]\cdot x\right)}{(1-x^2)^5} \\
&= -\frac{3\left((1-x^2)^{\frac{5}{2}}-\frac{5\left(\frac{\mathrm{d}}{\mathrm{d}x}[1]-\frac{\mathrm{d}}{\mathrm{d}x}[x^2]\right)x\left(1-x^2\right)^{\frac{3}{2}}}{2}\right)}{(1-x^2)^5} \\
&= -\frac{3\left((1-x^2)^{\frac{5}{2}}-\frac{5(0-2x)x\left(1-x^2\right)^{\frac{3}{2}}}{2}\right)}{(1-x^2)^5} \\
&= -\frac{3\left((1-x^2)^{\frac{5}{2}}+5x^2\,(1-x^2)^{\frac{3}{2}}\right)}{(1-x^2)^5} = -\frac{3}{(1-x^2)^{\frac{5}{2}}}-\frac{15x^2}{(1-x^2)^{\frac{7}{2}}} \\
&= -\frac{12x^2+3}{(1-x^2)^{\frac{7}{2}}}
\end{aligned} \tag{6.4.312}$$

Therefore based on the above results:

$$\begin{aligned}
f'(x) &= \frac{\mathrm{d}\sqrt{1-x^2}}{\mathrm{d}x} = -\frac{x}{\sqrt{1-x^2}} \\
f''(x) &= -\frac{1}{(1-x^2)^{\frac{3}{2}}} \\
f'''(x) &= -\frac{3x}{(1-x^2)^{\frac{5}{2}}} \\
f''''(x) &= -\frac{12x^2+3}{(1-x^2)^{\frac{7}{2}}}
\end{aligned} \tag{6.4.313}$$

Therefore we have:

$$\begin{aligned}
f_4(x) &\cong \sqrt{1+x}\\
&\cong \sum_{k=0}^{4}\frac{1}{k!}\frac{\mathrm{d}^kP(0)}{\mathrm{d}x^k}x^k=\frac{1}{0!}\frac{\mathrm{d}^0P(0)}{\mathrm{d}x^0}x^0+\frac{1}{1!}\frac{\mathrm{d}^1P(0)}{\mathrm{d}x^1}x^1+\frac{1}{2!}\frac{\mathrm{d}^2P(0)}{\mathrm{d}x^2}x^2+\frac{1}{3!}\frac{\mathrm{d}^3P(0)}{\mathrm{d}x^3}x^3+\frac{1}{4!}\frac{\mathrm{d}^4P(0)}{\mathrm{d}x^4}x^4\\
&=\frac{1}{0!}\sqrt{1-x^2}|_{x=0}+\frac{1}{1!}\left.\frac{\mathrm{d}\sqrt{1-x^2}}{\mathrm{d}x}\right|_{x=0}x^1+\frac{1}{2!}\left.\frac{\mathrm{d}^2\sqrt{1-x^2}}{\mathrm{d}x^2}\right|_{x=0}x^2+\frac{1}{3!}\left.\frac{\mathrm{d}^3\sqrt{1-x^2}}{\mathrm{d}x^3}\right|_{x=0}x^3\\
&+\frac{1}{4!}\left.\frac{\mathrm{d}^4\sqrt{1-x^2}}{\mathrm{d}x^4}\right|_{x=0}x^4\\
&=\frac{1}{0!}\left.\sqrt{1-x^2}\right|_{x=0}x^0-\frac{1}{1!}\left.\frac{x}{\sqrt{1-x^2}}\right|_{x=0}x^1-\frac{1}{2!}\left.\frac{1}{(1-x^2)^{\frac{3}{2}}}\right|_{x=0}x^2-\frac{1}{3!}\left.\frac{3x}{2\,(1-x^2)^{\frac{7}{4}}}\right|_{x=0}x^3\\
&-\frac{1}{4!}\left.\frac{12x^2+3}{(1-x^2)^{\frac{7}{2}}}\right|_{x=0}x^4\\
&=\frac{1}{0!}-\frac{1}{2!}x^2-\frac{1}{4!}3x^4=1-\frac{x^2}{2}-\frac{x^3}{8}
\end{aligned}\tag{6.4.314}$$

9. Taylor-Maclaurin development of $f(x)=\ln(1+x)$:

   First remember that we have proved in the section of Differential and Integral Calculus that:

$$\begin{aligned}
f'(x)&=\frac{\mathrm{d}\ln(1+x)}{\mathrm{d}x}=\frac{1}{1+x}\\
f''(x)&=\frac{\mathrm{d}^2\ln(1+x)}{\mathrm{d}x^2}=\frac{\mathrm{d}}{\mathrm{d}x}\frac{1}{1+x}=-\frac{1}{(1+x)^2}\\
f'''(x)&=\frac{\mathrm{d}^3\ln(1+x)}{\mathrm{d}x^3}=\frac{\mathrm{d}\left(-\dfrac{1}{(1+x)^2}\right)}{\mathrm{d}x}=\frac{2}{(1+x)^3}
\end{aligned}\tag{6.4.315}$$

   Therefore we have:

$$\begin{aligned}
f_3(x)&\cong \ln(1+x)\\
&\cong\sum_{k=0}^{3}\frac{1}{k!}\frac{\mathrm{d}^kP(0)}{\mathrm{d}x^k}x^k=\frac{1}{0!}\frac{\mathrm{d}^0P(0)}{\mathrm{d}x^0}x^0+\frac{1}{1!}\frac{\mathrm{d}^1P(0)}{\mathrm{d}x^1}x^1+\frac{1}{2!}\frac{\mathrm{d}^2P(0)}{\mathrm{d}x^2}x^2+\frac{1}{3!}\frac{\mathrm{d}^3P(0)}{\mathrm{d}x^3}x^3\\
&=\frac{1}{0!}\ln(1+x)|_{x=0}+\frac{1}{1!}\left.\frac{\mathrm{d}\ln(1+x)}{\mathrm{d}x}\right|_{x=0}x^1+\frac{1}{2!}\left.\frac{\mathrm{d}^2\ln(1+x)}{\mathrm{d}x^2}\right|_{x=0}x^2+\frac{1}{3!}\left.\frac{\mathrm{d}^3\ln(1+x)}{\mathrm{d}x^3}\right|_{x=0}x^3\\
&=\frac{1}{0!}\left.\ln(1+x)\right|_{x=0}x^0+\frac{1}{1!}\left.\frac{1}{1+x}\right|_{x=0}x^1-\frac{1}{2!}\left.\frac{1}{(1+x)^2}\right|_{x=0}x^2+\frac{1}{3!}\left.\frac{2}{(1+x)^3}\right|_{x=0}x^3\\
&=\frac{1}{1!}x+\frac{1}{2!}x^2+\frac{2}{3!}x^3=x-\frac{1}{2}x^2+\frac{1}{3}x^3
\end{aligned}\tag{6.4.316}$$

10. Now let us consider the important case for the Langevin model of paramagnetism that is the approximated Taylor expansion of the hyperbolic cotangent function (see section Trigonometry page 2532), that is for refresh defined by the relation:

$$\coth(x)=\frac{e^x+e^{-x}}{e^x-e^{-x}}\tag{6.4.317}$$

For this, we will use the Landau notation, with expressions like $\mathcal{O}(x^n)$ remembering that we proved a little before above:

$$e^x = 1 + x + \frac{x^2}{2!} + \mathcal{O}(x^3) \tag{6.4.318}$$

when $x \to 0$. For the hyperbolic cotangent we have then:

$$\begin{aligned}\coth(x) = \frac{e^x + e^{-x}}{e^x - e^{-x}} &= \frac{1 + x + \frac{x^2}{2} + \mathcal{O}(x^3) + 1 - x + \frac{x^2}{2} + \mathcal{O}(x^3)}{1 + x + \frac{x^2}{2} + \frac{x^3}{3!} + \mathcal{O}(x^4) - 1 + x - \frac{x^2}{2} + \frac{x^3}{3!} + \mathcal{O}(x^4)} \\ &= \frac{2 + x^2 + \mathcal{O}(x^3)}{2x + \frac{x^3}{3} + \mathcal{O}(x^4)} = \frac{2 + x^2 + \mathcal{O}(x^3)}{2x} \underbrace{\frac{1}{1 + \frac{x^2}{6} + \mathcal{O}(x^3)}}_{:=A}\end{aligned} \tag{6.4.319}$$

Now we must remember as we have just proved a little earlier that:

$$\frac{1}{1+x} = 1 - x + x^2 - x^3 + \ldots \tag{6.4.320}$$

for $|x| < 1$. Therefore:

$$A = \frac{1}{1 + \left(\frac{x^2}{6} + \mathcal{O}(x^3)\right)} = 1 - \frac{x^2}{6} + \mathcal{O}(x^4) \tag{6.4.321}$$

and finally replacing this in the previous expression we find:

$$\begin{aligned}\coth(x) = \frac{e^x + e^{-x}}{e^x - e^{-x}} &= \frac{2 + x^2 + \mathcal{O}(x^3)}{2x}\left(1 - \frac{x^2}{6} + \mathcal{O}(x^4)\right) \\ &= \frac{1}{2x}\left(2 + x^2 - 2\frac{x^2}{6} + \mathcal{O}(x^4)\right) = \frac{1}{x} + \frac{x}{3} + \mathcal{O}(x^4)\end{aligned} \tag{6.4.322}$$

11. Another famous Maclaurin series used thousand of times in the world for business application is the computation of the numerical values of the Normal distribution:

$$\mathcal{N}(\mu, \sigma) = \frac{1}{\sigma\sqrt{2\pi}} \int_a^b e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2} \mathrm{d}x \tag{6.4.323}$$

So first to simplify this integral, we typically let:

$$z = \frac{x - \mu}{\sigma} \tag{6.4.324}$$

that we know already (see section Statistics page 595) as being the z score of a data value. With this simplification, the integral above becomes:

$$\mathcal{N}(0, 1) = \frac{1}{\sqrt{2\pi}} \int_{(a-\mu)/\sigma}^{(b-\mu)/\sigma} e^{-z^2} \mathrm{d}z \tag{6.4.325}$$

The Maclaurin series for $e^{-x^2/2}$ is given by:

$$\begin{aligned} e^{-x^2/2} &= \sum_{n=0}^{+\infty} \frac{\left(-\dfrac{x^2}{2}\right)^2}{n!} = 1 - \frac{x^2}{2^1 1!} + \frac{x^4}{2^2 2!} - \frac{x^6}{2^3 3!} + \ldots + (-1)^n \frac{x^{2n}}{2^n n!} + \ldots \\ &= \sum_{n=0}^{+\infty} (-1)^n \frac{x^{2n}}{2^n n!} \end{aligned} \tag{6.4.326}$$

Therefore:

$$\begin{aligned} &\frac{1}{\sqrt{2\pi}} \int e^{-z^2/2} \mathrm{d}z = \frac{1}{\sqrt{2\pi}} \int \left(1 - \frac{z^2}{2^1 1!} + \frac{z^4}{2^2 2!} - \frac{z^6}{2^3 3!} + \ldots + (-1)^n \frac{z^{2n}}{2^n n!} + \ldots\right) \mathrm{d}z \\ &= \frac{1}{\sqrt{2\pi}} \left(c^{te} + z - \frac{z^3}{3 \cdot 2^1 \cdot 1!} + \frac{z^5}{5 \cdot 2^2 \cdot 2!} - \frac{z^7}{7 \cdot 2^3 \cdot 3!} + \ldots + (-1)^n \frac{z^{2n+1}}{(2n+1) \cdot 2^n \cdot n!} + \ldots\right) \end{aligned} \tag{6.4.327}$$

Therefore:

$$\frac{1}{\sqrt{2\pi}} \int_{a'}^{b'} e^{-z^2/2} \mathrm{d}z = \frac{1}{\sqrt{2\pi}} \left(c^{te} + z - \frac{z^3}{3 \cdot 2^1 \cdot 1!} + \frac{z^5}{5 \cdot 2^2 \cdot 2!} - \ldots + (-1)^n \frac{z^{2n+1}}{(2n+1) \cdot 2^n \cdot n!} + \ldots\right)\Bigg|_{a'}^{b'} \tag{6.4.328}$$

It is obvious that the constant will eliminate itself. Therefore!

$$\frac{1}{\sqrt{2\pi}} \int_{a'}^{b'} e^{-z^2/2} \mathrm{d}z = \frac{1}{\sqrt{2\pi}} \left(z - \frac{z^3}{3 \cdot 2^1 \cdot 1!} + \frac{z^5}{5 \cdot 2^2 \cdot 2!} - \ldots + (-1)^n \frac{z^{2n+1}}{(2n+1) \cdot 2^n \cdot n!} + \ldots\right)\Bigg|_{a'}^{b'} \tag{6.4.329}$$

and in the common case in business where $a = 0$ we get (with two terms only):

$$\begin{aligned} &\frac{1}{\sqrt{2\pi}} \int_{-\mu/\sigma}^{(b-\mu)/\sigma} e^{-z^2/2} \mathrm{d}z \\ &= \frac{1}{\sqrt{2\pi}} \left(\left(\frac{b-\mu}{\sigma}\right) - \frac{\left(\dfrac{b-\mu}{\sigma}\right)^3}{3 \cdot 2^1 \cdot 1!} + \frac{\left(\dfrac{b-\mu}{\sigma}\right)^5}{5 \cdot 2^2 \cdot 2!} \right) \\ &- \frac{1}{\sqrt{2\pi}} \left(\left(\frac{-\mu}{\sigma}\right) - \frac{\left(\dfrac{-\mu}{\sigma}\right)^3}{3 \cdot 2^1 \cdot 1!} + \frac{\left(\dfrac{-\mu}{\sigma}\right)^5}{5 \cdot 2^2 \cdot 2!} \right) \end{aligned} \tag{6.4.330}$$

To summarize here is a table with the most important Maclaurin series:

Function	**Maclaurin approximation**
e^x	$\sum\limits_{n=0}^{+\infty}\dfrac{x^n}{n!}=1+\dfrac{x}{1!}+\dfrac{x^2}{2!}+\dfrac{x^3}{3!}+\cdots$
$\sin(x)$	$\sum_{n=0}^{\infty}(-1)^n\frac{x^{2n+1}}{(2n+1)!}=x-\frac{x^3}{3!}+\frac{x^5}{5!}-\frac{x^7}{7!}+\cdots$
$\cos(x)$	$\sum\limits_{n=0}^{+\infty}(-1)^n\dfrac{x^{2n}}{(2n)!}=1-\dfrac{x^2}{2!}+\dfrac{x^4}{4!}-\dfrac{x^6}{6!}+\cdots$
$\tan(x)$	$\sum\limits_{n=1}^{+\infty}\dfrac{(-1)^{n-1}2^{2n}\left(2^{2n}-1\right)B_{2n}x^{2n-1}}{(2n)!}=x+\dfrac{1}{3}x^3+\dfrac{2}{15}x^5+\dfrac{17}{315}x^7+\cdots$
$\tan^{-1}(x)$	$\sum\limits_{k=0}^{+\infty}\dfrac{(-1)^k x^{2k+1}}{2k+1}=x-\dfrac{x^3}{3}+\dfrac{x^5}{5}-\cdots+\dfrac{(-1)^k x^{2k+1}}{2k+1}+\cdots$, for $\lvert x\rvert\leq 1$
$(1+x)^k$	$\sum\limits_{n=0}^{+\infty}\begin{pmatrix}k\\n\end{pmatrix}x^n=1+kx+\dfrac{k(k-1)}{2!}x^2+\dfrac{k(k-1)(k-2)}{3!}x^3+\cdots$
$\ln(1+x)$	$\sum\limits_{k=1}^{+\infty}\dfrac{(-1)^{k+1}x^k}{k}=x-\dfrac{x^2}{2}+\dfrac{x^3}{3}-\cdots+\dfrac{(-1)^{k+1}x^k}{k}+\cdots$, for $-1<x\leq 1$
$-\ln(1-x)$	$\sum\limits_{k=1}^{+\infty}\dfrac{x^k}{k}=x+\dfrac{x^2}{2}+\dfrac{x^3}{3}+\cdots+\dfrac{x^k}{k}+\cdots$, for $-1\leq x<1$
$\dfrac{1}{1-x}$	$\sum\limits_{k=0}^{+\infty}x^k=1+x+x^2+\cdots+x^k+\cdots$, for $\lvert x\rvert<1$
$\dfrac{1}{1+x}$	$\sum\limits_{k=0}^{+\infty}(-1)^k x^k=1-x+x^2-\cdots+(-1)^k x^k+\cdots$, for $\lvert x\rvert<1$
$\sinh(x)$	$\sum\limits_{k=0}^{+\infty}\dfrac{x^{2k+1}}{(2k+1)!}=x+\dfrac{x^3}{3!}+\dfrac{x^5}{5!}+\cdots+\dfrac{x^{2k+1}}{(2k+1)!}+\cdots$, for $\lvert x\rvert<+\infty$
$\cosh(x)$	$\sum\limits_{k=0}^{+\infty}\dfrac{x^{2k}}{(2k)!}=1+\dfrac{x^2}{2!}+\dfrac{x^4}{4!}+\cdots+\dfrac{x^{2k}}{(2k)!}+\cdots$, for $\lvert x\rvert<+\infty$
$\sqrt{1+x}$	$1+\dfrac{1}{2}x-\dfrac{1}{2\cdot 4}x^2+\dfrac{1\cdot 3}{2\cdot 4\cdot 6}x^3+\cdots$
$\dfrac{1}{\sqrt{1+x}}$	$1-\dfrac{1}{2}x+\dfrac{1\cdot 3}{2\cdot 4}x^2+\cdots$
$\coth(x)$	$\dfrac{1}{x}+\dfrac{x}{3}-\dfrac{x^3}{45}+\dfrac{2x^5}{945}+\cdots+\dfrac{(-1)^{n-1}2^{2n}B_n x^{2n-1}}{(2n)!}+\cdots$, for $0<\lvert x\rvert<\pi$
$\dfrac{1}{\sqrt{2\pi}}\displaystyle\int_{\alpha'}^{\sigma'}e^{-z^2/2}\mathrm{d}z$	$\dfrac{1}{\sqrt{2\pi}}\left(z-\dfrac{z^3}{3\cdot 2^1\cdot 1!}+\dfrac{z^5}{5\cdot 2^2\cdot 2!}-\ldots+(-1)^n\dfrac{z^{2n+1}}{(2n+1)\cdot 2^n\cdot n!}+\ldots\right)\Bigg\rvert_{\alpha'}^{b}$

Table 6.16: **Most common Maclaurin series**

6.4.2.6.2 Taylor series of bivariate functions (multivariate Taylor series)

We will see now how to approach a function $f(x,y)$ of two real variables by a sum of powers (Taylor series). This type of approximation is widely used in many fields of engineering (see sections of Industrial Engineering page 8786 and Numerical Methods page 6673).

We are looking for an approximation of $f(x,y)$ at point $f(x_0+h,y_0+h)$. For this, let us write (a priori nothing prevents us from doing so) that:

$$x=x(t)=x_0+ht \qquad y=y(t)=y_0+kt \tag{6.4.331}$$

Then we have:

$$f(t)=f(x(t),y(t)) \tag{6.4.332}$$

The value of (the trick is here!):

$$f(1)=f(x(1),y(1))=f(x_0+h,y_0+k) \tag{6.4.333}$$

can be approximated using a Taylor series around the value 0 such that:

$$\begin{aligned}f(1)&=\sum_{k=0}^{n}\frac{1}{k!}\frac{{}^k f(t_0)}{\mathrm{d}t^k}(t-t_0)^k=\sum_{k=0}^{n}\frac{1}{k!}\frac{{}^k f(0)}{\mathrm{d}t^k}(1-0)^k=\sum_{k=0}^{n}\frac{1}{k!}\frac{{}^k f(0)}{\mathrm{d}t^k}\\&=f(0)+1\cdot\frac{\mathrm{d}f}{\mathrm{d}t}(0)+\frac{1}{2!}\frac{\mathrm{d}^2f}{\mathrm{d}t^2}(0)+\ldots+\frac{1}{n!}\frac{\mathrm{d}^nf}{\mathrm{d}t^n}(0)\\&=f(x_0,y_0)+1\cdot\frac{\mathrm{d}f(x(t),y(t))}{\mathrm{d}t}(0)+\frac{1}{2!}\frac{\mathrm{d}^2f(x(t),y(t))}{\mathrm{d}t^2}(0)+\ldots+\frac{1}{n!}\frac{\mathrm{d}^nf(x(t),y(t))}{\mathrm{d}t^n}(0)\end{aligned} \tag{6.4.334}$$

But we have:

$$\begin{aligned}\frac{\mathrm{d}f(x(t),y(t))}{\mathrm{d}t}&=\frac{\dfrac{\partial f}{\partial x}\mathrm{d}x+\dfrac{\partial f}{\partial y}\mathrm{d}y}{\mathrm{d}t}=\frac{\dfrac{\partial f}{\partial x}\mathrm{d}(x_0+ht)+\dfrac{\partial f}{\partial y}\mathrm{d}(y_0+kt)}{\mathrm{d}t}=\frac{\dfrac{\partial f}{\partial x}h\mathrm{d}t+\dfrac{\partial f}{\partial y}k\mathrm{d}t}{\mathrm{d}t}\\&=\frac{\partial f}{\partial x}h+\frac{\partial f}{\partial y}k=\left(h\frac{\partial}{\partial x}+k\frac{\partial}{\partial y}\right)f\end{aligned} \tag{6.4.335}$$

and:

$$\begin{aligned}\frac{\mathrm{d}^2f(x(t),y(t))}{\mathrm{d}t^2}&=\frac{\mathrm{d}\left(\mathrm{d}f(x(t),y(t))\right)}{\mathrm{d}t^2}=\frac{\dfrac{\partial(\mathrm{d}x)}{\partial x}\mathrm{d}x+\dfrac{\partial(\mathrm{d}f)}{\partial y}\mathrm{d}f}{\mathrm{d}t^2}\\&=\frac{\partial\left(\dfrac{\partial f}{\partial x}\mathrm{d}x+\dfrac{\partial f}{\partial y}\mathrm{d}y\right)+\mathrm{d}y\dfrac{\partial}{\partial y}\left(\dfrac{\partial f}{\partial x}\mathrm{d}x+\dfrac{\partial f}{\partial y}\mathrm{d}y\right)}{\mathrm{d}t^2}\\&=\frac{\left[(\mathrm{d}x)^2\dfrac{\partial^2f}{\partial x^2}+\mathrm{d}x\mathrm{d}y\dfrac{\partial^2f}{\partial x\partial y}\right]+\left[\mathrm{d}x\mathrm{d}y\dfrac{\partial^2f}{\partial y\partial x}+(\mathrm{d}y)^2\dfrac{\partial^2f}{\partial y^2}\right]}{\mathrm{d}t^2}\end{aligned} \tag{6.4.336}$$

According to Schwarz's theorem (see section Differential and Integral Calculus page 1469):

$$\frac{\partial^2f}{\partial y\partial x}=\frac{\partial^2f}{\partial x\partial y} \tag{6.4.337}$$

Then we have:

$$\begin{aligned}\frac{\mathrm{d}^2 f(x(t),y(t))}{\mathrm{d}t^2}&=\frac{(\mathrm{d}x)^2\dfrac{\partial^2 f}{\partial x^2}+2\mathrm{d}x\mathrm{d}y\dfrac{\partial^2 f}{\partial x\partial y}+(\mathrm{d}y)^2\dfrac{\partial^2 f}{\partial y^2}}{\mathrm{d}t^2}=\frac{\left(\dfrac{\partial}{\partial x}\mathrm{d}x+\dfrac{\partial}{\partial y}\mathrm{d}y\right)^2 f}{\mathrm{d}t^2}\\&=\left(h\frac{\partial}{\partial x}+k\frac{\partial}{\partial y}\right)^2 f\end{aligned}\tag{6.4.338}$$

and we show by induction that:

$$\frac{\mathrm{d}^n f(x(t),y(t))}{\mathrm{d}t^2}=\left(h\frac{\partial}{\partial x}+k\frac{\partial}{\partial y}\right)^n f\tag{6.4.339}$$

Therefore we finally get:

$$\begin{aligned}f(x_0+h,y_0+k)&=f(x_0,y_0)+1\cdot\frac{\mathrm{d}f(x(t),y(t))}{\mathrm{d}t}(0)+\frac{1}{2!}\frac{\mathrm{d}^2 f(x(t),y(t))}{\mathrm{d}t^2}(0)+\ldots\\&=f(x_0,y_0)+\frac{1}{1!}\left(h\frac{\partial f}{\partial x}+k\frac{\partial f}{\partial y}\right)(0)+\frac{1}{2!}\left(h\frac{\partial}{\partial x}+k\frac{\partial}{\partial y}\right)^2(0)+\ldots\\&=f(x_0,y_0)+\frac{1}{1!}\frac{\partial f}{\partial x}(x_0,y_0)h+\frac{1}{1!}\frac{\partial f}{\partial y}(x_0,y_0)k\\&+\frac{1}{2!}\left[\frac{\partial^2 f}{\partial x^2}(x_0,y_0)h^2+2\frac{\partial^2 f}{\partial x\partial y}(x_0,y_0)hk+\frac{\partial^2 f}{\partial y^2}(x_0,y_0)k^2\right]\end{aligned}\tag{6.4.340}$$

or in another equivalent simplified form:

$$\boxed{\begin{aligned}f(x_0+h,y_0+k)=f(x_0,y_0)+\frac{1}{1!}\frac{\partial f}{\partial x}(x_0,y_0)h+\frac{1}{1!}\frac{\partial f}{\partial y}(x_0,y_0)k\\+\frac{1}{2!}\left[\frac{\partial^2 f}{\partial x^2}(x_0,y_0)h^2+2\frac{\partial^2 f}{\partial x\partial y}(x_0,y_0)hk+\frac{\partial^2 f}{\partial y^2}(x_0,y_0)k^2\right]\end{aligned}}\tag{6.4.341}$$

Or if we define a matrix H named "Hessian matrix" given by:

$$H=\begin{bmatrix}\dfrac{\partial^2 f}{\partial x^2} & \dfrac{\partial^2 f}{\partial x\partial y}\\ \dfrac{\partial^2 f}{\partial y\partial x} & \dfrac{\partial^2 f}{\partial y^2}\end{bmatrix}\tag{6.4.342}$$

we can also write:

$$f(x_0+h,y_0+k)=f(x_0,y_0)+\frac{\partial f}{\partial x}(x_0,y_0)h+\frac{\partial f}{\partial y}(x_0,y_0)k+\frac{1}{2!}(h\;k)H\begin{pmatrix}h\\k\end{pmatrix}\tag{6.4.343}$$

In Maple™ 4.00b we use the following command to make a development of order 3 around 0:

```
>readlib(mtaylor):
>mtaylor(f(x,y), [x,y], 3);
```

✍**Example:**

Let us see an example with the quite famous "humpback whale function":

```
>with(plots):  with(plottools):
>readlib(mtaylor):
>fct:=x^2*(4-2.1*x^2+1/3*x^4)+x*y+y^2*(-4+4*y^2);
>poly2 :=mtaylor(fct,[x=1,y=1],6);
>#Convert all the coefficients to floating point numbers
>poly2n := map(evalf,poly2):
>gr1:= plot3d(poly2n,x=-2..2,y=-1..1,color=red):
>gr2:= plot3d(fct,x=-2..2,y=-1..1,color=blue):
>display3d(gr1,gr2,view=-3..8,axes=framed);
```

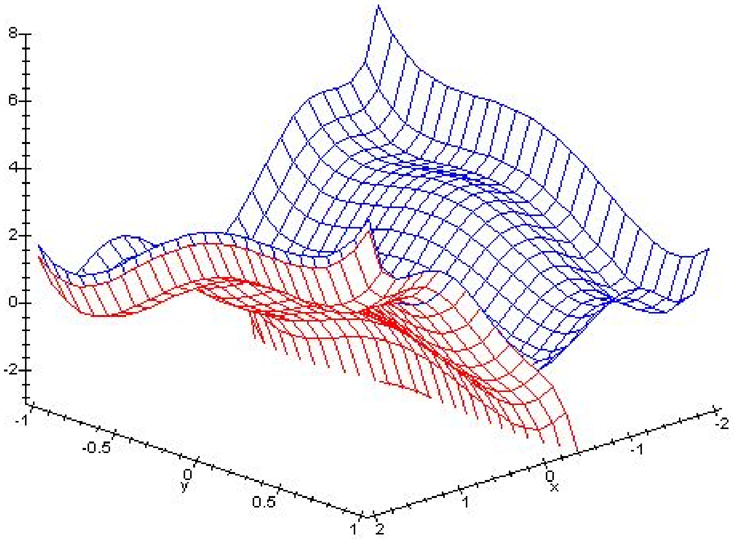


Figure 6.74: **Bivariate Taylor example in Maple™ 4.00b**

The previous relation can also be written in the multivariate case in a point $\vec{x}$ near the origin of the coordinate system $\vec{p}$ as following (common notation in computer science):

$$f(\vec{x})=f(\vec{p})+\sum_i \frac{\partial f}{\partial x_i}x_i+\frac{1}{2}\sum_{i,j}\frac{\partial^2 f}{\partial x_i \partial x_j}x_i x_j+\ldots \cong c-\vec{b}\circ\vec{x}+\frac{1}{2}\vec{x}\circ(H\vec{x}) \tag{6.4.344}$$

where:

$$c:=f(\vec{p}) \qquad \vec{b}:=\vec{\nabla}(\vec{f})|_P \qquad H_{ij}:=\left.\frac{\partial^2 f}{\partial x_i \partial x_j}\right|_P \tag{6.4.345}$$

6.4.2.6.3 Quadratic Form

Now we will need for the section of Numerical Methods to state an important property (which would have also its place only in the section of Differential and Integral Calculus):

Let f be a function defined and derived over an interval I and given a an element of I. If f is such that $f'(a)=0$ then we say it has a "local extremum" on a.

Remark

The reciprocal is false, the function x^3 is such an example. Its derivative is zero at 0 but there is no local extreme at this point. So be careful!

However, let f be a function defined and derived over an interval I and given a an element of I. If f is such that $f'(a)=0$ and if f' changes sign in a then f has a local extremum at a.

To return now to our bivariate development Taylor, we know that if (x_0,y_0) is a local extremum of f then we have in a first time (see section Differential and Integral Calculus page 1717):

$$\frac{\partial f}{\partial x}(x_0,y_0)=\frac{\partial f}{\partial y}(x_0,y_0)=0 \tag{6.4.346}$$

However we have seen that this condition is not sufficient to ensure that (x_0,y_0) is a local extremum.

Reconsider the Taylor expansion of f above taking into account the above condition. Development simplifies then to:

$$f(x_0+h,y_0+h)=f(x_0,y_0)+\frac{1}{2}\left[\frac{\partial^2 f}{\partial x^2}(x_0,y_0)h^2+2\frac{\partial^2 f}{\partial x\partial y}(x_0,y_0)hk+\frac{\partial^2}{\partial y^2}(x_0,y_0)k^2\right] \tag{6.4.347}$$

Then we know that by definition so that the (x_0,y_0) is a local minimum (respectively a local maximum) it is sufficient that the expression in brackets is positive (respectively negative). Since the second derivatives of f are continuous, it is sufficient that the expression:

$$\boxed{q:=\frac{\partial^2 f}{\partial x^2}(x_0,y_0)h^2+2\frac{\partial^2 f}{\partial x\partial y}(x_0,y_0)hk+\frac{\partial^2}{\partial y^2}(x_0,y_0)k^2} \tag{6.4.348}$$

to be positive (negative resp.) regardless of h or k and it is zero only if $h=k=0$. Then we say that q is a "positive definite quadratic form (resp. negative definite)".

To simplify the notations and to comply with traditions we put now:

$$a=\frac{\partial^2 f}{\partial x^2}(x_0,y_0),b=\frac{\partial^2 f}{\partial x\partial y}(x_0,y_0),c=\frac{\partial^2}{\partial y^2}(x_0,y_0),h=\Delta x,k=\Delta y \tag{6.4.349}$$

Then we can rewrite q as follows:

$$\begin{aligned}q(\Delta x,\Delta y)&=a\Delta x^2+2b\Delta x\Delta y+c\Delta y^2\\&=\frac{ac-b^2}{a}\Delta y^2+a\left(\Delta x+\frac{b\Delta y}{a}\right)^2=\frac{1}{a}\det(H)\Delta y^2+a\left(\Delta x+\frac{b\Delta y}{a}\right)^2\end{aligned} \tag{6.4.350}$$

where H remains the Hessian matrix of f evaluated on (x_0, y_0).

So we see that q is positive definite (local minimum) if $a > 0$ and $\det(H) > 0$, negative definite (local maximum) if $a < 0$ and $\det(H) > 0$. In other words everything is determined by what is commonly denoted in many textbooks:

$$\det(H) = D = \begin{vmatrix} f_{xx} & f_{xy} \\ f_{yx} & f_{yy} \end{vmatrix} = f_{xx}f_{yy} - f_{xy}^2 \tag{6.4.351}$$

Returning to the partial derivatives these conditions named "second derivative test" are described as follows:

- Positive definite (local minimum) if:

  $$\frac{\partial^2 f}{\partial x^2}(x_0, y_0) > 0 \text{ and } \det(H) = \frac{\partial^2}{\partial x^2}(x_0, y_0)\frac{\partial^2}{\partial y^2}(x_0, y_0) - \left(\frac{\partial^2}{\partial y \partial x}(x_0, y_0)\right)^2 > 0 \tag{6.4.352}$$

  Or in condensed form:

  $$\frac{\partial^2 f}{\partial x^2} > 0, \text{ and } \frac{\partial^2 f}{\partial x^2}\frac{\partial^2 f}{\partial y^2} > \left(\frac{\partial^2 f}{\partial x \partial y}\right)^2 \tag{6.4.353}$$

- Negative definite (local maximum) if:

  $$\frac{\partial^2 f}{\partial x^2}(x_0, y_0) < 0 \text{ and } \det(H) = \frac{\partial^2}{\partial x^2}(x_0, y_0)\frac{\partial^2}{\partial y^2}(x_0, y_0) - \left(\frac{\partial^2}{\partial y \partial x}(x_0, y_0)\right)^2 > 0 \tag{6.4.354}$$

  Or in condensed form:

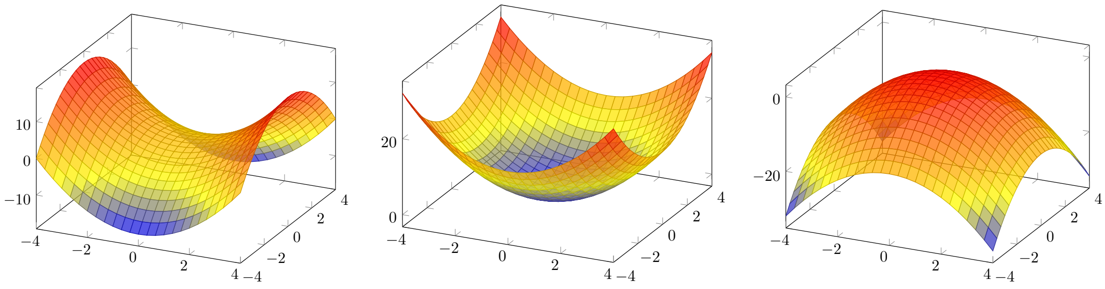
  $$\frac{\partial^2 f}{\partial x^2} < 0, \quad \text{and} \quad \frac{\partial^2 f}{\partial x^2}\frac{\partial^2 f}{\partial y^2} > \left(\frac{\partial^2 f}{\partial x \partial y}\right)^2 \tag{6.4.355}$$

- Indefinite (saddle point) if:

  $$\det(H) = \frac{\partial^2}{\partial x^2}(x_0, y_0)\frac{\partial^2}{\partial y^2}(x_0, y_0) - \left(\frac{\partial^2}{\partial y \partial x}(x_0, y_0)\right)^2 < 0 \tag{6.4.356}$$

  Or in condensed form:

  $$\frac{\partial^2 f}{\partial x^2}\frac{\partial^2 f}{\partial y^2} < \left(\frac{\partial^2 f}{\partial x \partial y}\right)^2 \tag{6.4.357}$$



(a) Saddle point (b) Local minimum (c) Local maximum

Figure 6.75: **Types of stationary points (second derivative test of quadratic forms)**

Finally we see that the sign of the determinant of Hessian matrix and that of $\dfrac{\partial^2 f}{\partial x^2}(x_0,y_0)$ allow us to get a sufficient condition to determine if we are in the presence of a local extremum.

If we now consider a general 2×2 symmetric matrix:

$$A=\begin{bmatrix} a & b\\ b & c\end{bmatrix} \tag{6.4.358}$$

It should be almost obvious to the reader that this matrix induces, in the sense of the Hessian matrix, the quadratic form:

$$\mathrm{Q}_A(x,y)=ax^2+2bxy+cy^2 \tag{6.4.359}$$

If $y=0$, then we have $\mathrm{Q}_A(x,0)=ax^2$ (parabola), so we must certainly have $a>0$ in order for A to be positive definite.

The following examples illustrate that in general, it cannot easily be determined whether a symmetric matrix is positive definite from inspection of the entries.

✍**Examples:**

E1. As first example, consider the matrix:

$$A=\begin{bmatrix} 1 & 4\\ 4 & 1\end{bmatrix} \tag{6.4.360}$$

Then:

$$\mathrm{Q}_A(x,y)=x^2+y^2+8xy \tag{6.4.361}$$

and we have whatever (x_0,y_0):

$$\dfrac{\partial^2 f}{\partial x^2}(x_0,y_0)>0 \text{ but } \det(H)=\dfrac{\partial^2}{\partial x^2}(x_0,y_0)\dfrac{\partial^2}{\partial y^2}(x_0,y_0)-\left(\dfrac{\partial^2}{\partial y\partial x}(x_0,y_0)\right)^2<0 \tag{6.4.362}$$

Therefore, even though all of the entries of A are positive, A is not positive definite.

E2. Consider the matrix:

$$A=\begin{bmatrix} 1 & -1\\ -1 & 4\end{bmatrix} \tag{6.4.363}$$

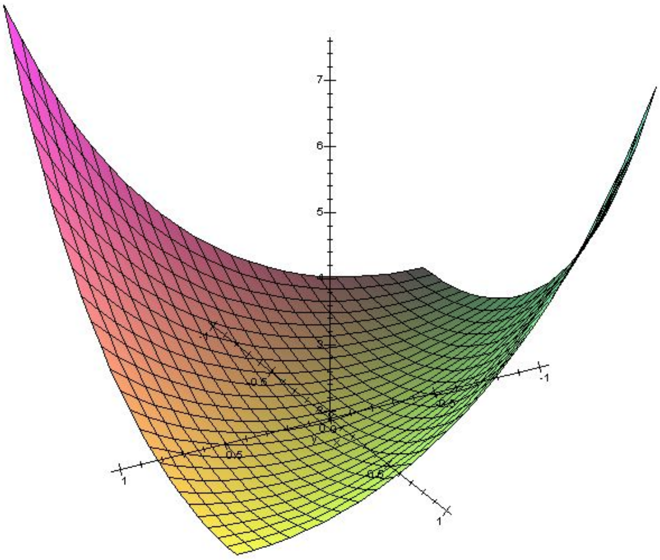
Then:

$$\mathrm{Q}_A(x,y)=x^2+4y^2-2xy=x^2-2xy+y^2+3y^2=(x-y)^2+3y^2 \tag{6.4.364}$$

which can be seen to be always non-negative. Furthermore, $\mathrm{Q}_A(x,y)=0$ if and only if $x=y$ and $y=0$, so for all non-zero vectors (x,y), $\mathrm{Q}_A(x,y)>0$ and A is positive definite, even though A does not have all positive entries.

E3. Let:

$$f(x,y) = e^{x-y} + e^{y-x} \qquad (6.4.365)$$



We have:

$$\vec{\nabla} f(x,y) = (e^{x-y} - e^{y-x}, -e^{x-y} + e^{y-x}) \qquad (6.4.366)$$

which yields the critical points (x,x) for all $x \in \mathbb{R}$. We also have:

$$\mathrm{H}f(x,y,z) = \begin{bmatrix} e^{x-y} + e^{y-x} & -e^{x-y} - e^{y-x} \\ -e^{x-y} - e^{y-x} & e^{x-y} + e^{y-x} \end{bmatrix} \qquad (6.4.367)$$

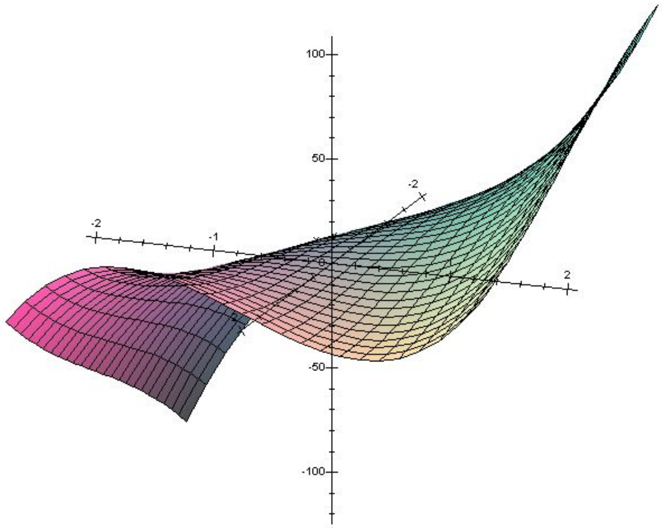
which yields:

$$\Delta_1 = e^{x-y} + e^{y-x} > 0, \quad \Delta_2 = (e^{x-y} + e^{y-x})^2 - (-e^{x-y} - e^{y-x})^2 = 0 \qquad (6.4.368)$$

That is, $\mathrm{H}f(x,x)$, is positive semidefinite, making (x,x) a global minimizer of $f(x,y)$.

E4. Let:

$$f(x,y) = x^3 - 12xy + 8y^3 \qquad (6.4.369)$$



We have:

$$\nabla f(x,y)=(3x^2-12y,\quad -12x+24y^2) \tag{6.4.370}$$

which yields the critical points $(0,0)$ and $(2,1)$. We also have:

$$\mathrm{H}f(x,y)=\begin{bmatrix} 6x & -12 \\ -12 & 48x \end{bmatrix} \tag{6.4.371}$$

and therefore:

$$\mathrm{H}f(0,0)=\begin{bmatrix} 0 & -12 \\ -12 & 0 \end{bmatrix},\quad \mathrm{H}f(2,1)=\begin{bmatrix} 12 & -12 \\ -12 & 48 \end{bmatrix} \tag{6.4.372}$$

We see that $\mathrm{H}f(2,1)$ is positive definite, because its principal minors are positive, but $\mathrm{H}f(0,0)$ is not, as $\Delta_1=0$ and $\Delta_2=-144$. That is, $\mathrm{H}f(0,0)$ is indefinite, so $(0,0)$ is a saddle point.

Furthermore:

$$\lim_{x\to+\infty} f(x,y)=+\infty,\quad \lim_{x\to-\infty} f(x,y)=-\infty \tag{6.4.373}$$

so $f(x,y)$ has no global minimizer on $\mathbb{R}^2$. We can conclude, however, that $(2,1)$ is a strict local minimizer.

It should be emphasized that if the Hessian is positive semidefinite or negative semidefinite at a critical point, then it cannot be concluded that the critical point is necessarily a minimizer, maximizer or saddle point of the function.

6.4.2.6.4 Lagrange Remainder

There may be an interest for some numerical applications (see section Numerical Methods page 6272) to know the approximation error of the polynomial $P_n(x)$ in relation to the function $f(x), \forall x$.

Let us define for this purpose a "remainder", such that:

$$R_n(x) = f(x) - P_n(x) \tag{6.4.374}$$

The function $R_n(x)$ is named "Lagrange rest" or "Lagrange remainder" or "Lagrange error".

Theorem 6.22. Now consider a function $f(x)$ which is $(n+1)$ times differentiable on an interval that contains x_0. For a value x of the interval, different from x_0, we propose to prove that there exists a number z situated between x_0 and x such that:

$$\boxed{R_n(x) = \frac{f^{(n+1)}(z)}{(n+1)!}(x-x_0)^{n+1}} \tag{6.4.375}$$

Proof 6.22.1. Given a function $g(t)$ defined by the difference of a function $f(x)$ assumed to be known and a Taylor approximation of the same function:

$$\begin{aligned} g(t) =& f(x) - \left(f(t) + \frac{f'(t)}{1!}(x-t) + \frac{f''(t)}{2!}(x-t)^2 + \cdots + \frac{f^{(n)}(t)}{n!}(x-t)^n + \frac{f^{(n+1)}(t)}{(n+1)!}(x-t)^{(n+1)}\right) \\ =& f(x) - \left(f(t) + \frac{f'(t)}{1!}(x-t) + \frac{f''(t)}{2!}(x-t)^2 + \cdots + \frac{f^{(n)}(t)}{n!}(x-t)^n - R_n(x)\frac{(x-t)^{n+1}}{(x-x_0)^{n+1}}\right) \end{aligned} \tag{6.4.376}$$

with, of course:

$$R_n(x)\frac{1}{(x-x_0)^{n+1}} = \frac{f^{(n+1)}(x-t)}{(n+1)!} \tag{6.4.377}$$

We see that $g(t)$ vanishes as expected for value $t = x$.

Now let us derive $g(t)$ with respect to t, we find:

$$\begin{aligned} g'(t) =& -f'(t) - f'(t)(-1) - f''(t)(x-t) - f''(t)(x-t)(-1) + \frac{f''(t)}{2}(x-t)^2 \\ &+ \cdots - \frac{f^{(n+1)}(t)}{n!}(x-t)^n + R_n(x)(n+1)\frac{(x-t)^n}{(x-x_0)^{n+1}} \end{aligned} \tag{6.4.378}$$

After simplification:

$$g'(t) = -\frac{f^{(n+1)}(t)}{n!}(x-t)^n + R_n(x)(n+1)\frac{(x-t)^n}{(x-x_0)^{n+1}} \tag{6.4.379}$$

According to Rolle's theorem (see section Differential and Integral Calculus page 1459), there exist a value $t = z$ for which the derivative $g'(t)$ is zero. So:

$$0 = -\frac{f^{(n+1)}(z)}{n!}(x-z)^n + R_n(x)(n+1)\frac{(x-z)^n}{(x-x_0)^{n+1}} \tag{6.4.380}$$

We can simplify the equation by $(x-z)^n$:

$$R_n(x)\frac{(n+1)}{(x-x_0)^{n+1}}-\frac{f^{(n+1)}(z)}{n!}=0 \tag{6.4.381}$$

which can also be written as:

$$R_n(x)-\frac{f^{(n+1)}(z)}{(n+1)!}(x-x_0)^{n+1}=0 \tag{6.4.382}$$

so we find for the maximum of R_n:

$$R_n(x)=\frac{f^{(n+1)}(z)}{(n+1)!}(x-x_0)^{n+1} \tag{6.4.383}$$

■ Q.E.D.

We see that as the polynomial $P_n(x)$ is of high degree, the more it approximates the function $f(x)$ with accuracy. What will happen when $n\rightarrow+\infty$?:

$$P_n(x)=\sum_{k=0}^{+\infty}\frac{f^{(k)}(x_0)}{k!}(x-x_0)^k \tag{6.4.384}$$

Suppose that $f(x)$ has derivatives of all orders (what we denote for reminder $\mathcal{C}^n$) for all values of any interval containing x_0 and let the rest of Lagrange R_n of $f(x)$ on x_0. If, for any x in the range:

$$\lim_{n\rightarrow+\infty}R_n(x)=0 \tag{6.4.385}$$

then $f(x)$ is exactly represented by $P(x)$ on the interval.

Proof 6.22.2. The proof simply stems from the expression of $P_n(x)$ when $n\rightarrow+\infty$.

Indeed, if we take an infinity of terms for $P_n(x)$, the correspondence with the approximated function is perfect and so the rest is zero.

■ Q.E.D.

The polynomial:

$$\boxed{P(x)=\sum_{k=0}^{+\infty}\frac{f^{(k)}(x_0)}{k!}(x-x_0)^k} \tag{6.4.386}$$

is named "Taylor polynomial" or "Taylor series". If $x_0=0$, it is named "Maclaurin polynomial" or "Maclaurin series".

6.4.2.6.5 Taylor Series with Integral Remainder

We'll see if a theorem that will be useful in the section of Statistics to link the Poisson and Chi-2 laws and that is used in statistical software for Poisson test of rare events (that is the only business practical application that is known to us at this day).

Remark

If anyone has a more educational proof whose beginning is a little less "formula fell from the sky", we are takers!

Theorem 6.23. Let $f(x)$ be $n+1$ times differentiable on the interval $[a,b]$. Then we have:

$$\boxed{f(b)-f(a)=(b-a)f'(a)+\frac{(b-a)^2}{2!}f''(a)+\ldots+\frac{(b-a)^n}{n!}f^{(n)}(a)+\frac{1}{k!}\int_a^b(b-t)^k f^{(k+1)}(t)\mathrm{d}t} \tag{6.4.387}$$

where it is important (for the good understanding of what we will do in the section of Statistics) that the reader notices in the development that when the derivative stops at the n-th term in the series, the integral (the remainder) has a factor of $1/n!$, a power n and a derivative of order $n+1$. So verbatim, as we shall prove it below, if we stop the development of the terms to $n-1$, the integral (the remainder) will have a factor of $1/(n-1)!$, a power $n-1$ and a derivative of order n-th.

Proof 6.23.1. The proof is made by induction. We first consider the formula fallen from the sky:

$$f(b)-f(a)=(b-a)f'(a)+\frac{(b-a)^2}{2!}f''(a)+\ldots+\frac{(b-a)^n}{n!}f^{(n)}(a)+\frac{1}{k!}\int_a^b(b-t)^k f^{(k+1)}(t)\mathrm{d}t \tag{6.4.388}$$

We show that it is correct for $k=0$, then we do an induction on k for $k\in\mathbb{N}$.

For $k=0$, we have the well-known relation (see section Differential and Integral Calculus page 1509):

$$f(b)-f(a)=\int f'(t)\mathrm{d}t \tag{6.4.389}$$

Suppose the property true for $k<n$:

$$f(b)-f(a)=(b-a)f'(a)+\frac{(b-a)^2}{2!}f''(a)+\ldots+\frac{(b-a)^n}{n!}f^{(n)}(a)+\frac{1}{k!}\int_a^b(b-t)^k f^{(k+1)}(t)\mathrm{d}t \tag{6.4.390}$$

We integrate by parts (see section Differential and Integral Calculus page 1532) the term:

$$\frac{1}{k!}\int_a^b(b-t)^k f^{(k+1)}(t)\mathrm{d}t \tag{6.4.391}$$

Then we have:

$$\frac{1}{k!}\int\limits_a^b (b-t)^k f^{(k+1)}(t)\mathrm{d}t = \left[-\frac{1}{(k+1)!}(b-t)^{k+1}f^{(k+1)(t)}\right]_a^b + \frac{1}{(k+1)!}\int\limits_a^b (b-t)^{k+1}f^{(k+2)}(t)\mathrm{d}t \tag{6.4.392}$$

Therefore:

$$\begin{gathered} f(b)-f(a)= \\ (b-a)f'(a)+\frac{(b-a)^2}{2!}f''(a)+\ldots+\frac{(b-a)^{k+1}}{(k+1)!}f^{(k+1)}(a)+\frac{1}{(k+1)!}\int\limits_a^b (b-t)^{k+1}f^{(k+2)}(t)\mathrm{d}t \end{gathered} \tag{6.4.393}$$

■ Q.E.D.

6.4.2.6.6 Lagrange inversion theorem

In mathematical analysis, the "Lagrange inversion theorem", also known as the "Lagrange–Bürmann formula", gives the Taylor series expansion of the inverse function of an analytic function.

For information, this theorem was proved by Lagrange and generalized by Hans Heinrich Bürmann, both in the late 118th century (holocene calendar). There is a straightforward derivation using complex analysis and contour integration too. Here we will use an even simpler derivation found by Pierre-Simon de Laplace during the same period in 11780 (holocene calendar).

This theorem will be useful to us during our derivation of the Equation of Time and its corresponding famous analemma (see page 5404).

Lagrange's inversion theorem gives the series expansion of an implicitly defined function. The application of this theorem allows, among other things, to obtain a numerical solution to Kepler's equation $\hat{E}=\hat{M}+e\sin(\hat{E})$ (see 5404), or to write useful expansions of the two-body problem.

Here is how the theorem is stated:

Theorem 6.24. Let y be a function of two variables x and α and of an infinitely differentiable function f of the form: $y=x+\alpha f(y)$ with α small.

Then:

$$y=x+\sum_{k=1}^{+\infty}\frac{\alpha^k}{k!}\frac{\partial^{k-1}}{\partial x^{k-1}}f^k(x) \tag{6.4.394}$$

So how said before, we propose here to prove it by a method based on partial derivatives, revealed by Pierre-Simon Laplace.

Proof 6.24.1. We start by developing $y(x,\alpha)$ at the neighbourhood of $\alpha = 0$.

For this we use the univariate Taylor series proved earlier above and we get:

$$y(x,\alpha=0)=\sum_{k\geq 0}\frac{\alpha^k}{k!}\frac{\partial^k}{\partial\alpha^k}y(x,0)=x+\sum_{k\geq 1}\frac{\alpha^k}{k!}\frac{\partial^k}{\partial\alpha^k}y(x,0) \tag{6.4.395}$$

Now we need also to prove first an intermediate result, i.e.:

$$\frac{\partial y}{\partial\alpha}=f(y)\frac{\partial y}{\partial x} \tag{6.4.396}$$

For this we start from $y=x+\alpha f(y)$, and rearrange it as:

$$y(x,\alpha)-x-\alpha f(y(x,\alpha))=0 \tag{6.4.397}$$

Therefore:

$$\frac{\partial y}{\partial x}-1-\alpha\frac{\partial f}{\partial y}\frac{\partial y}{\partial x}=0\Longleftrightarrow\frac{\partial y}{\partial x}\left[1-\alpha f'(y)\right]=1 \tag{6.4.398}$$

and respectively:

$$\frac{\partial y}{\partial\alpha}-f(y(x,\alpha))-\alpha\frac{\partial f}{\partial y}\frac{\partial y}{\partial\alpha}=0\Longleftrightarrow\frac{\partial y}{\partial\alpha}\left[1-\alpha f'(y)\right]=f(y)=1\cdot f(y) \tag{6.4.399}$$

Hence mixing both results:

$$\frac{\partial y}{\partial\alpha}\left[1-\alpha f'(y)\right]=\frac{\partial y}{\partial x}\left[1-\alpha f'(y)\right]f(y) \tag{6.4.400}$$

After simplification:

$$\frac{\partial y}{\partial\alpha}=f(y)\frac{\partial y}{x} \tag{6.4.401}$$

Now we need a second intermediate result, i.e., that fact that for $n>0$, we have:

$$\frac{\partial^n y}{\partial\alpha^n}=\frac{\partial^{n-1}}{\partial x^{n-1}}\left(f^n(y)\cdot\frac{\partial y}{\partial x}\right) \tag{6.4.402}$$

To prove this we will use the first intermediate result in the physicist/engineer way (...):

$$\frac{\partial^2 y}{\partial\alpha^2}=\frac{\partial}{\partial\alpha}\left(\frac{\partial y}{\partial\alpha}\right)=\frac{\partial}{\partial\alpha}\left(f(y)\frac{\partial y}{\partial x}\right)=f(y)\frac{\partial}{\partial x}\left(f(y)\frac{\partial y}{\partial x}\right)=\frac{\partial}{\partial x}\left(f^2(y)\frac{\partial y}{\partial x}\right) \tag{6.4.403}$$

Therefore by recurrence:

$$\frac{\partial^n y}{\partial\alpha^n}=\frac{\partial^{n-1}}{\partial x^{n-1}}\left(f^n(y)\cdot\frac{\partial y}{\partial x}\right) \tag{6.4.404}$$

Now with this result we can go the final step! Notice that for $(x,0)$ we have:

$$y=x+\alpha f(y)=x \tag{6.4.405}$$

Therefore:

$$\frac{\partial y}{\partial x}=1 \tag{6.4.406}$$

and using the relation we just got by recurrence:

$$\frac{\partial^n}{\partial \alpha^n}y(x,0)=\frac{\partial^{n-1}}{\partial x^{n-1}}\left(f^n(x)\right) \tag{6.4.407}$$

and from earlier above:

$$y(x,\alpha=0)=x+\sum_{k\geq 1}\frac{\alpha^k}{k!}\frac{\partial^k}{\partial \alpha^k}y(x,0) \tag{6.4.408}$$

we get finally (keep in mind that's for α near zero!):

$$\boxed{y=x+\sum_{k=1}^{+\infty}\frac{\alpha^k}{k!}\frac{\partial^{k-1}}{\partial x^{k-1}}f^k(x)} \tag{6.4.409}$$

■ Q.E.D.

6.4.2.7 Fourier Series (trigonometric series)

Definitions (#6.4.223): We name "trigonometric series" a series of the form:

$$a_0\cdot\cos(0\cdot x)+b_0\cdot\sin(0\cdot x)+a_1\cdot\cos(x)+b_1\cdot\sin(x)+\cdots a_n\cdot\cos(nx)+b_0\cdot\sin(nx) \tag{6.4.410}$$

or in a more compact form:

$$\sum_{n=0}^{+\infty}\left(a_n\cos(nx)+b_0\sin(nx)\right) \tag{6.4.411}$$

The constants a_n,b_n with $n\in\mathbb{N}^*$ are the coefficients of the trigonometric series usually named "Fourier coefficients".

Remark

We have already mentioned this type of series in our study of the types of existing polynomials since Fourier series are in fact only trigonometric polynomials (see section Calculus page 1397). Furthermore, we saw as example in the section of Functional Analysis during our study of scalar functional product that the sine and cosine functions were the bases of a vector space!

If the series converges, its sum is a periodic function $f(x)$ of period $T=2\pi$, since $\sin(nx)$ and $\cos(nx)$ are periodic functions of period 2π. So that:

$$f(x)=f(x+2\pi) \tag{6.4.412}$$

Let us now state the following problem: We give ourselves a known periodic function $f(x)$, piece-wise continuous of period 2π. We ask ourselves if there is a trigonometric series converging to $f(x)$ under some conditions that must be satisfied on this series.

Suppose now that the function $f(x)$, periodic and of period 2π, can be effectively represented by a trigonometric series converging to $f(x)$ in the interval $[0,T]$, that is to say it the sum of this series:

$$f(x)=\sum_{n=0}^{+\infty}\big(a_n\cos(nx)+b_n\sin(nx)\big) \tag{6.4.413}$$

Suppose that the integral of the function of the left member of this equality is equal to the sum of the integral of all the terms of the above series. This will occur, for example, if we assume that the proposed trigonometric series converges absolutely, that is to say, the numerical series converges (by the property that the trigonometric functions are bounded):

$$|a_0|+|b_0|+|a_1|+|b_1|+|a_2|+|b_2|+\ldots+|a_n|+|b_n| \tag{6.4.414}$$

The series:

$$f(x)=\sum_{n=0}^{+\infty}\big(a_n\cos(nx)+b_n\sin(nx)\big) \tag{6.4.415}$$

is then majorable and can be integrated term by term from 0 to T (where $T=2\pi$) which allows us to determine the different Fourier coefficients. But before we start let us present the following integrals that will be very useful later:

$$\text{(I)}\begin{cases}\displaystyle\int_0^T\cos(nx)\cos(kx)\mathrm{d}x=0\\ \displaystyle\int_0^T\cos(nx)\sin(kx)\mathrm{d}x=0\\ \displaystyle\int_0^T\sin(nx)\sin(kx)\mathrm{d}x=0\end{cases}\qquad\text{(II)}\begin{cases}\displaystyle\int_0^T\cos^2(kx)\mathrm{d}x=\frac{T}{2}\\ \displaystyle\int_0^T\cos(kx)\sin(kx)\mathrm{d}x=0\\ \displaystyle\int_0^T\sin^2(kx)\mathrm{d}x=\frac{T}{2}\end{cases} \tag{6.4.416}$$

with $n,k\in\mathbb{N}$ and $n\neq k$ with $n,k\in\mathbb{N}$ and $n=k$

Before continuing, let us prove the value taken by these six integrals (following the request of readers). But first, remember that as $n,k\in\mathbb{N}$ then:

$$(n+k)=w\in\mathbb{N}\quad\text{and}\quad(n-k)=v\in\mathbb{Z} \tag{6.4.417}$$

1. We proceed using the remarkable trigonometric relations (see section Trigonometry page 2519) and the primitive of elementary trigonometric functions (see section Differential

and Integral Calculus page 1534):

$$\begin{aligned}\int\limits_0^T \cos(nx)\cos(kx)\mathrm{d}x &= \frac{1}{2}\int\limits_0^T \big(\cos(nx+kx)+\cos(nx-kx)\big)\mathrm{d}x\\ &= \frac{1}{2}\left(\frac{\sin(nx+kx)}{n+k}-\frac{\sin(nx-kx)}{n-k}\right)\Bigg|_0^T\\ &= \frac{1}{2}\left(\frac{\sin(nx+kx)}{n+k}-\frac{\sin((n-k)x)}{n-k}\right)\Bigg|_0^T\\ &= \frac{1}{2}\left(\frac{\sin(wx)}{w}-\frac{\sin(vx)}{v}\right)\Bigg|_0^T\\ &= \frac{1}{2}\left(\frac{\sin(wT)}{w}-\frac{\sin(vT)}{v}\right)-\frac{1}{2}\left(\frac{\sin(w0)}{w}-\frac{\sin(v0)}{v}\right)\\ &= \frac{1}{2}\left(\frac{\sin(wT)}{w}-\frac{\sin(vT)}{v}\right)=\frac{1}{2}\left(\frac{0}{w}-\frac{0}{v}\right)=0\end{aligned} \tag{6.4.418}$$

because as we have seen it in the section Trigonometry $\sin(k\pi)=0, k\in\mathbb{Z}$ and as $T=2\pi$ the two previous differences have all terms equal to zero such that at the end:

$$\int\limits_0^T \cos(nx)\cos(kx)\mathrm{d}x=0 \tag{6.4.419}$$

2. For the second integral, we proceed using the same techniques and the same properties of trigonometric functions:

$$\begin{aligned}\int\limits_0^T \cos(nx)\sin(kx)\mathrm{d}x &= \frac{1}{2}\int\limits_0^T \big(\sin(nx+kx)+\sin(nx-kx)\big)\mathrm{d}x\\ &= \frac{1}{2}\left(-\frac{\cos(nx+kx)}{n+k}-\frac{\cos(nx-kx)}{n-k}\right)\Bigg|_0^T\\ &= \frac{1}{2}\left(-\frac{\cos(wx)}{w}-\frac{\cos(vx)}{v}\right)\Bigg|_0^T\\ &= \frac{1}{2}\left(-\frac{\cos(wT)}{w}-\frac{\cos(vT)}{v}\right)-\frac{1}{2}\left(-\frac{\cos(w0)}{w}-\frac{\cos(v0)}{v}\right)\\ &= \frac{1}{2}\left(-\frac{1}{w}-\frac{1}{v}\right)-\frac{1}{2}\left(-\frac{1}{w}-\frac{1}{v}\right)\\ &= \frac{1}{2}\left[\left(-\frac{1}{w}-\frac{1}{v}\right)-\left(-\frac{1}{w}-\frac{1}{v}\right)\right]=0\end{aligned} \tag{6.4.420}$$

3. And we continue like this also for the third one, according to the same properties:

$$\begin{aligned}\int_0^T \sin(nx)\sin(kx)\mathrm{d}x &= \frac{1}{2}\int_0^T \big(\cos(nx-kx)-\cos(nx+kx)\big)\mathrm{d}x\\ &= \frac{1}{2}\left(\frac{\sin(nx-kx)}{n-k}-\frac{\sin(nx+kx)}{n+k}\right)\Bigg|_0^T\\ &= \frac{1}{2}\left(\frac{\sin(vx)}{v}-\frac{\sin(wx)}{w}\right)\Bigg|_0^T\\ &= \frac{1}{2}\left(\frac{\sin(vT)}{v}-\frac{\sin(wT)}{w}\right)-\frac{1}{2}\left(\frac{\sin(v0)}{v}-\frac{\sin(w0)}{w}\right)=0\end{aligned} \tag{6.4.421}$$

4. Once gain using the same methods (this becomes routine ...) first for $k \neq 0$:

$$\begin{aligned}\int_0^T \cos^2(kx)\mathrm{d}x &= \int_0^T \left(\frac{1+\cos(2kx)}{2}\right))\mathrm{d}x\\ &= \frac{1}{2}\int_0^T \mathrm{d}x+\frac{1}{2}\int_0^T \cos(2kx)\mathrm{d}x\\ &= \frac{1}{2}x\Big|_0^T+\frac{1}{4k}\sin(2kx)\Big|_0^T\\ &= \frac{1}{2}(T-0)+\frac{1}{4k}\big(\sin(2kT)-\sin(2k\cdot 0)\big)\\ &= \frac{1}{2}T+\frac{1}{4k}(0-0)=\frac{T}{2}\end{aligned} \tag{6.4.422}$$

and for $k=0$ it comes immediately:

$$\int_0^T \cos^2(0\cdot x)\mathrm{d}x = \int_0^T \mathrm{d}x = T \tag{6.4.423}$$

5. Again ... (soon finish...) first for $k \neq 0$:

$$\begin{aligned}\int_0^T \cos(kx)\sin(kx)\mathrm{d}x &= \frac{1}{2}\int_0^T \big(\sin(kx+kx)+\sin(kx-kx)\big)\mathrm{d}x = \frac{1}{2}\int_0^T \sin(2kx)\mathrm{d}x\\ &= \frac{1}{2}\left(-\frac{\cos(2kx)}{2k}\right)\Bigg|_0^T = -\frac{1}{4}\left(\frac{\cos(2kx)}{k}\right)\Bigg|_0^T\\ &= -\frac{1}{4}\left(\frac{\cos(2kT)}{k}-\frac{\cos(2k\cdot 0)}{k}\right) = -\frac{1}{4}\left(\frac{1}{k}-\frac{1}{k}\right)=0\end{aligned} \tag{6.4.424}$$

and for $k=0$ it comes immediately:

$$\int_0^T \cos(kx)\sin(kx)\mathrm{d}x = 0 \tag{6.4.425}$$

6. And finally the last (...):

$$\begin{aligned}\int\limits_0^T \sin^2(kx)\mathrm{d}x=\int\limits_0^T\left(\frac{1-\cos(2kx)}{2}\right)\mathrm{d}x&=\frac{1}{2}\int\limits_0^T\mathrm{d}x-\frac{1}{2}\int\limits_0^T\cos(2kx)\mathrm{d}x\\ &=\frac{1}{2}x\bigg|_0^T-\frac{1}{2k}\sin(2kx)\bigg|_0^T\\ &=\frac{1}{2}(T-0)-\frac{1}{2k}\big(\sin(2kT)-\sin(2k\cdot 0)\big)=\frac{1}{2}T+\frac{1}{2k}(0-0)\\ &=\frac{T}{2}\end{aligned}\tag{6.4.426}$$

This small work done let us now come back on our topic... To determine the coefficients a_n both members of equality:

$$f(x)=\sum_{n=0}^{+\infty}\big(a_n\cos(nx)+b_n\sin(nx)\big)\tag{6.4.427}$$

by $\cos(kx)$:

$$f(x)\cos(kx)=\sum_{n=0}^{+\infty}\big(a_n\cos(nx)\cos(kx)+b_n\sin(nx)\cos(nx)\big)\tag{6.4.428}$$

The series of the second member of equality is majorable, since its terms do not exceed in absolute to the terms of the positive convergent series. So we can integrate term by term on every bounded segment 0 to T:

$$\int\limits_0^T f(x)\cos(kx)\mathrm{d}x=\sum_{n=0}^{+\infty}\left(a_n\int\limits_0^T\cos(nx)\cos(kx)\mathrm{d}x+b_n\int\limits_0^T\sin(nx)\cos(nx)\mathrm{d}x\right)\tag{6.4.429}$$

We have proved above that whatever the integer values that take k or n the second term in the parenthesis is always zero. It then remains only:

$$\int\limits_0^T f(x)\cos(kx)\mathrm{d}x=\sum_{n=0}^{+\infty}\cos(nx)\cos(kx)\mathrm{d}x\tag{6.4.430}$$

But we have proved above that the integral on the right is always zero if n and k are different. This leaves only the case where n and k are equal. Meaning:

$$\int\limits_0^T f(x)\cos(kx)\mathrm{d}x=a_k\int\limits_0^T\cos(kx)\cos(kx)\mathrm{d}x=a_k\int\limits_0^T\cos^2(kx)\mathrm{d}x\tag{6.4.431}$$

In this situation, we first the special case where k is zero. In that case:

$$\int\limits_0^T f(x)\mathrm{d}x=a_0\int\limits_0^T\mathrm{d}x=a_0T\tag{6.4.432}$$

Therefore:

$$a_0 = \frac{1}{T}\int_0^T f(x)\mathrm{d}x \qquad (6.4.433)$$

It is obvious that the coefficient a_0 represents the average of the signal or of its DC component, if it exists.

In the case where k it is not zero, we have:

$$\int_0^T f(x)\cos(kx)\mathrm{d}x = a_k \int_0^T \cos^2(kx)\mathrm{d}x = a_k\frac{T}{2} \qquad (6.4.434)$$

Therefore:

$$a_k = \frac{2}{T}\int_0^T f(x)\cos(kx)\mathrm{d}x \qquad (6.4.435)$$

To determine the coefficients b_n we proceed the same way but this time multiplying both members of equality by $\sin(kx)$:

$$f(x)\sin(kx) = \sum_{n=0}^{+\infty}\big(a_n\cos(nx)\sin(kx) + b_n\sin(nx)\sin(kx)\big) \qquad (6.4.436)$$

The series of the second member of equality is majorable because its terms are not higher in absolute values to the terms in the convergent positive series. So we can integrate term by term on every bounded segment from 0 to T:

$$\int_0^T f(x)\sin(kx)\mathrm{d}x = \sum_{n=0}^{+\infty}\left(a_n\int_0^T \cos(nx)\sin(kx)\mathrm{d}x + b_n\int_0^T \sin(nx)\sin(kx)\mathrm{d}x\right) \qquad (6.4.437)$$

We have proved before that whatever are the integer values that taken by k or n the first term of the parenthesis is always zero. It remains then only:

$$\int_0^T f(x)\sin(kx)\mathrm{d}x = \sum_{n=0}^{+\infty}\left(b_n\int_0^T \sin(nx)\sin(kx)\mathrm{d}x\right) \qquad (6.4.438)$$

But we have proved before that the integral on the right is always zero if n and k are different. This leaves only the case where n and k are equal. Meaning:

$$\int_0^T f(x)\sin(kx)\mathrm{d}x = b_k\int_0^T \sin(kx)\sin(kx)\mathrm{d}x = b_k\int_0^T \sin^2(kx)\mathrm{d}x \qquad (6.4.439)$$

In this situation, we first have the special case where k is zero. But we see now that we have a zero indeterminacy. It is better to consider the general case from which have:

$$\int_0^T f(x)\sin(kx)\mathrm{d}x = b_k\int_0^T \sin^2(kx)\mathrm{d}x = b_k\frac{T}{2} \qquad (6.4.440)$$

Hence we easily derive that:

$$b_k = \frac{2}{T}\int_0^T f(x)\sin(kx)\mathrm{d}x \tag{6.4.441}$$

Therefore, for the situation where k is zero the coefficient is therefore equal to zero!

So finally the Fourier coefficients are determined by the integrals:

$$a_0 = \frac{1}{T}\int_0^T f(x)\mathrm{d}x \qquad a_n = \frac{2}{T}\int_0^T f(x)\cos(nx)\mathrm{d}x \qquad b_n = \frac{2}{T}\int_0^T f(x)\sin(nx)\mathrm{d}x \tag{6.4.442}$$

But as it's annoying to have three results for the coefficients we'll play a little with the definition of the Fourier series.

Indeed by summing from 1 to $+\infty$, rather than 0 to $+\infty$, we have:

$$\boxed{f(x) = \frac{a_0}{2} + \sum_{n=1}^{+\infty}\big(a_n\cos(nx) + b_n\sin(nx)\big)} \tag{6.4.443}$$

This then allows us only to have to remember (a_0 therefore included!):

$$\boxed{a_n = \frac{2}{T}\int_0^T f(x)\cos(nx)\mathrm{d}x} \qquad \boxed{b_n = \frac{2}{T}\int_0^T f(x)\sin(nx)\mathrm{d}x} \tag{6.4.444}$$

Physicists have for habit to write the last two relations as follows:

$$\begin{aligned}
a_k &= \frac{2}{T}\int_{-\frac{T}{2}}^{\frac{T}{2}} f(t)\cos\left(\frac{2\pi}{T}kt\right)\mathrm{d}t = \frac{2}{T}\int_{-\frac{T}{2}}^{\frac{T}{2}} f(t)\cos(\omega kt)\mathrm{d}t\\
b_k &= \frac{2}{T}\int_{-\frac{T}{2}}^{\frac{T}{2}} f(t)\sin\left(\frac{2\pi}{T}kt\right)\mathrm{d}t = \frac{2}{T}\int_{-\frac{T}{2}}^{\frac{T}{2}} f(t)\sin(\omega kt)\mathrm{d}t
\end{aligned} \tag{6.4.445}$$

The possible decomposition of any periodic piecewise continuous function approximated by an infinite sum of trigonometric functions (sine or cosine) consisting of a basic function and its harmonics is named "Fourier theorem" or "Fourier-Dirichlet theorem".

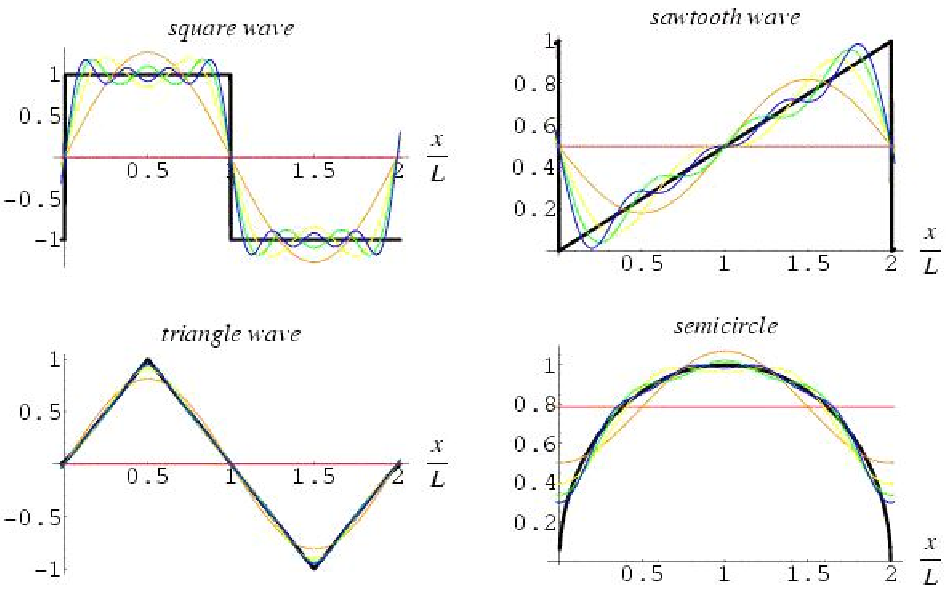


Figure 6.76: **Examples of some Fourier series (source: Mathworld)**

It can also happen that sometimes we know the Fourier series and we are looking for the original function $f(x)$. As a companion example consider that we want to calculate:

$$\sum_{n=1}^{+\infty}\frac{1}{n}\cos(nx) \tag{6.4.446}$$

So this is like searching the original $f(x)$ of the above Fourier series.

It follows therefore that $a_0=0$ and $b_n=0$ and:

$$\frac{1}{n}=a_n=\frac{2}{T}\int\limits_0^T f(x)\cos(nx)\mathrm{d}x \tag{6.4.447}$$

But as far as we know there is no easy way to extract $f(x)$ that seems accurate! So using hyperbolic trigonometry (see section Trigonometry page 2532), we write:

$$f(x)=\sum_{n=1}^{+\infty}\frac{1}{n}\cos(nx)=\frac{1}{2}\sum_{n=1}^{+\infty}\frac{e^{inx}}{n}+\frac{1}{2}\sum_{n=1}^{+\infty}\frac{e^{-inx}}{n} \tag{6.4.448}$$

Now these power series may be identifies as Maclaurin expansions of $-\ln(1-z)$ (see proof above) with $z=e^{\mathrm{i}x}$ for the first term and $z=e^{-\mathrm{i}x}$ for the second term.

Therefore:

$$\begin{aligned}f(x)=\sum_{n=1}^{+\infty}\frac{1}{n}\cos(nx)&=-\frac{1}{2}\left[\ln(1-e^{\mathrm{i}x})+\ln(1-e^{-\mathrm{i}x})\right]\\&=-\ln\left((1-e^{\mathrm{i}x})(1+e^{-\mathrm{i}x})\right)^{1/2}=-\ln\left(1-e^{-\mathrm{i}x}-e^{\mathrm{i}x}+e^{\mathrm{i}x}e^{-\mathrm{i}x}\right)^{1/2}\\&=-\ln\left(2-e^{-\mathrm{i}x}-e^{\mathrm{i}x}\right)^{1/2}=-\ln\left(2-2\cos(x)\right)^{1/2}=-\ln\left(2\sin\left(\frac{x}{2}\right)\right)\end{aligned} \tag{6.4.449}$$

The Fourier series allows implicitly to represent all the frequencies in a periodical signal whose function is known mathematically (closed form). We can wonder why talk about Fourier series when, in practice, we do not really know the mathematical representation of a signal? This will bring us to a better understanding of the concept of the Fourier transform in discrete-time that we will see a little further, which does not need a mathematical representation of a continuous and periodic signal.

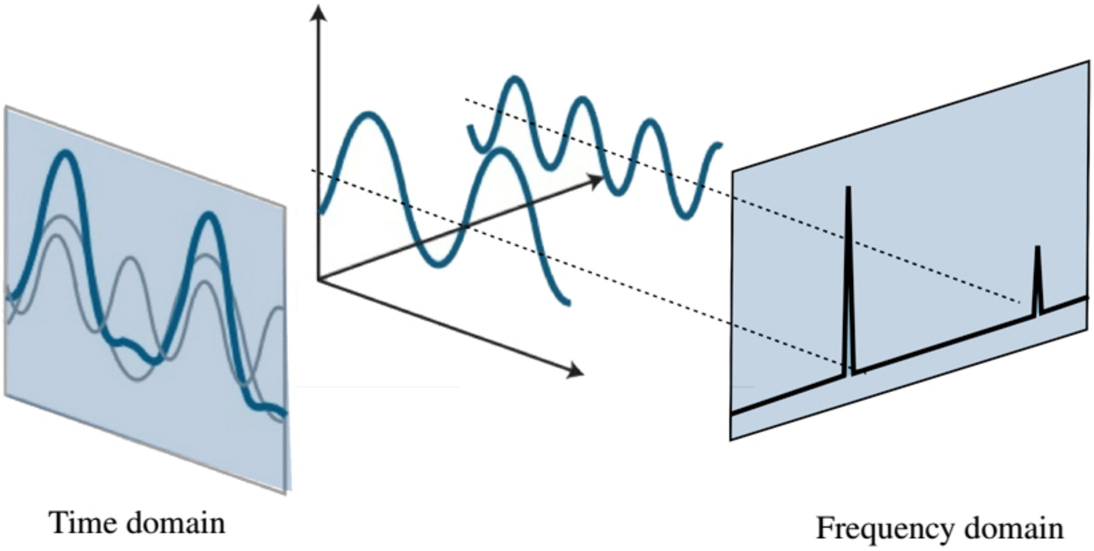

Figure 6.77: Time and frequency domain

We notice also that if $f(x)$, that is to say the periodic function of which we seek expression in trigonometric Fourier series, is even then the series will also be even and thus contain only cosine terms (the cosine function being an even function) implying that $b_n=0$ and otherwise in the case of an odd function $a_n=0$ (the sine being for reminder an odd function)!

It should be noted, and this is important for what will follow, that as we have seen in the section of Calculus during our study of trigonometric polynomials (see page 1397), Fourier series could be written in the following complex form (by changing some notations and passing the sum to infinity):

$$f(x)=\sum_{n=-\infty}^{+\infty} c_n e^{inx} \qquad (6.4.450)$$

and we have seen that (always in the section of Calculus) that:

$$a_0=2c_0 \qquad a_n=c_n+c_{-n} \qquad b_n=\mathrm{i}(c_n-c_{-n}) \qquad (6.4.451)$$

Therefore:

$$c_n=\frac{a_n-\mathrm{i}b_n}{2} \qquad (6.4.452)$$

This gives us:

$$\begin{aligned}c_n &= \frac{\dfrac{2}{T}\displaystyle\int_0^T f(x)\cos(nx)\mathrm{d}x - \dfrac{2}{T}\mathrm{i}\int_0^T f(x)\sin(nx)\mathrm{d}x}{2}\\ &= \frac{1}{T}\int_0^T f(x)\big(\cos(nx)-\mathrm{i}\sin(nx)\big)\mathrm{d}x\\ &= \frac{1}{T}\int_0^T f(x)e^{-\mathrm{i}nx}\mathrm{d}x\end{aligned} \tag{6.4.453}$$

Therefore:

$$c_n = \frac{1}{T}\int_0^T f(x)e^{-\mathrm{i}nx}\mathrm{d}x \tag{6.4.454}$$

Or more generally:

$$\boxed{c_n = \frac{1}{T}\int_{t_0}^{T+t_0} f(x)e^{-\mathrm{i}nx}\mathrm{d}x} \tag{6.4.455}$$

So if we take the famous case where $t_0 = -T/2$ we get:

$$c_n = \frac{1}{T}\int_{-T/2}^{T/2} f(x)e^{-\mathrm{i}nx}\mathrm{d}x \tag{6.4.456}$$

Obviously the two relation above are the Fourier coefficient in the "time space" (or "time domain") point of view. We will see in the section of Electrical Engineering that there is an equivalent if we work with Fourier series in the frequency space (or "frequency domain").

✍**Examples:**

E1. Upon decomposition of a continuous signal, we say (improperly at our point of view) that the coefficients a_n, b_n are each (implicitly) a separate frequency associated with an amplitude that we visualize on a graph by vertical lines. This graph shows the "frequency spectrum" of the decomposed signal. We can also add another representation which is named "phase spectrum". This spectrum gives us the phase of the harmonic signal (in phase advance or delay).

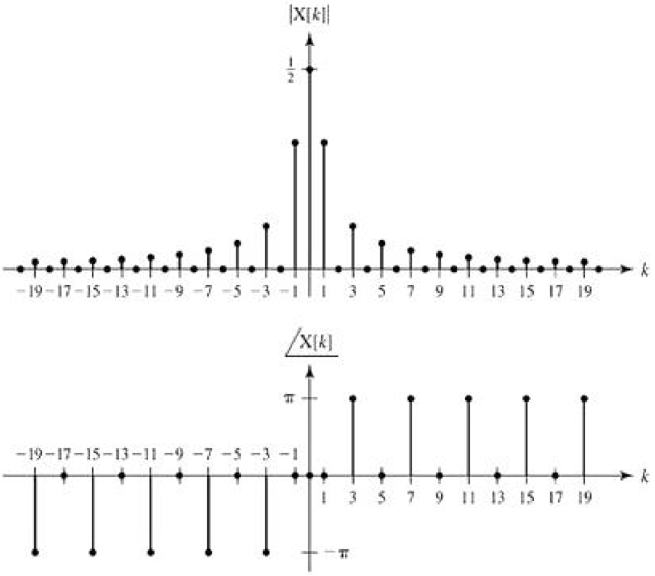

Figure 6.78: Example of amplitudes and frequencies associated to the different coefficients

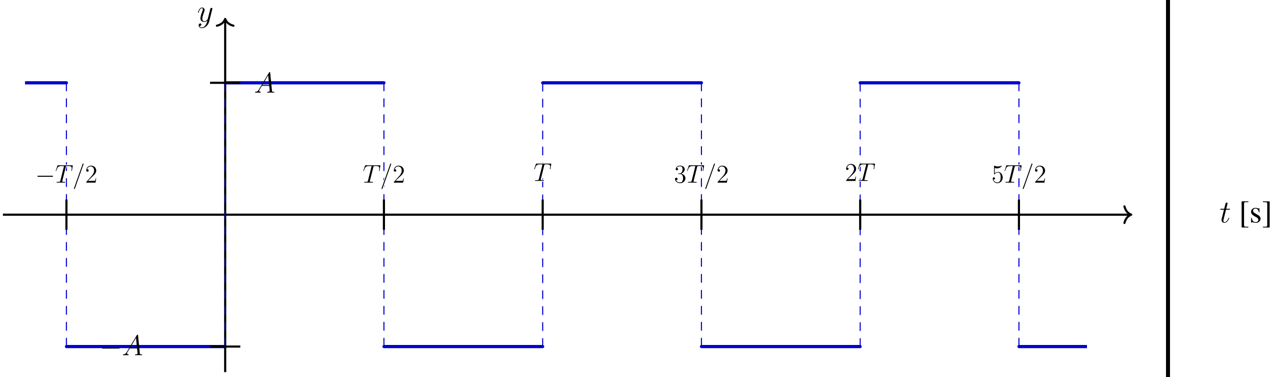
Let us see now how to decompose a known periodic signal into several distinct amplitudes and frequencies signals.

Let us take for example, a periodic square wave (or "rectangular wave") signal defined over a period $T=2$ and of amplitude A such that:

$$f(t)=\begin{cases}-A & -1<t<0\\ A & 0<t<1\end{cases} \tag{6.4.457}$$



At period $T=2$ corresponds as we know a pulsation:

$$\omega=\frac{2\pi}{T}=\pi \tag{6.4.458}$$

Let us calculate first the coefficients c_k thanks to the integral that determine the coefficients (the choice of the bounds of the integral is therefore assumed that the signal is periodic by construction!):

$$\begin{aligned}c_k&=\frac{1}{T}\int\limits_{T} f(t)e^{-\mathrm{i}kwt}\mathrm{d}t=\frac{1}{2}\int\limits_{-1}^{1} f(t)e^{-\mathrm{i}k\pi t}\mathrm{d}t=\frac{1}{2}\left(\int\limits_{-1}^{0}-Ae^{-\mathrm{i}k\pi t}\mathrm{d}t+\int\limits_{0}^{1}Ae^{-\mathrm{i}k\pi t}\mathrm{d}t\right)\\&=\frac{-A}{2}\left(\int\limits_{-1}^{0}e^{-\mathrm{i}k\pi t}\mathrm{d}t-\int\limits_{0}^{1}e^{-\mathrm{i}k\pi t}\mathrm{d}t\right)=\frac{-A}{2}\left(\frac{-1}{ik\pi}\right)\left[e^{-\mathrm{i}k\pi t}\Big|_{-1}^{0}\right]+\frac{A}{2}\left(\frac{-1}{\mathrm{i}k\pi}\right)\left[e^{-\mathrm{i}k\pi t}\Big|_{0}^{1}\right]\\&=\frac{A}{2\mathrm{i}k\pi}\left[1-e^{-\mathrm{i}k\pi}\right]-\frac{A}{2\mathrm{i}k\pi}\left[e^{-\mathrm{i}k\pi}-1\right]=\frac{A}{2}\left[\frac{1-e^{-\mathrm{i}k\pi}}{\mathrm{i}k\pi}+\frac{e^{-\mathrm{i}k\pi}-1}{-\mathrm{i}k\pi}\right]\\&=\frac{A}{\mathrm{i}k\pi}\left[1-\frac{1}{2}\left(e^{\mathrm{i}k\pi}+e^{-\mathrm{i}k\pi}\right)\right]=\frac{A}{\mathrm{i}k\pi}\left[1-\cos(k\pi)\right]\end{aligned}\tag{6.4.459}$$

Taking $k=2$, we have:

$$c_2=\frac{A}{i2\pi}\left[1-\frac{1}{2}\left(e^{\mathrm{i}2\pi}+e^{-\mathrm{i}2\pi}\right)\right]=0\tag{6.4.460}$$

Similarly for $k=4,6,8$ and for any even number.

About odd numbers, we will have:

$$c_1=\frac{A}{\mathrm{i}\pi}\left[1-\frac{1}{2}\left(e^{\mathrm{i}\pi}+e^{-\mathrm{i}\pi}\right)\right]=\frac{2A}{\mathrm{i}\pi},\qquad c_3=\frac{A}{\mathrm{i}3\pi}\left[1-\frac{1}{2}\left(e^{\mathrm{i}3\pi}+e^{-\mathrm{i}3\pi}\right)\right]=\frac{2A}{\mathrm{i}3\pi}\tag{6.4.461}$$

The coefficients will then be:

$$c_k=\begin{cases}0 & k\text{ even}\\ \dfrac{2A}{\mathrm{i}k\pi} & k\text{ odd}\end{cases}\tag{6.4.462}$$

There is only problem in this relations, the coefficient c_0 cannot be calculated according to this relation because you can see that if $k=0$ in the result above, we have an infinite value and it is at least impossible. The coefficient is null or not null but never infinite (at least in physics because this implies and infinite energy).

To find the coefficient c_0, we must calculate the integral for $k=0$. The coefficient c_0 is then determined by:

$$\begin{aligned}c_0&=\frac{1}{T}\int\limits_{T} f(t)e^{-\mathrm{i}k\omega t}\mathrm{d}t=\frac{1}{2}\int\limits_{-1}^{1} f(t)\mathrm{d}t=\frac{1}{2}\int\limits_{-1}^{0} f(t)\mathrm{d}t+\frac{1}{2}\int\limits_{0}^{1} f(t)\mathrm{d}t\\&=\frac{1}{2}\int\limits_{-1}^{0}(-A)\mathrm{d}t+\frac{1}{2}\int\limits_{0}^{1}(A)\mathrm{d}t=0\end{aligned}\tag{6.4.463}$$

The "frequency" spectrum (caution to the abuse of language!) and amplitude will be of the following form for $k=-5\ldots+5$ and $A=1$ null frequencies not being shown:

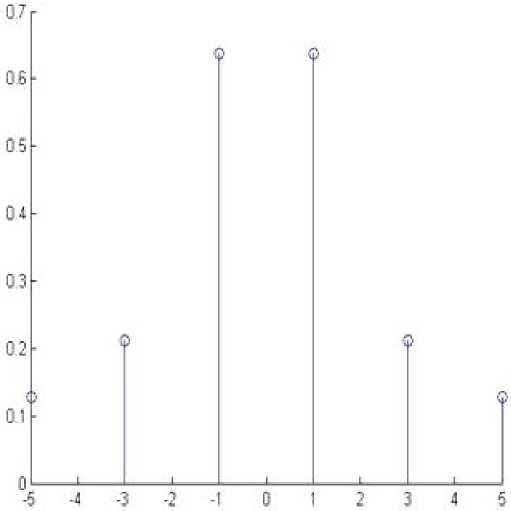


Figure 6.79: Frequency spectrum of the example Fourier series coefficients

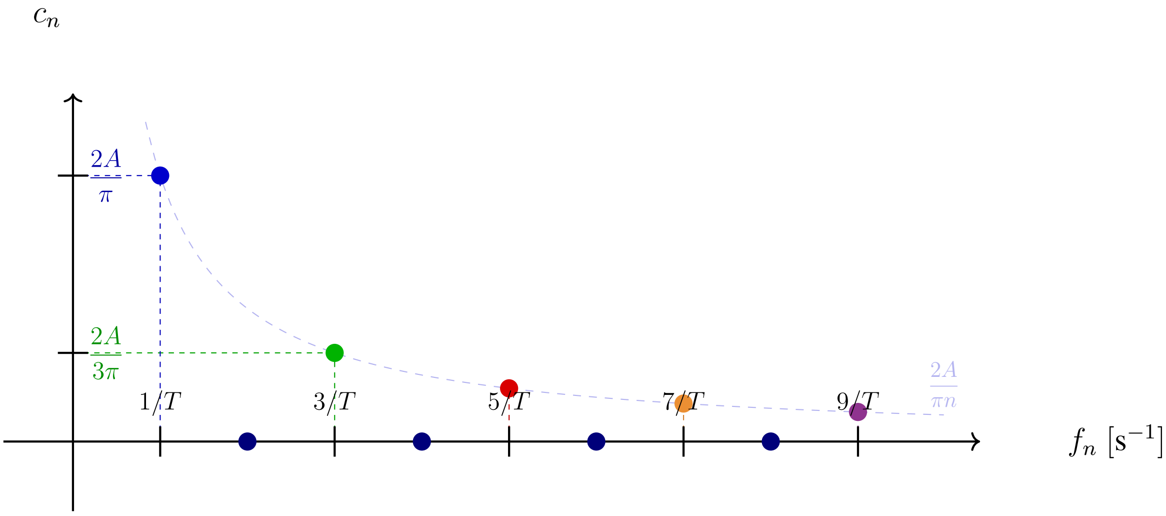
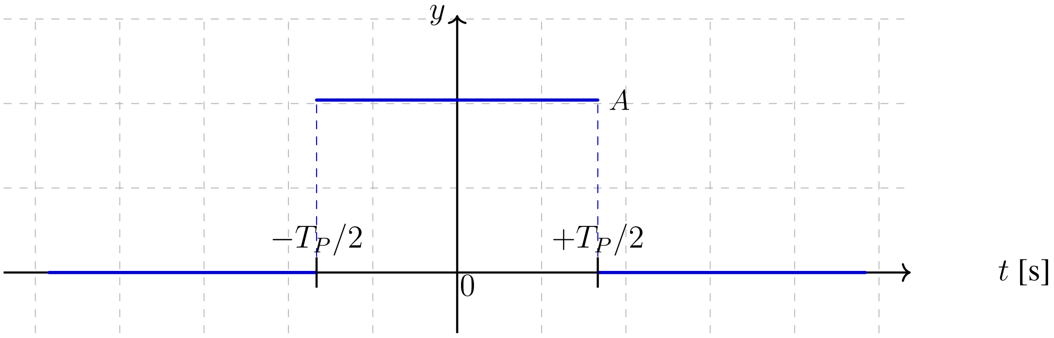
Or as the frequency spectrum is symmetric it is also often represented as following:



c_n
$\frac{2A}{\pi}$
$\frac{2A}{3\pi}$
$1/T$
$3/T$
$5/T$
$7/T$
$9/T$
$\frac{2A}{\pi n}$
f_n [s^{-1}]

E2. Let us consider another famous case! The signal decomposition of the square of amplitude A and width T_p (this function is sometimes denoted $\Pi_P(t)$) and of period T:



y
A
$-T_P/2$
$+T_P/2$
0
t [s]

$$f(t)=\begin{cases}A & -T_P/2\geq t\geq +T_P/2\\ 0 & |t|>T_P/2\end{cases}\tag{6.4.464}$$

and:

$$\begin{aligned}c_k&=\frac{1}{T}\int_T f(t)e^{-\mathrm{i}k\omega t}\mathrm{d}t=\frac{1}{T}\int\limits_{-T_P/2}^{+T_P/2}Ae^{-\mathrm{i}k\omega t}\mathrm{d}t=\frac{A}{-\mathrm{i}k\omega T}\left[e^{-\mathrm{i}\omega t}\Big|_{-T_P/2}^{+T_P/2}\right]\\&=\frac{A}{-\mathrm{i}k2\pi fT}\left[e^{-\mathrm{i}k\omega\frac{T_P}{2}}-e^{\mathrm{i}k\omega\frac{T_P}{2}}\right]=\frac{A}{-\mathrm{i}k2\pi fT}\left[e^{-\mathrm{i}k2\pi f\frac{T_P}{2}}-e^{\mathrm{i}k2\pi f\frac{T_P}{2}}\right]\\&=\frac{A}{k\pi}\left[\frac{e^{\mathrm{i}k\pi fT_P}-e^{-\mathrm{i}k\pi fT_P}}{2\mathrm{i}}\right]=\frac{A}{k\pi}\sin(k\pi fT_P)\\&=AfT_p\frac{\sin(k\pi fT_P)}{k\pi fT_P}=\frac{A}{k\pi}\mathrm{sinc}(kfT_p)\end{aligned}\tag{6.4.465}$$

So we fall back on a discrete version of the famous cardinal sine function (see section Trigonometry page 2517)!

The abuse to talk about "frequencies" for Fourier coefficients thus leads us to have negative frequencies on the x-axis... but it's only a question of vocabulary (there is no direct relation with the real frequencies) with which you must be familiar.

The amplitude spectrum and phase is calculated according to the following relations:

$$|c_k|=\sqrt{(\Re(c_k))^2+(\Im(c_k))^2}\quad\text{and}\quad\angle\theta=\tan^{-1}\left(\frac{\Im(c_k)}{\Re(c_k)}\right)\tag{6.4.466}$$

It is then relatively easy to notice that if T tends to a larger and larger number, the spectrum peaks approach increasingly. So when T tends to infinity the spectrum becomes continuous!!!

The phase spectrum of the above example will give the following for the odd values:

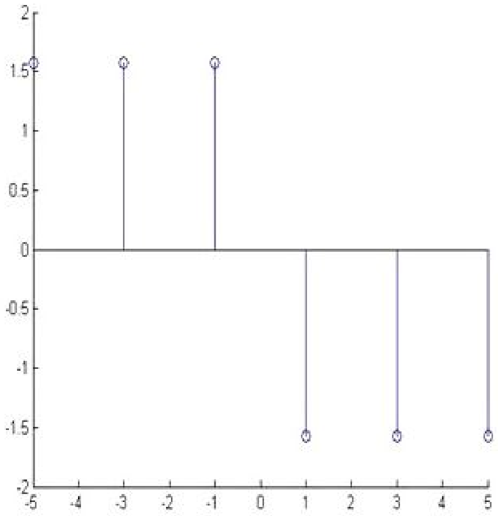


Figure 6.80: **Phase spectrum for the Fourier Series**

It is even possible for example to get relatively easily the frequency spectrum in a software like Microsoft® Excel® 11.8346 (the reader will find an example much more detailed and interesting on the companion exercise server in the section Sequences and Series) !!!

Indeed, it is enough for this purpose to sample for example our signal 128 times (Microsoft® Excel® 11.8346 needs 2^n samples and works only under this condition!). Then we divide the interval $-1<t<0$ in 64 samples and ditto for the interval $0>t>1$:

	A	B
1	*t*	*A*
2	-1	-1
3	-0.9844	-1
4	-0.9688	-1
5	-0.9531	-1
6	-0.9375	-1
7	-0.9219	-1

Figure 6.85: **Corresponding Fourier coefficients to sampled signal with Microsoft® Excel® 11.8346**

It remains to calculate the module of the complex numbers with the native function `IMABS( )` function in Microsoft® Excel® 11.8346 and divide the result by 128 for each of the coefficients c_n but we already see that each pair even coefficient is zero and this match well the theoretical result obtained previously.

We then have putting the index n in front of each module:

	A	B	C	D	E
1	t	A	C_n	$\|C_n\|$	n
2	-1	-1	0	0	0

$\frac{9}{T}$
$\frac{11}{T}$
Frequency domain

Figure 6.89: **Pedagogical way to see the Fourier Transform (author: Izaak Neutelings)**

✍**Example:**

Let us now consider another example identical to the previous with a different approach. We define a periodic function of period $T=2\pi$ as follows:

$$f(x)=\begin{cases}-1 & -\pi<x<0\\ +1 & 0\leq x\leq\pi\end{cases} \tag{6.4.467}$$

Let us calculate the Fourier coefficients (we translate the bounds of the integral since the function is periodic, this does not change anything but makes the calculations easier!):

$$\begin{aligned}a_n&=\frac{2}{2\pi}\int\limits_0^{2\pi}f(x)\cos(nx)\mathrm{d}x=\frac{1}{\pi}\left(\int\limits_0^{\pi}1\cos(nx)\mathrm{d}x+\int\limits_{\pi}^{2\pi}-1\cos(nx)\mathrm{d}x\right)\\&=\frac{1}{\pi}\left(\int\limits_0^{\pi}\cos(nx)\mathrm{d}x-\int\limits_{\pi}^{2\pi}\cos(nx)\mathrm{d}x\right)=\frac{1}{\pi}\left(\left.\frac{\sin(nx)}{n}\right|_0^{\pi}-\left.\frac{\sin(nx)}{n}\right|_{\pi}^{2\pi}\right)=0\end{aligned}\tag{6.4.468}$$

and:

$$\begin{aligned}b_n&=\frac{2}{2\pi}\int\limits_0^{2\pi}f(x)\sin(nx)\mathrm{d}x=\frac{1}{\pi}\left(\int\limits_0^{\pi}1\sin(nx)\mathrm{d}x+\int\limits_{\pi}^{2\pi}-1\sin(nx)\mathrm{d}x\right)\\&=\frac{1}{\pi}\left(\int\limits_0^{\pi}\sin(nx)\mathrm{d}x-\int\limits_{\pi}^{2\pi}\sin(nx)\mathrm{d}x\right)=\frac{1}{\pi}\left(-\left.\frac{\cos(nx)}{n}\right|_0^{\pi}+\left.\frac{\cos(nx)}{n}\right|_{\pi}^{2\pi}\right)\\&=\frac{1}{\pi}\left(\left.\frac{\cos(nx)}{n}\right|_{\pi}^{2\pi}-\left.\frac{\cos(nx)}{n}\right|_0^{\pi}\right)=\frac{1}{n\pi}\left(\cos(nx)\Big|_{\pi}^{2\pi}-\cos(nx)\Big|_0^{\pi}\right)\\&=\frac{1}{n\pi}\big(\cos(2\pi n)-\cos(\pi n)-\cos(\pi n)+1\big)=\frac{1}{n\pi}\big(\cos(2\pi n)-2\cos(\pi n)+1\big)\end{aligned}\tag{6.4.469}$$

We notice that b_n is equal to 0 for n even and equal to $4\pi/n$ when n is odd. The Fourier series of the function under consideration is thus written:

$$\begin{aligned}f(x)&=\sum_{n=0}^{+\infty}\big(a_n\cos(nx)+b_n\sin(nx)\big)=\sum_{n=0}^{+\infty}b_n\sin(nx)\\&=4\pi\left[\frac{\sin(x)}{1}+\frac{\sin(3x)}{3}+\frac{\sin(5x)}{5}+\ldots+\frac{\sin(2x+1)}{2x+1}+\ldots\right]\end{aligned}\tag{6.4.470}$$

What in Maple™ 4.00b will be written:

```
>S:=(4/Pi)*Sum(sin((2*n+1)*x)/(2*n+1),n=0..N);
```

and that we can plot using the command:

```
>plot(subs(N=4,S),subs(N=8,S),subs(N=16,S),x=-Pi..Pi,
color=[red,green,blue],numpoints=200);
```

What gives three plots for 4, 8 and 16 of the series in red, green and blue:

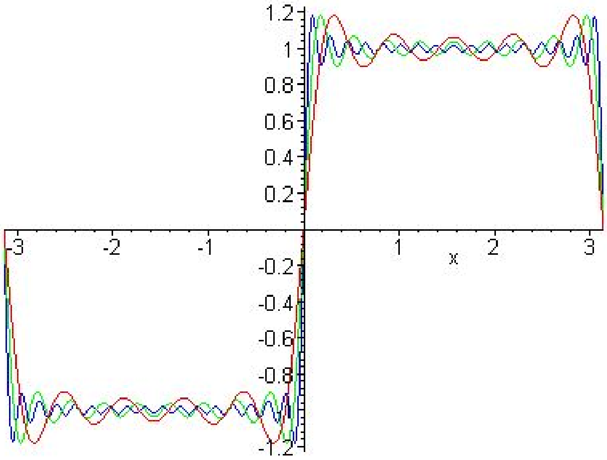

Figure 6.90: **Example of Fourier series in Maple™ 4.00b with 4, 8 and 16 terms**

For 50 terms we get:

```
> plot(subs(N=50,S),x=-Pi..Pi,numpoints=800);
```

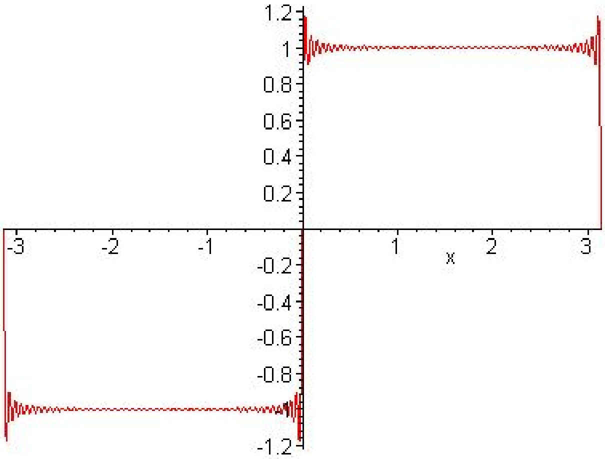

Figure 6.91: **Example of Fourier series in Maple™ 4.00b with 50 terms**

We see on the example above the side effects named "Gibbs phenomenon". It is possible to prove they occur to the value of the abscissa corresponding to $x=\pi/2n$ and matching equation and the peak rises to ± 1.179 for all values of n. Let's see this!

We proved just before for our example that:

$$\begin{aligned} f(x) &= \sum_{n=0}^{+\infty}\left(a_n\cos(nx)+b_n\sin(nx)\right)=\sum_{n=0}^{+\infty} b_n\sin(nx) \\ &= 4\pi\left[\frac{\sin(x)}{1}+\frac{\sin(3x)}{3}+\frac{\sin(5x)}{5}+\ldots\frac{\sin(2x+1)}{2x+1}+\ldots\right] \end{aligned} \tag{6.4.471}$$

Which can be written:

$$f(x)=\frac{4}{\pi}\int_0^x\left[\cos(t)+\cos(3t)+\ldots+\cos(2n+1)\right]\mathrm{d}t=\frac{4}{\pi}\int_0^x\Re\left[e^{\mathrm{i}t}+e^{3\mathrm{i}t}+\ldots+e^{\mathrm{i}(2n+1)t}\right]\mathrm{d}t \tag{6.4.472}$$

using the proof made much more earlier at the beginning of this section as that:

$$S_n = x + x^3 + x^5 + \ldots + x^{2n-1} = \frac{x^{2n+1} - x}{x^2 - 1} \tag{6.4.473}$$

Then we have:

$$\begin{aligned}
f(x) &= \frac{4}{\pi}\int\limits_0^x \Re\left[e^{\mathrm{i}t} + e^{3\mathrm{i}t} + \ldots + e^{\mathrm{i}(2n+1)t}\right]\mathrm{d}t \\
&= \frac{4}{\pi}\int\limits_0^x \Re\left[\frac{e^{(2n+1)\mathrm{i}t} - e^{\mathrm{i}t}}{e^{2\mathrm{i}t} - 1}\right]\mathrm{d}t = \frac{4}{\pi}\int\limits_0^x \Re\left[\frac{e^{\mathrm{i}t\left(e^{2n\mathrm{i}t}-1\right)}}{e^{\mathrm{i}t}\left(e^{\mathrm{i}t} - e^{-\mathrm{i}t}\right)}\right]\mathrm{d}t = \frac{4}{\pi}\int\limits_0^x \Re\left[\frac{e^{2n\mathrm{i}t} - 1}{e^{\mathrm{i}t} - e^{-\mathrm{i}t}}\right]\mathrm{d}t
\end{aligned} \tag{6.4.474}$$

Remember that during our study of complex numbers (see section Numbers page 243) we proved that:

$$\sin(x) = \frac{e^{\mathrm{i}x} - e^{-\mathrm{i}x}}{2\mathrm{i}} \tag{6.4.475}$$

Which brings us to:

$$\begin{aligned}
f(x) &= \frac{4}{\pi}\int\limits_0^x \Re\left[\frac{e^{2n\mathrm{i}t} - 1}{e^{\mathrm{i}t} - e^{-\mathrm{i}t}}\right]\mathrm{d}t = \frac{4}{\pi}\int\limits_0^x \Re\left[\frac{e^{2n\mathrm{i}t} - 1}{2\mathrm{i}\sin(t)}\right]\mathrm{d}t \\
&= \frac{4}{\pi}\int\limits_0^x \Re\left[\frac{\cos(2nt) + \mathrm{i}\sin(2nt) - 1}{2\mathrm{i}\sin(t)}\right]\mathrm{d}t = \frac{2}{\pi}\int\limits_0^x \Re\left[\frac{\cos(2nt)}{\mathrm{i}\sin(t)} + \frac{\mathrm{i}\sin(2nt)}{\mathrm{i}\sin(t)} - \frac{1}{\mathrm{i}\sin(t)}\right]\mathrm{d}t \\
&= \frac{2}{\pi}\int\limits_0^x \Re\left[-\frac{\mathrm{i}\cos(2nt)}{\sin(t)} + \frac{\sin(2nt)}{\sin(t)} + \frac{\mathrm{i}}{\sin(t)}\right]\mathrm{d}t = \frac{2}{\pi}\int\limits_0^x \Re\left[\frac{\sin(2nt)}{\sin(t)} - \mathrm{i}\frac{\cos(2nt) - 1}{\sin(t)}\right]\mathrm{d}t \\
&= \frac{2}{\pi}\int\limits_0^x \frac{\sin(2nt)}{\sin(t)}\mathrm{d}t
\end{aligned} \tag{6.4.476}$$

We will now focus on small values of x. So we can then make a Maclaurin development of first order at the denominator (but not the numerator because of the presence of the n):

$$f(x) \cong \frac{2}{\pi}\int\limits_0^x \frac{\sin(2nt)}{t}\mathrm{d}t \tag{6.4.477}$$

We make a change of variable:

$$f(x) \cong \frac{2}{\pi}\int\limits_0^{2nx} \frac{\sin(s)}{\dfrac{s}{2n}}\frac{\mathrm{d}s}{2n} = \int\limits_0^{2nx} \frac{\sin(s)}{s}\mathrm{d}s = \int\limits_0^{2nx} \operatorname{sinc}(s)\mathrm{d}s \tag{6.4.478}$$

where we used the traditional notation of the "sine cardinal" in the last relation as defined in the section Trigonometry at page 2517 (remember that this fraction is common in physics this is why it has a specific notation).

As what interest us is to determine the maximum of the Gibbs phenomenon (the disturbance), we see that it takes place in this particular case that we presented (see figure above) for each multiple of π and as the denominator of the expression of the integral will decrease as the multiple is higher, it follows that the greatest maximum is at the point where $2nx=\pi$ (the point 0 at the opposite will cancel the integral therefore we must this latter of our choice). Then we have:

$$f_{\text{Gibbs}}(x)\cong\int\limits_0^\pi\frac{\sin(s)}{s}\mathrm{d}s \tag{6.4.479}$$

the evaluation of this integral can be done only numerically as far as we know, therefore we get:

$$f_{\text{Gibbs}}(x)\cong 1.179 \tag{6.4.480}$$

That is about 18% above the expected threshold value.

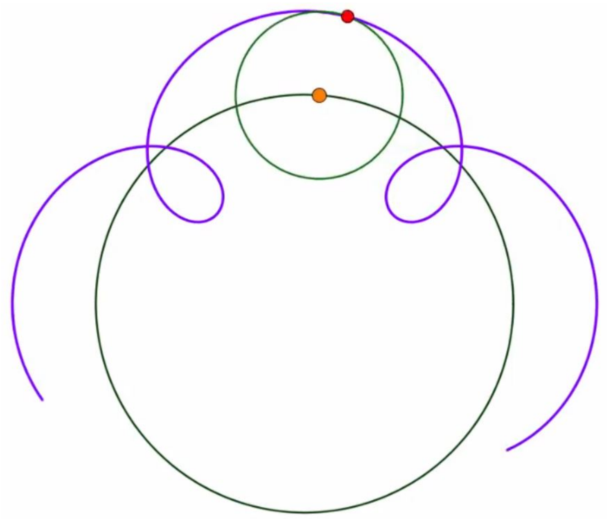
6.4.2.7.1 Fourier series generative art

Before continuing on hard mathematical topics about Fourier series, let us open a parenthesis where the purpose here take the science out of this quote:

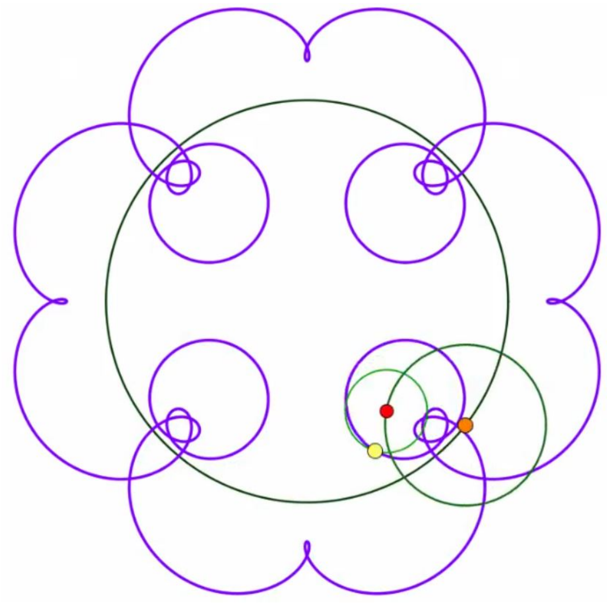
> ❞ *With four parameters I can fit an elephant.* ❞
>
> J. Von Neumann

quote 6.4:1749.#58

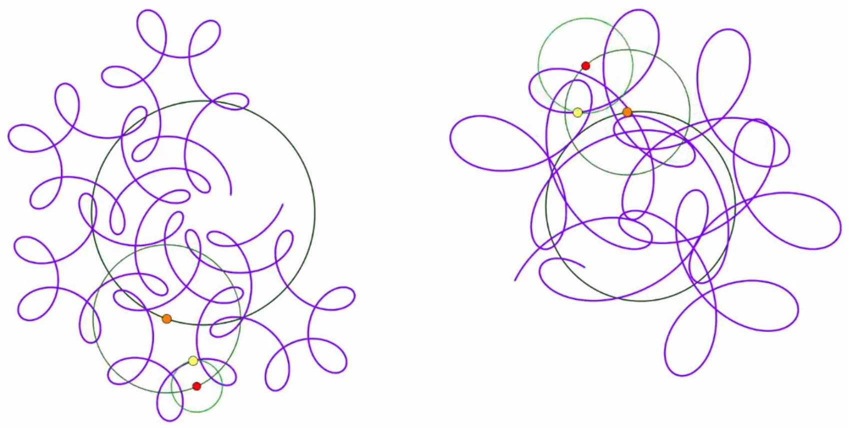
With computer it is easy to drawing stuffs using points moving on a circle, that are themselves centered on another circle like illustrated below (an epicycloid):



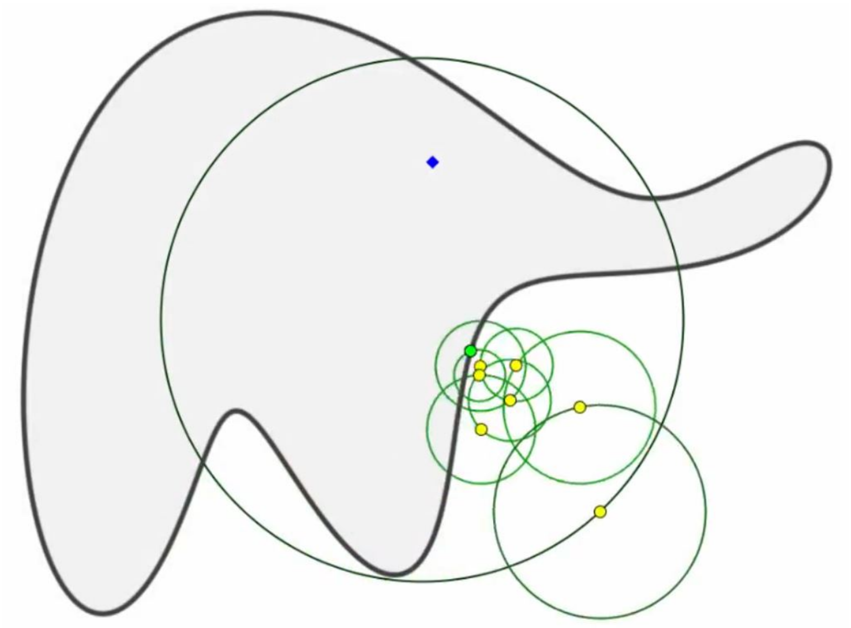
or a more complicated example:



Obviously as the examples above, the results change vary depending on the rotating speed of each point on its circle:

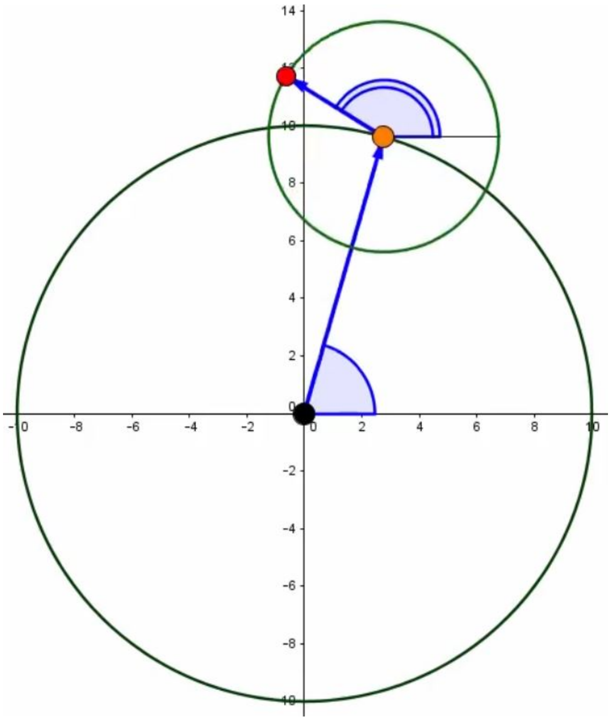


or a case with eight circles (each of them have a point moving at a specific rotation speed):



is based in fact on Fourier series!

To understand why consider the following example:



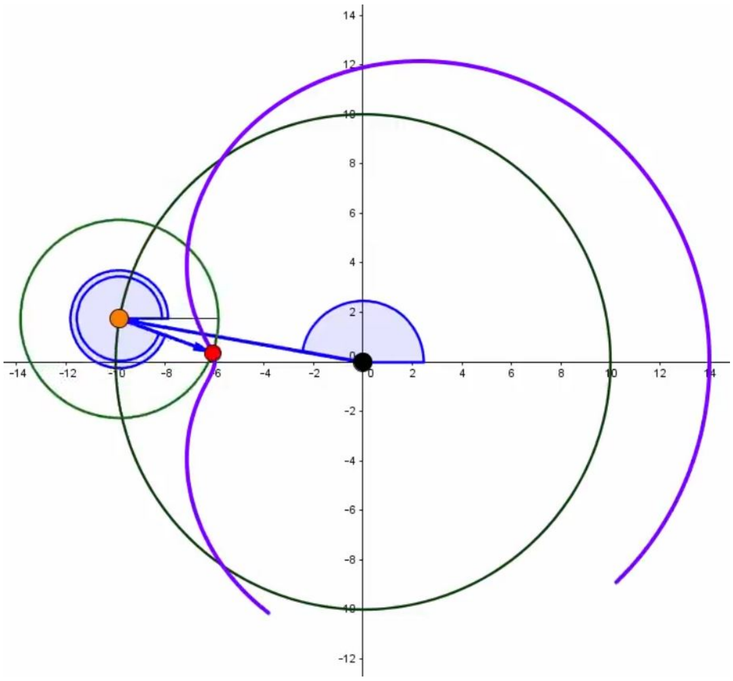
The first point is described obviously by the parametric equation:

$$\begin{pmatrix} 10\cos(t) \\ 10\sin(t) \end{pmatrix} \qquad (6.4.481)$$

and the second point therefore by (if it turns two time faster than the angle in the main circle):

$$\begin{pmatrix} x(t) \\ y(t) \end{pmatrix} = \begin{pmatrix} 10\cos(t)+4\cos(2t) \\ 10\sin(t)+4\sin(2t) \end{pmatrix} \qquad (6.4.482)$$

This is the parametric equation of the following epicycloid:



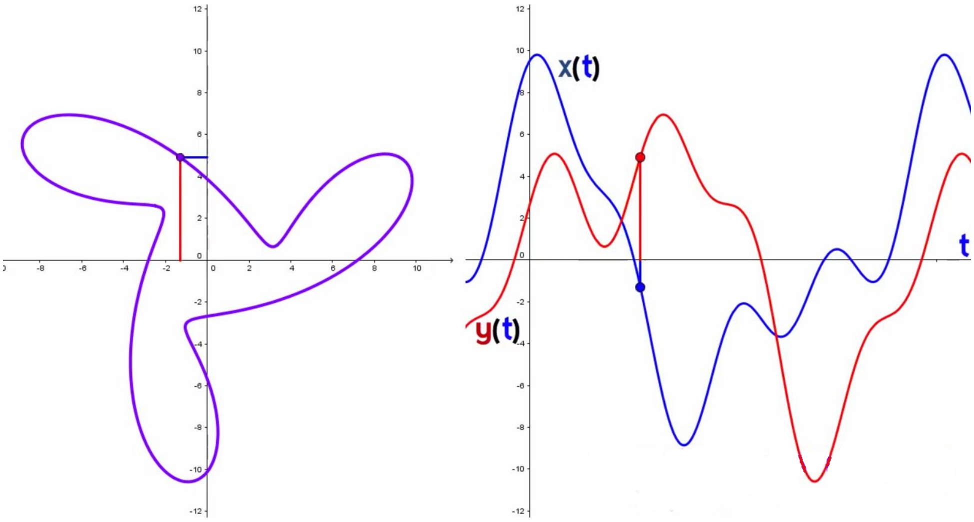
In the general case we have:

$$\begin{pmatrix} x(t) \\ y(t) \end{pmatrix} = \begin{pmatrix} a_0 + a_1\cos(n_1 t + \varphi_{x1}) + a_2\cos(n_2 t + \varphi_{x2}) + \ldots + a_N\cos(n_N t + \varphi_{x3}) \\ a_0 + a_1\sin(n_1 t + \varphi_{y1}) + a_2\sin(n_2 t + \varphi_{y2}) + \ldots + a_N\sin(n_N t + \varphi_{y3}) \end{pmatrix} \tag{6.4.483}$$

where a_i are the radius of the circles and n are the various circles speed (pulsation).

But the question is rather the opposite. From a given curve, how can find the values of the parameters?

The idea is quite simple. It's to follow respectively each coordinate in function of another one as illustrated below, where the closed shape is transformed into two curves:

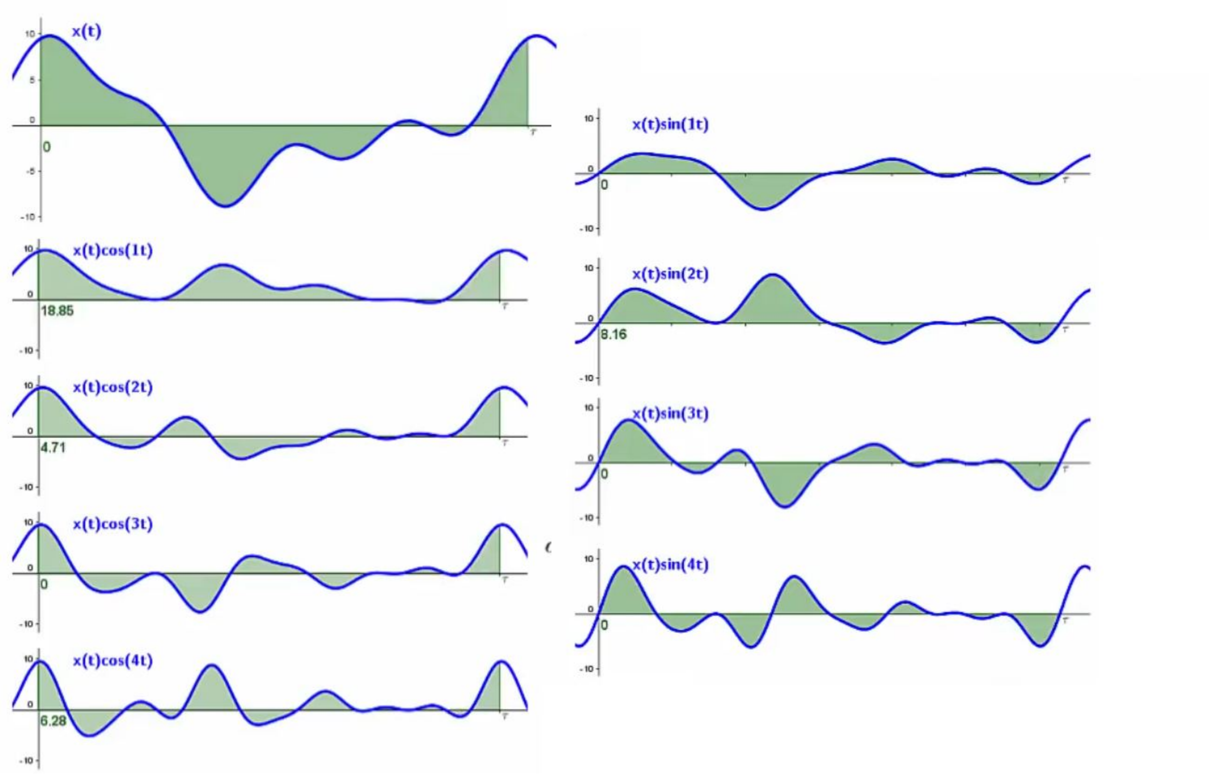


and as seen during our study of the Fourier series, we know how to find the Fourier series of such curves!

We know that the Fourier coefficients are given by:

$$\begin{aligned}
&\forall k\neq 0, a_k=\frac{2}{\tau}\int\limits_0^{\tau} x(t)\cos(kt)\mathrm{d}t\\
&\forall k\neq 0, b_k=\frac{2}{\tau}\int\limits_0^{\tau} x(t)\sin(kt)\mathrm{d}t\\
&\text{and } a_0=\frac{1}{\tau}\int\limits_0^{\tau} x(t)\mathrm{d}t
\end{aligned}\tag{6.4.484}$$

If we do that numerically for example with $x(t)$:



That gives:

$$\begin{aligned}
a_0 &= \frac{1}{\tau}\int_0^\tau x(t)\mathrm{d}t = 0\\
a_1 &= \frac{2}{\tau}\int_0^\tau x(t)\cos(1t)\mathrm{d}t = 6\\
b_1 &= \frac{2}{\tau}\int_0^\tau x(t)\sin(1t)\mathrm{d}t = 0\\
a_2 &= \frac{2}{\tau}\int_0^\tau x(t)\cos(2t)\mathrm{d}t = 1.5\\
b_2 &= \frac{2}{\tau}\int_0^\tau x(t)\sin(2t)\mathrm{d}t = 2.6\\
a_3 &= \frac{2}{\tau}\int_0^\tau x(t)\cos(3t)\mathrm{d}t = 0\\
b_3 &= \frac{2}{\tau}\int_0^\tau x(t)\sin(3t)\mathrm{d}t = 0\\
a_4 &= \frac{2}{\tau}\int_0^\tau x(t)\cos(4t)\mathrm{d}t = 2\\
b_4 &= \frac{2}{\tau}\int_0^\tau x(t)\sin(4t)\mathrm{d}t = 0
\end{aligned} \tag{6.4.485}$$

Therefore:

$$x(t) \cong 6\cos(t) + 1.5\cos(2t) + 2\cos(4t) + 2.6\sin(2t) \tag{6.4.486}$$

and using the same procedure, we could find:

$$\begin{aligned}
a_2 = \frac{2}{\tau}\int_0^\tau y(t)\cos(2t)\mathrm{d}t = 2.6 \quad & b_1 = \frac{2}{\tau}\int_0^\tau y(t)\sin(1t)\mathrm{d}t = 6\\
b_2 = \frac{2}{\tau}\int_0^\tau y(t)\sin(2t)\mathrm{d}t = -1.5 \quad & b_4 = \frac{2}{\tau}\int_0^\tau y(t)\sin(4t)\mathrm{d}t = 2
\end{aligned} \tag{6.4.487}$$

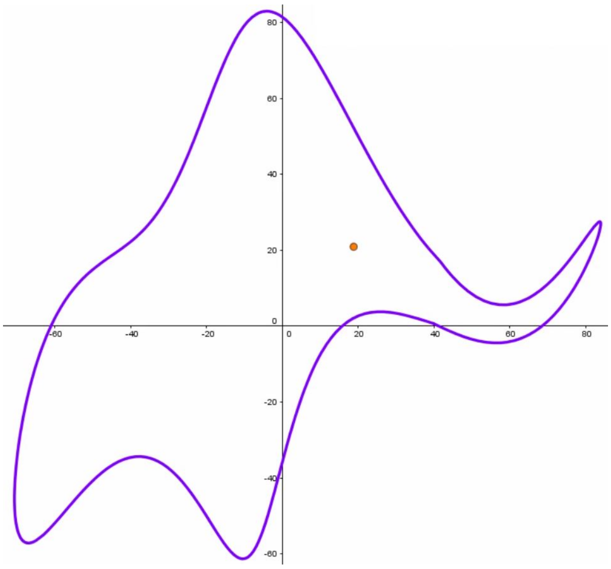
Therefore:

$$y(t) \cong 2.6\cos(2t) + 6\sin(t) - 1.5\sin(2t) + 2\sin(4t) \tag{6.4.488}$$

We see however that $x(t)$ doesn't have only cosine terms and that $y(t)$ doesn't have only sine terms. Then playing a bit with elementary trigonometric identities we can find (it's not absolutely a necessary transformation but like this it will be in adequation with the general expression given earlier above):

$$\begin{aligned}
x(t) &= 6\cos(t) + 3\cos\left(2t - 60^\circ\right) + 2\cos(4t)\\
y(t) &= 6\sin(t) + 3\sin\left(2t + 120^\circ\right) + 2\sin(4t)
\end{aligned} \tag{6.4.489}$$

Now let us come back on the four parameter elephant challenge. A satisfying result is:



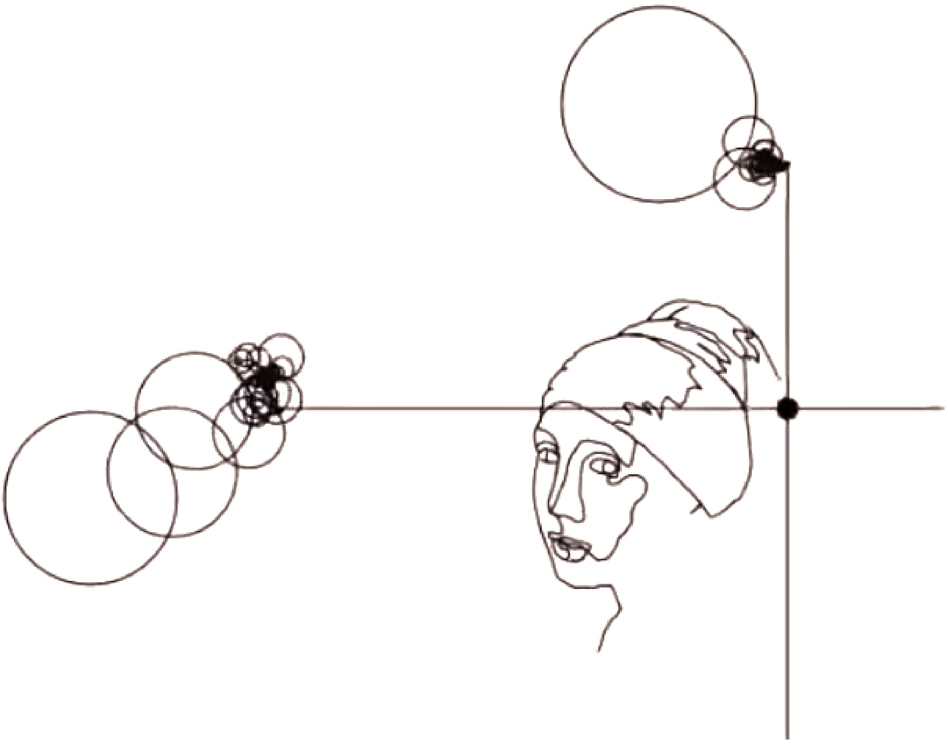
with:

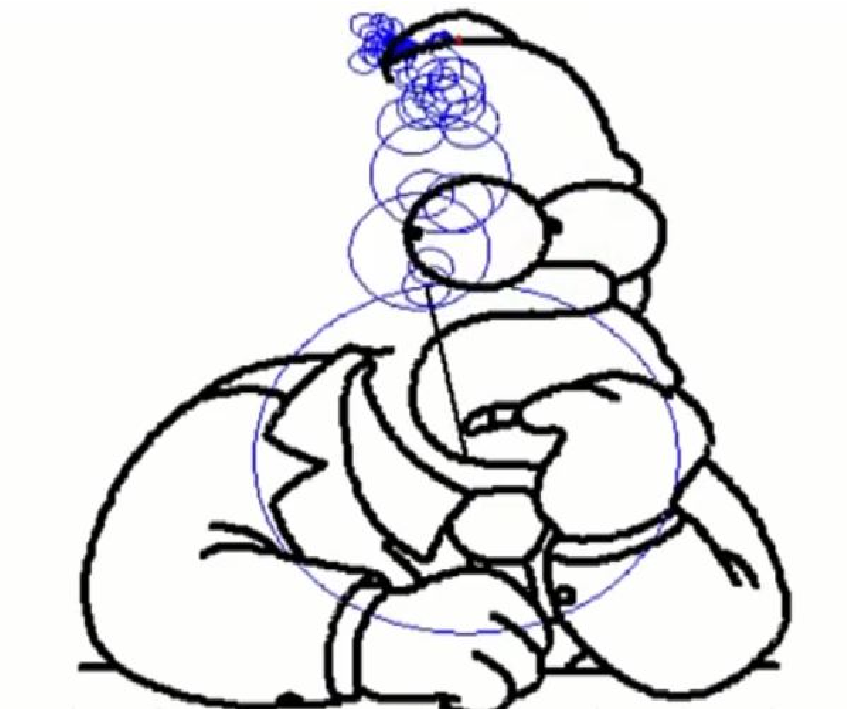
$$\begin{aligned}x(t)&=\Re(a)\cos(t)+\Re(b)\sin(t)+\Re(c)\sin(2t)+\Re(d)\sin(3t)\\y(t)&=\Im(a)\sin(t)+\Im(b)\sin(2t)+\Im(c)\cos(3t)+\Im(d)\cos(5t)\end{aligned}\tag{6.4.490}$$

with the four parameters:

$$\begin{aligned}a&=-60+50\mathrm{i}\\b&=30+18\mathrm{i}\\c&=-8-12\mathrm{i}\\d&=10+14\mathrm{i}\end{aligned}\tag{6.4.491}$$

Some people have fun doing other things:





Remark

If the reader want to see how we plot the Fermi's elephant, he can refer to our `R` companion book.

6.4.2.7.2 Power of a signal

A periodic signal has an infinite energy and null average power (see section Electrical Engineering page 8451). Its average power over a period is then defined by:

$$P_f=\frac{1}{T}\int\limits_{T}|f(t)|^2\mathrm{d}t \tag{6.4.492}$$

If we develop this equation, we have:

$$\begin{aligned}P_f&=\frac{1}{T}\int\limits_{T}f(t)\bar{f}(t)\mathrm{d}t=\frac{1}{T}\int\limits_{T}f(t)\left(\sum_{k=-\infty}^{+\infty}\bar{c}_k e^{-\mathrm{i}k\omega_0 t}\right)\mathrm{d}t\\&=\frac{1}{T}\sum_{k=-\infty}^{+\infty}\bar{c}_k\int\limits_{T}f(t)e^{-\mathrm{i}k\omega_0 t}\mathrm{d}t=\sum_{k=-\infty}^{+\infty}\bar{c}_k c_k=\sum_{k=-\infty}^{+\infty}|c_k|^2\end{aligned} \tag{6.4.493}$$

This means that the power of a continuous-time periodic signal is equal to the sum of the squared Fourier coefficients. This is what we name the "Parseval's theorem". This means that if we have any signal that can be decomposed in Fourier series, we can know the power of that signal using only the spectral coefficients.

In reality, we can't mathematically determine the expression of this signal, we use therefore discretization or sampling and then we use a discrete Fourier transform, we can calculate the power of this signal using only the spectral coefficients. This gives us a characteristic of the signal.

Let us also indicate the following result which will be very useful to us in the section of Thermodynamics for the study of the black-body and is also very closely related to important properties of the Riemann zeta function:

$$\begin{aligned}\sum_{k=-\infty}^{+\infty}|c_k|^2=\sum_{k=-\infty}^{+\infty}\left|\frac{a_k-\mathrm{i}b_k}{2}\right|=\frac{1}{4}\sum_{k=-\infty}^{+\infty}\left(\sqrt{a_k^2+b_k^2}\right)^2\\=\frac{1}{4}\sum_{k=-\infty}^{+\infty}a_k^2+b_k^2=\frac{1}{4}\sum_{k=-\infty}^{-1}\left(a_k^2+b_k^2\right)+\frac{1}{4}\left(a_0^2+b_0^2\right)+\frac{1}{4}\sum_{k=1}^{+\infty}\left(a_k^2+b_k^2\right)\\=\frac{1}{4}a_0^2+2\frac{1}{4}\sum_{k=1}^{+\infty}\left(a_k^2+b_k^2\right)=\frac{a_0^2}{4}+\frac{1}{2}\sum_{k=1}^{+\infty}\left(a_k^2+b_k^2\right)\end{aligned}\tag{6.4.494}$$

The following relation:

$$\boxed{\sum_{k=-\infty}^{+\infty}|c_k|^2=\frac{a_0^2}{4}+\frac{1}{2}\sum_{k=1}^{+\infty}\left(a_k^2+b_k^2\right)}\tag{6.4.495}$$

is named "Parseval's equality".

According to the definition of the Fourier series and the definition of the coefficient a_0 which follows immediately, we also have frequently in the literature:

$$\sum_{k=-\infty}^{+\infty}|c_k|^2=a_0+\frac{1}{2}\sum_{k=1}^{+\infty}\left(a_k^2+b_k^2\right)\tag{6.4.496}$$

6.4.2.7.3 Fourier Transform

Fourier series are a very powerful tool for the analysis of periodic signals for example, but the set of periodic functions is small compared to all the functions that we encounter in physical and engineering problems. So, will we introduce a new extremely powerful analytical tool that extends to a class of more general functions that have very important applications in signal processing, image processing, sound processing, statistics, finance (fourier option pricing techniques) and markets advanced statistics!!!

Remark

Many teachers and authors associate Fourier Series and Fourier Transform in the field of Functional Analysis. This is right in fact but it seemed to us more appropriate to put the study of the basics of this two subjects in this section because closely related to Sequences and Series. However, the subjects that follows normally the study of Fourier Transform, that is to say: Laplace Transforms, Hilbert Transform and others will be given in the section of Functional Analysis of this textbook (see page 2305). The Fast Fourier Transform study can be found in the section of Numerical Methods.

The Fourier transform (FT) is then used for both periodic signals and for aperiodic signals.

For this, we start from study of Fourier series with the complex notation of a periodic function of period T by considering that the period is becoming increasingly big to such that $T\rightarrow+\infty$. Therefore the spectral lines gradually approach to turn into a continuous spectrum.

Therefore, let us resume the expressions proved just earlier:

$$f(x)=\sum_{n=-\infty}^{+\infty}c_n e^{\mathrm{i}nx} \qquad c_n=\frac{1}{T}\int\limits_{-\frac{T}{2}}^{\frac{T}{2}}f(x)e^{-\mathrm{i}nx}\mathrm{d}x \tag{6.4.497}$$

that we can write equivalently in the following traditional form (wherein it is customary to put the factor $1/T$ rather in $f(t)$):

$$f(t)=\frac{1}{T}\sum_{n=-\infty}^{+\infty}c_k e^{\mathrm{i}\frac{2\pi n}{T}t} \qquad c_n=\int\limits_{-\frac{T}{2}}^{\frac{T}{2}}f(t)e^{-\mathrm{i}\frac{2\pi n}{T}t}\mathrm{d}t \tag{6.4.498}$$

and let us write this for future needs in the following form:

$$f(t)=\frac{1}{2\pi}\sum_{n=-\infty}^{+\infty}\frac{2\pi}{T}c_n e^{\mathrm{i}\frac{2\pi n}{T}t} \qquad c_n=\int\limits_{-\frac{T}{2}}^{\frac{T}{2}}f(t)e^{-\mathrm{i}\frac{2\pi n}{T}t}\mathrm{d}t \tag{6.4.499}$$

and let us put naturally that:

$$\omega_n=\frac{2\pi n}{T} \tag{6.4.500}$$

Thus, when $T\rightarrow+\infty$, the pulsation tends to zero and we have $\omega_n\rightarrow\omega$ because we move from discrete values in continuous values that browse through the set of real number $\mathbb{R}$ (for all k).

Therefore:

$$f(t)=\frac{1}{2\pi}\sum_{n=-\infty}^{+\infty}\frac{2\pi}{T}c_k e^{\mathrm{i}\omega_n t} \qquad c_n=\int\limits_{-\frac{T}{2}}^{\frac{T}{2}} f(t)e^{-\mathrm{i}\omega_n t}\mathrm{d}t \tag{6.4.501}$$

we pass to the limit that is to say:

$$T\rightarrow+\infty \qquad \omega_n\rightarrow\omega \tag{6.4.502}$$

This implies that:

$$\frac{2\pi}{T}=\frac{2\pi(n+1)}{T}-\frac{2\pi n}{T}=\frac{2\pi\Delta n}{T}\underset{T\rightarrow+\infty}{=}\mathrm{d}\omega \tag{6.4.503}$$

Therefore we get for the coefficients (we change the notation because the previous one is inadequate):

$$F(\omega)=\int\limits_{-\infty}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t \tag{6.4.504}$$

and for the infinite series (the sum becomes an integral)

$$f(t)=\frac{1}{2\pi}\int\limits_{-\infty}^{+\infty} F(\omega)e^{\mathrm{i}\omega t}\mathrm{d}\omega \tag{6.4.505}$$

Caution!!! To make the difference between the given function and its equivalent in which we seek expression in infinite sum, we will denote them differently now. Thus, we get:

$$f(t)=\frac{1}{2\pi}\int\limits_{-\infty}^{+\infty} F(\omega)e^{\mathrm{i}\omega t}\mathrm{d}\omega \qquad F(\omega)=\int\limits_{-\infty}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t \tag{6.4.506}$$

Thus the discrete Fourier series becomes a continuous function.

Definitions (#6.4.224):

D1. We name "Fourier Transform (FT)" of f, or more rigorously the "Continuous Time Fourier Transform (CTFT)", the relation:

$$\boxed{\mathcal{F}\big(f(t)\big)(\omega)=F(\omega)=\int\limits_{-\infty}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t} \tag{6.4.507}$$

sometimes also denoted as follows:

$$\hat{f}(\omega)=\int f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t \tag{6.4.508}$$

sometimes also named "spectral density amplitude".

D2. We name "Inverse Fourier Transform (IFT)", or more rigorously the Continuous Time Inverse Fourier Transform (CTIFT)", of F the relation:

$$\boxed{\mathcal{F}^{-1}\big(F(\omega)\big)(t)=f(t)=\frac{1}{2\pi}\int\limits_{-\infty}^{+\infty}F(\omega)e^{\mathrm{i}\omega t}\mathrm{d}\omega} \tag{6.4.509}$$

Any such transformation technique (as there are many as we will see in the section of Functional Analysis!) is named an "integral transformation".

Remark

There are many ways of writing the Fourier transform according to the choice of the initial value of T! The reader must also know that it is quite common in physics to invert the definitions...the Fourier transform may be designated as the Inverse Fourier transform and reciprocally...

Some physicist and engineers prefer to make the two previous relations symmetrical by putting the same coefficient in both directions, which will be for example $1/\sqrt{2}$. This will give:

$$\begin{aligned}\mathcal{F}\big(f(t)\big)(\omega)=F(\omega)&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t\\ \mathcal{F}^{-1}\big(F(\omega)\big)(t)=f(t)&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}F(\omega)e^{\mathrm{i}\omega t}\mathrm{d}\omega\end{aligned} \tag{6.4.510}$$

Let us also give the corresponding three-dimensional version that will serve us many times in wave mechanics, electrodynamics, wave optics or in the various sections of quantum physics of this textbook:

$$\mathcal{F}(\vec{k})=\frac{1}{(2\pi)^{\frac{3}{2}}}\iiint f(\vec{r})e^{-\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^3r \qquad f(\vec{r})=\frac{1}{(2\pi)^{\frac{3}{2}}}\iiint \mathcal{F}(\vec{k})e^{\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^3k \tag{6.4.511}$$

To make things perhaps clearer (at least we hope so), let us prove generally that the previous Fourier transform $\mathcal{F}$ is isometric (retains the "norm" - or "modulus" if you prefer...)

Theorem 6.25. For any functions f,g we have the functional inner product:

$$f\circ\mathcal{F}(g)=\mathcal{F}^{-1}(f)\circ g \tag{6.4.512}$$

But since the functions are in the complex space, as we saw in the section of Vector Calculus, then we must use the notation of the hermitian product:

$$\langle f|\mathcal{F}(g)\rangle=\langle\mathcal{F}^{-1}(f)|g\rangle \tag{6.4.513}$$

Remember that:

$$\langle f|g\rangle=\int\limits_{\mathbb{R}^n}f(\vec{r})\overline{g(\vec{r})}\mathrm{d}^nr \tag{6.4.514}$$

Proof 6.25.1. Then we want to prove the equality:

$$\langle f|g\rangle=\int\limits_{\mathbb{R}^n} f(\vec{r})\overline{g(\vec{r})}\mathrm{d}^n r \qquad (6.4.515)$$

Explicitly:

$$\langle f|\mathcal{F}(g)\rangle=\int\limits_{\mathbb{R}^n} f(\vec{r})\overline{\mathcal{F}(g)}\mathrm{d}^n r \qquad (6.4.516)$$

But the variable to integrate but must be the same and for $\mathcal{F}(g)$ to be implicitly dependent of $\vec{r}$ it is necessary to take the Fourier transform on $\vec{k}$. Such as:

$$\mathcal{F}(\vec{r})=\frac{1}{(2\pi)^{\frac{3}{2}}}\iiint f(\vec{k})e^{-\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^3 k \qquad (6.4.517)$$

Therefore:

$$\begin{aligned}\langle f(\vec{r})|\mathcal{F}(g)(\vec{r})\rangle&=\int\limits_{\mathbb{R}^n} f(\vec{r})\overline{\mathcal{F}(g)}\mathrm{d}^n r\int\limits_{\mathbb{R}^n} f(\vec{r})\overline{\left(\frac{1}{(2\pi)^{\frac{n}{2}}}\int\limits_{\mathbb{R}^n} g(\vec{k})e^{-\mathrm{i}\vec{k}\circ\vec{r}}d^n k\right)}\mathrm{d}^n r\\&=\int\limits_{\mathbb{R}^n} f(\vec{r})\left(\frac{1}{(2\pi)^{\frac{n}{2}}}\int\limits_{\mathbb{R}^n} \overline{g(\vec{k})}e^{-\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^n k\right)\mathrm{d}^n r\end{aligned} \qquad (6.4.518)$$

Therefore using the Fubini's theorem (see section Differential and Integral page 1521):

$$\begin{aligned}\langle f|\mathcal{F}(g)\rangle&=\int\limits_{\mathbb{R}^n} \overline{g(\vec{k})}\left(\frac{1}{(2\pi)^{\frac{n}{2}}}\int\limits_{\mathbb{R}^n} f(\vec{r})e^{\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^n r\right)\mathrm{d}^n k\\&=\int\limits_{\mathbb{R}^n} \overline{g(\vec{k})}\mathcal{F}^{-1}(f)(\vec{k})\mathrm{d}^n k=\langle\mathcal{F}^{-1}(f),g\rangle\end{aligned} \qquad (6.4.519)$$

Thanks to this result, we have also proved (this is immediate):

$$\langle\mathcal{F}(f),\mathcal{F}(g)\rangle=\langle\mathcal{F}^{-1}(\mathcal{F}(f)),g\rangle=\langle f,g\rangle \qquad (6.4.520)$$

We have not specified the bounds: they are infinite in every definition (we include all possible $\vec{k}$ or $\vec{r}$).

■ Q.E.D.

Let us now see and prove three interesting properties of the Fourier transform:

P1. If the function f is an even function (see section Functional Analysis page 2212), it comes a simplification of the Fourier Transform such that:

$$\begin{aligned}\mathcal{F}\big(f(x)\big)(\omega)&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t=\frac{1}{\sqrt{2\pi}}\left(\int\limits_{-\infty}^{0} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t+\int\limits_{0}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t\right)\\&=\frac{1}{\sqrt{2\pi}}\left(-\int\limits_{-\infty}^{0} f(t)e^{\mathrm{i}\omega t}\mathrm{d}t+\int\limits_{0}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t\right)\\&=\frac{1}{\sqrt{2\pi}}\left(\int\limits_{0}^{+\infty} f(t)e^{\mathrm{i}\omega t}\mathrm{d}t+\int\limits_{0}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t\right)\\&=\frac{1}{\sqrt{2\pi}}\int\limits_{0}^{+\infty} f(t)\left(e^{\mathrm{i}\omega t}+e^{-\mathrm{i}\omega t}\right)\mathrm{d}t=\frac{2}{\sqrt{2\pi}}\int\limits_{0}^{+\infty} f(t)\cos(\omega t)\mathrm{d}t\end{aligned} \tag{6.4.521}$$

P2. If f is odd, we proceed in the same manner as above, and we get:

$$\mathcal{F}\big(f(x)\big)(\omega)=-\frac{2\mathrm{i}}{\sqrt{2\pi}}\int\limits_{0}^{+\infty} f(t)\sin(\omega t)\mathrm{d}t \tag{6.4.522}$$

P3. Very important property of the Fourier transforms which will be useful to us in finance (see section Economy page 7485), and also as part of the study of the heat equation (see section of Thermodynamics page 3694).

First remember that the Fourier transform is given by:

$$\mathcal{F}\big(f(t)\big)(\omega)=F(\omega)=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t \tag{6.4.523}$$

We want to see what happens if:

$$\mathcal{F}\big(\partial_t f(t)\big)(\omega)=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} \partial_t f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t \tag{6.4.524}$$

By doing an integration by parts (see section Integral and Differential page 1532):

$$\int\limits_{a}^{b} f(t)g'(t)\mathrm{d}t=f(t)g(t)|_a^b+\int\limits_{a}^{b} f'(t)g(t)\mathrm{d}t \tag{6.4.525}$$

we get:

$$\begin{aligned}\mathcal{F}\big(\partial_t f(t)\big)(\omega)&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} e^{-\mathrm{i}\omega t}\partial_t f(t)\mathrm{d}t=\frac{1}{\sqrt{2\pi}}e^{-\mathrm{i}\omega t}f(t)|_{-\infty}^{+\infty}-\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} -\mathrm{i}\omega^{-\mathrm{i}\omega t}f(t)\mathrm{d}t\\&=\mathrm{i}\omega\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} e^{-\mathrm{i}\omega t}f(t)\mathrm{d}t=\mathrm{i}\omega\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t=\mathrm{i}\omega\mathcal{F}(\omega)\end{aligned} \tag{6.4.526}$$

where we put ourselves in the situation where:

$$\lim_{t\to\pm\infty} f(t)=0 \tag{6.4.527}$$

Therefore:

$$\boxed{\mathcal{F}\big(\partial_t f(t)\big)=\mathrm{i}\omega\mathcal{F}(\omega)} \tag{6.4.528}$$

More generally:

$$\boxed{\mathcal{F}\big(\partial_t^n f(t)\big)=(\mathrm{i}\omega)^n\mathcal{F}(\omega)} \tag{6.4.529}$$

This property can be useful for the following scheme:

$$\begin{matrix}\text{origin}\\ \text{space}\end{matrix}\left\{\begin{tikzcd} \begin{matrix}\text{ODE}\\ \text{in } t\end{matrix} \arrow[r, "\mathcal{F}"] \arrow[d, dashed] & \begin{matrix}\text{eqn.}\\ \text{in } \omega\end{matrix} \arrow[d] \\ f(t) & F(\omega) \arrow[l, "\mathcal{F}^{-1}"'] \end{tikzcd}\right\}\begin{matrix}\text{transform}\\ \text{space}\end{matrix}$$

Remark

The branch of "harmonic analysis", or "2D Fourier analysis", is the branch of mathematics that studies the representation of functions or signals as a superposition of basic waves. It deepens and generalizes the notions of Fourier series and Fourier transform. The basic waves are named "harmonics", hence the name of discipline. During the last two centuries it has had numerous applications in physics and economics under the name "spectral analysis" and knows recent applications including signal processing, quantum mechanics, neuroscience, stratigraphy, statistics, etc.

✍**Examples:**

E1. Let us see now a first example (among the three fundamentals one) of a Fourier transform that we will use again in the sections about Quantum Physics as well as in Wave Optics. We want to calculate the Fourier transform (spectrum) of the following function (rectangular pulse):

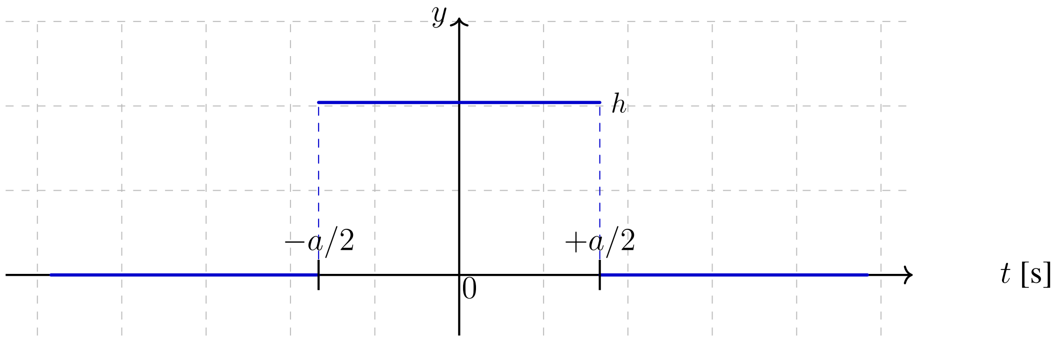


Figure 6.92: **Rectangular pulse example for Fourier Transform (author: Izaak Neutelings)**

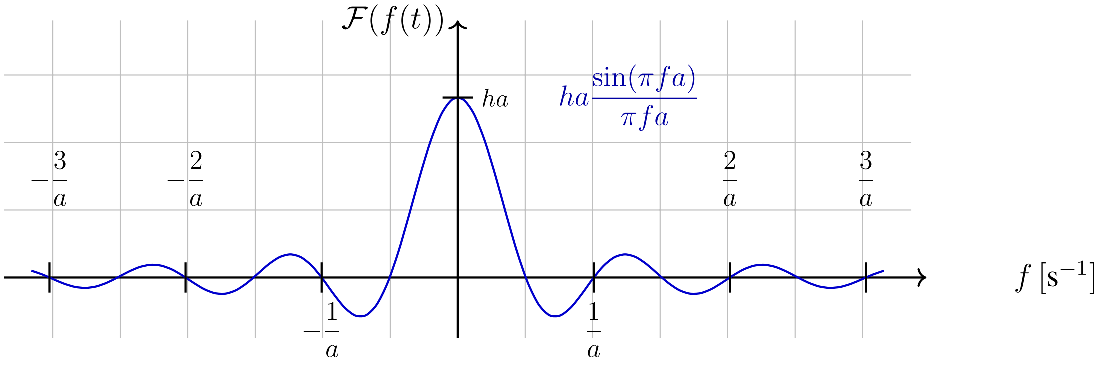
We have therefore:

$$\begin{aligned}\mathcal{F}(f(t)) &= \int_{-\infty}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t = \int_{-\infty}^{+\infty} f(t)e^{-\mathrm{i}2\pi f t}\mathrm{d}t = \int_{-\frac{a}{2}}^{+\frac{a}{2}} h e^{-\mathrm{i}2\pi f t}\mathrm{d}t \\ &= h\int_{-\frac{a}{2}}^{+\frac{a}{2}} e^{-\mathrm{i}2\pi f t}\mathrm{d}t = -\frac{h}{\mathrm{i}2\pi f}\left[e^{-\mathrm{i}2\pi f t}\right]_{-\frac{a}{2}}^{+\frac{a}{2}} = -\frac{h}{\mathrm{i}2\pi f}\left(e^{-\mathrm{i}\pi f a} - e^{\mathrm{i}\pi f a}\right) \\ &= -\frac{h}{\mathrm{i}2\pi f}\left(e^{\mathrm{i}(-\pi f a)} - e^{\mathrm{i}(\pi f a)}\right) = -\frac{h}{\mathrm{i}2\pi f}(-2\mathrm{i}\sin(\pi f a)) = h\frac{\sin(\pi f a)}{\pi f} \\ &= ha\frac{\sin(\pi f a)}{\pi f a} = ha\mathrm{sinc}(\pi f a)\end{aligned} \tag{6.4.530}$$

where sinc is the sine cardinal as we already know (see section Trigonometry page 2517).



So we fall back on the sinc and if we take the squared modulus squared we therefore get the decomposition of a theoretical monochromatic wave diffracted by a rectangular slot!!! Thus, it seems possible to study the diffraction phenomena using the Fourier transform and this field is named "Fourier optics". We'll come back on this later in the section of Functional Analysis when we deepen the Fourier transforms.

We know that the spectrum (described by the sinc function) crosses zero every time that the sine function is zero, that is to say, every time the frequency is a multiple of $1/a$.

The spectrum of this pulse illustrates two important points regarding the limited time signals:

P1. A short signal has a broadband spectrum.

P2. To a narrow spectrum correspond a long-term signal.

E2. The Fourier transform of an integrable function f is given as we know now by:

$$F(\omega) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{+\infty} f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t \tag{6.4.531}$$

Consider the integrable Gaussian function of the type :

$$f(t)=e^{-at^2} \tag{6.4.532}$$

with $a>0$ defined on $\mathbb{R}$.

We want to compute its Fourier transform because it is a very important case and particularly useful for solving the heat equation that we will treat in the section of Thermodynamics and also to solve the differential equation of Black & Scholes in the section Economy.

The brilliant trick, if we want to avoid making complex analysis on 3 A4 pages, is to notice that $F(\omega)$ is the solution of the following linear differential equation:

$$y'(\omega)+\frac{\omega}{2a}y=0 \tag{6.4.533}$$

where y is a function of ω.

Indeed deriving $F(\omega)$ we get:

$$\begin{aligned}F'(\omega)&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}f(t)e^{-\mathrm{i}\omega t}\mathrm{d}t=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}e^{-at^2}\frac{\mathrm{d}}{\mathrm{d}\omega}e^{-\mathrm{i}\omega t}\mathrm{d}t\\&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}e^{-at^2}\left(-\mathrm{i}te^{-\mathrm{i}\omega t}\right)\mathrm{d}t=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}\left(-\mathrm{i}te^{-at^2}\right)e^{-\mathrm{i}\omega t}\mathrm{d}t\end{aligned} \tag{6.4.534}$$

Integration by parts gives us:

$$\begin{aligned}F'(\omega)&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}e^{-\mathrm{i}\omega t}\left(-\mathrm{i}te^{-at^2}\right)\mathrm{d}t\\&=\frac{1}{\sqrt{2\pi}}\left[e^{-\mathrm{i}\omega t}\frac{\mathrm{i}e^{-at^2}}{2a}\bigg|_{-\infty}^{+\infty}-\int\limits_{-\infty}^{+\infty}\left(-\mathrm{i}\omega e^{-\mathrm{i}\omega t}\right)\left(\frac{\mathrm{i}e^{-at^2}}{2a}\right)\mathrm{d}t\right]\\&=\frac{-\omega}{2a}\frac{1}{\sqrt{2a}}\int\limits_{-\infty}^{+\infty}e^{-\mathrm{i}\omega t}e^{-at^2}\mathrm{d}t=-\frac{\omega}{2a}\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty}e^{-at^2}e^{-\mathrm{i}\omega t}\mathrm{d}t\end{aligned} \tag{6.4.535}$$

We recognize the expression of the Fourier transform of f. Therefore:

$$F'(\omega)=-\frac{\omega}{2a}F(\omega) \tag{6.4.536}$$

This shows that the $F(\omega)$ is solution of the differential equation above.

We have proved in the section of Differential and Integral Calculus that the general solution of this differential equation is given by:

$$y=Ae^{-G(\omega)} \tag{6.4.537}$$

where $A \in \mathbb{R}$. And as in the present case:

$$g(x)=\frac{\omega}{2a} \tag{6.4.538}$$

The primitive $G(x)$ is therefore easy to calculate and we get:

$$y=Ae^{-\frac{\omega^2}{4a}} \tag{6.4.539}$$

Therefore:

$$F(\omega)=Ae^{-\frac{\omega^2}{4a}} \tag{6.4.540}$$

To determine the constant A it suffices to note that:

$$F(0)=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} e^{-at^2}e^{-\mathrm{i}0t}\mathrm{d}t=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} e^{-at^2}\mathrm{d}t=\frac{1}{\sqrt{2\pi}}\sqrt{\frac{\pi}{a}}=\frac{1}{\sqrt{2a}} \tag{6.4.541}$$

and therefore:

$$F(\omega)=\frac{1}{\sqrt{2a}}e^{-\frac{\omega^2}{4a}} \tag{6.4.542}$$

It is then usual to say that the Fourier transform of a Gaussian is another Gaussian!!

E3. This last example is very important to understand the Nyquist sampling (see section Electrical Engineering page 8506). We consider a square pulse in the frequency domain:

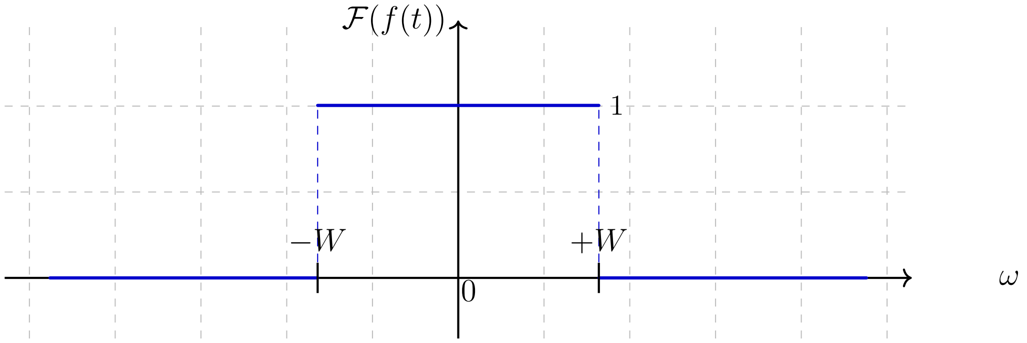


Figure 6.93: **Rectangular pulse example for Inverse Fourier Transform (author: Izaak Neutelings)**

Let us calculate its inverse Fourier transform:

$$\begin{aligned}\mathcal{F}^{-1}(F(\omega))(t)&=\frac{1}{2\pi}\int\limits_{-\infty}^{+\infty} F(\omega)e^{\mathrm{i}\omega t}\mathrm{d}\omega=\frac{1}{2\pi}\int\limits_{-W}^{+W} 1\cdot e^{\mathrm{i}\omega t}\mathrm{d}\omega\\&=\frac{1}{2\pi}\frac{1}{\mathrm{i}t}\left[e^{\mathrm{i}\omega t}\Big|_{-W}^{+W}\right]=\frac{1}{2\pi}\frac{1}{\mathrm{i}t}\left(e^{\mathrm{i}\omega t}-e^{-\mathrm{i}\omega t}\right)=\frac{1}{\pi t}\sin(Wt)=\frac{W}{\pi}\mathrm{sinc}(Wt)\end{aligned} \tag{6.4.543}$$

There is something important to notice here (or to remember whatever...)!!! First, we know that sinc is equal to 1 at $t=0$. But we also know that every time $Wt=k\pi$ with $k\in\mathbb{N}^*$ we have $\text{sinc}=0$. Therefore, every time $t=k\pi/W$ we have:

$$\mathcal{F}^{-1}(F(\omega))(t)=\frac{W}{\pi}\text{sinc}(Wt)=0 \tag{6.4.544}$$

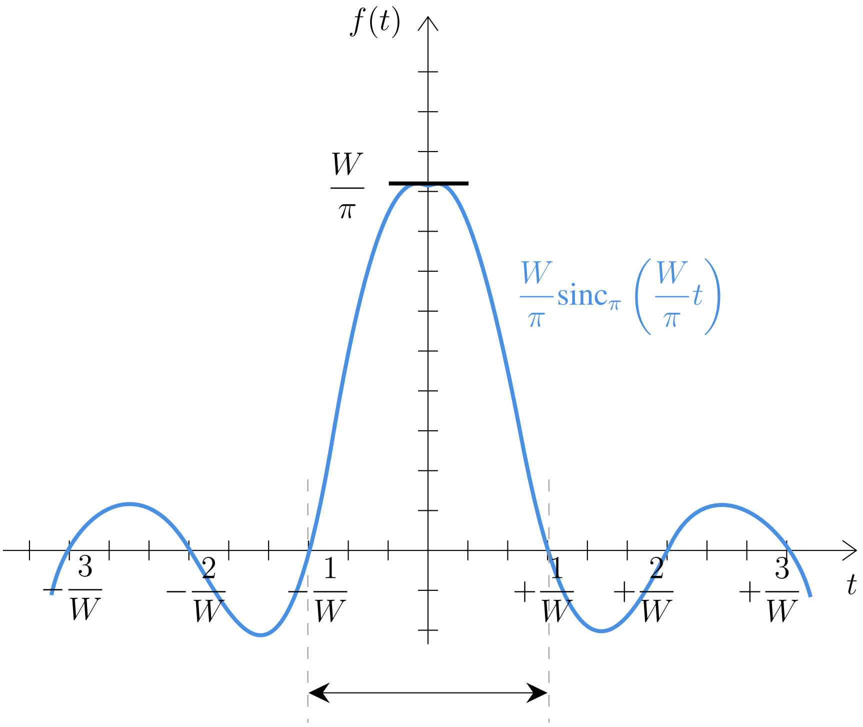
To make things more nice, signal processing engineers like to write rather the previous result into the form:

$$\mathcal{F}^{-1}(F(\omega))(t)=\frac{W}{\pi}\text{sinc}\left(\pi\frac{W}{\pi}t\right)=\frac{W}{\pi}\text{sinc}_\pi\left(\frac{W}{\pi}t\right) \tag{6.4.545}$$

and as you have almost surely noticed... this introduce a new type of sine cardinal (sic...!). You may ask yourself why....????? That's quite easy. Written this way the sinc_π cancels for:

$$t=\frac{k}{W}\qquad\forall k\in\mathbb{N}^* \tag{6.4.546}$$

This is prettier.... and even has a name: the "normalized sinc function" and result in the following well known plot in signal processing for the study of the Nyquist sampling theorem:



width of the main lobe is equal to $2/W$

We will see plenty of other Fourier transform in the section of Function Analysis page 2319.

6.4.2.8 Bessel Series

Bessel functions are very useful in many advanced fields of physics involving delicate differential equations to solve. The areas in which we find them most often are calorimetry (heat conduction), nuclear physics (physics of reactors), optics and fluid mechanics.

This series are still not study too much in the graduate curriculum and it is often the role of the student to seek the additional information it needs on this subject in the library of his school. We wanted to present here the developments that avoid this approach while staying at home in front of our computer (furthermore books on the subject are quite rare...).

> **Remark**
>
> We usually speak by abuse of language of "Bessel functions" instead of "Bessel series".

There is a significant amount of Bessel functions but we will restrict ourselves to the study of those most used one in physics.

6.4.2.8.1 Zero order Bessel's Functions

The function known as the "Zero order Bessel's function", is defined by the power series:

$$\boxed{J_0(x)=1-\frac{x^2}{2^2}+\frac{x^4}{2^2\cdot 4^2}-\frac{x^6}{2^2\cdot 4^2\cdot 6^2}+\ldots} \tag{6.4.547}$$

It is during the study of the properties of derivation and integration that Friedrich Bessel found that this series of power is a solution to a differential equation that is found frequently in physics. That is why it bears his name.

If u_r represents the r-th term of the series, we easily see that:

$$\frac{u_{r+1}}{u_r}=\frac{-x^2}{(2r)^2} \tag{6.4.548}$$

which tends to zero as $r\rightarrow +\infty$, regardless of the value of x. This has for consequence that the series converges for all values of x. Since this is a series of positive power, the function $J_0(x)$ and all its derivatives are continuous function for all values of x, real or complex.

6.4.2.8.2 n order Bessel's Functions

The function $J_n(x)$, known as the "n order Bessel's function", is defined, when n is a positive integer, by the power series:

$$\boxed{J_n(x)=\frac{x^n}{2^n n!}\left(1-\frac{x^2}{2\cdot(2n+2)}+\frac{x^4}{2\cdot 4(2n+2)(2n+4)}-\ldots\right)} \tag{6.4.549}$$

which converges for all values of x, real or complex.

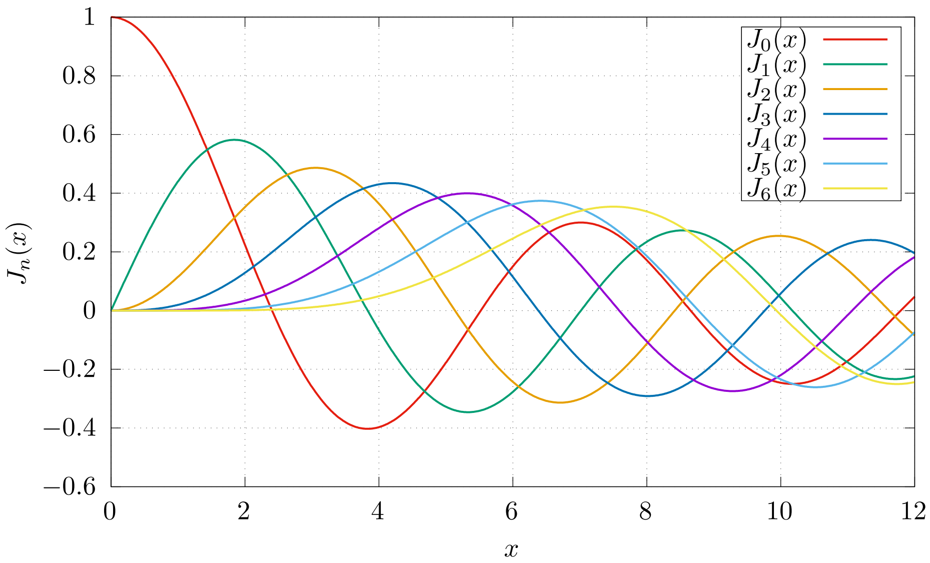


Figure 6.94: **Plot of a few Bessel functions (source: Wikipedia)**

and in Microsoft® Excel® or Maple™ 4.00b the previous function can be found under the name `BESSELJ( )`. For example for the previous graph in Maple™, we just write:

```
>plot([BesselJ(0,x),BesselJ(1,x),BesselJ(2,x),BesselJ(3,x)],x=0..20);
```

Let us see in particular, that for $n=1$ we have:

$$J_1(x)=\frac{x}{2}-\frac{x^3}{2^2\cdot 4}+\frac{x^5}{2^2\cdot 4^2\cdot 6}-\frac{x^7}{2^2\cdot 4^2\cdot 6^2\cdot 8}+\ldots \qquad (6.4.550)$$

and when $n=2$:

$$J_2(x)=\frac{x^2}{2\cdot 4}-\frac{x^4}{2^2\cdot 4\cdot 6}+\frac{x^6}{2^2\cdot 4^2\cdot 6\cdot 8}-\frac{x^8}{2^2\cdot 4^2\cdot 6^2\cdot 8\cdot 10}+\ldots \qquad (6.4.551)$$

We can notice that $J_n(x)$ is an even function of x when n is even and odd if n is odd (see section Functional Analysis page 2212).

If we play to do engineering maths we notice by trial and errors that:

$$\begin{aligned}J_n(x)&=\frac{x^n}{2^n n!}\left(1-\frac{x^2}{2\cdot(2n+2)}+\frac{x^4}{2\cdot 4(2n+2)(2n+4)}-\ldots\right)\\&=\left(\frac{x}{2}\right)^n\frac{1}{n!}\sum_{k=0}^{+\infty}\left((-1)^k\cdot(???)\right)\left(\frac{x}{2}\right)^{2k}\end{aligned} \qquad (6.4.552)$$

Based on this trial and error approach we have using the above expression by factorizing the $(x/2)^{2k}$ term only:

$$\begin{aligned}J_0&=1-\frac{1}{1}\frac{x^2}{2^2}+\frac{1}{2}\frac{x^4}{2^4}-\frac{1}{36}\frac{x^6}{2^6}+\ldots\\J_1&=\frac{x}{2\cdot 1!}\left(1-\frac{x^2}{2^2\cdot 2}+\frac{x^4}{2^2\cdot 4^2\cdot 3}-\frac{x^6}{2^2\cdot 4^2\cdot 6^2\cdot 4}+\ldots\right)\\&=\frac{x}{2}\left(\frac{1}{1}-\frac{1}{2}\frac{x^2}{2^2}+\frac{1}{2^2\cdot 3}\frac{x^4}{2^4}-\frac{1}{6^2\cdot 4}\frac{x^6}{2^6}+\ldots\right)\\J_2&=\ldots\end{aligned} \qquad (6.4.553)$$

So finally we see after trial and errors again (instead than doing 5 pages of mathematical developments as do mathematicians) that:

$$\boxed{J_n=\left(\frac{x}{2}\right)^n\sum_{k=0}^{+\infty}\frac{(-1)^k}{k!(n+k)!}\left(\frac{x}{2}\right)^{2k}=\sum_{k=0}^{+\infty}\frac{(-1)^k}{k!(n+k)!}\left(\frac{x}{2}\right)^{2k+n}} \tag{6.4.554}$$

More generally for n that is non-integer we use the Euler Gamma function (see section Differential and Integral Calculus page 1574):

$$J_n=\sum_{k=0}^{+\infty}\frac{(-1)^k}{k!\Gamma(n+k+1)}\left(\frac{x}{2}\right)^{2k+n} \tag{6.4.555}$$

That is also sometimes written by pure mathematicians (...):

$$J_n=\sum_{k=0}^{+\infty}\frac{(-1)^k}{\Gamma(k+1)\Gamma(n+k+1)}\left(\frac{x}{2}\right)^{2k+n} \tag{6.4.556}$$

Now by differentiating the function $J_0(x)$ and comparing the result with the series $J_1(x)$, we see that without much pain that:

$$\frac{\mathrm{d}J_0(x)}{\mathrm{d}x}=-J_1(x) \tag{6.4.557}$$

We also find without too much difficulty, the following relation:

$$\frac{\mathrm{d}}{\mathrm{d}x}xJ_1(x)=xJ_0(x) \tag{6.4.558}$$

Remark

In general by recursive reasoning we get:

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}x}(x^nJ_n(x))=x^nJ_{n-1}(x)} \tag{6.4.559}$$

Therefore:

$$\boxed{x^nJ_n(x)=\int_0^x y^nJ_{n-1}(y)\mathrm{d}y} \tag{6.4.560}$$

This last relation will be useful to us in the section of Wave Optics for our study of the circular aperture diffraction (Airy disk).

Using the fact that:

$$\frac{\mathrm{d}J_0(x)}{\mathrm{d}x}=-J_1(x) \tag{6.4.561}$$

and including it in the previous relation, we find:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(x\frac{\mathrm{d}J_0(x)}{\mathrm{d}x}\right)+xJ_0(x)=0 \tag{6.4.562}$$

written in another way:

$$x\frac{\mathrm{d}^2J_0(x)}{\mathrm{d}x^2}+\frac{\mathrm{d}J_0(x)}{\mathrm{d}x}+xJ_0(x)=0 \tag{6.4.563}$$

$y=J_0(x)$ is therefore a solution of the differential equation of the second order:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(x\frac{\mathrm{d}y}{\mathrm{d}x}\right)+xy=0 \tag{6.4.564}$$

written otherwise:

$$x\frac{\mathrm{d}^2y}{\mathrm{d}x^2}+\frac{\mathrm{d}y}{\mathrm{d}x}+xy=0 \tag{6.4.565}$$

or even:

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2}+\frac{1}{x}\frac{\mathrm{d}y}{\mathrm{d}x}+y=0 \tag{6.4.566}$$

A solution to an equation of parameter n which is not a multiple of $J_n(x)$ is named "Bessel function of the second kind". Let us suppose now that u is such a function and let us put $v=J_0(x)$; then according to the relation:

$$x\frac{\mathrm{d}^2y}{\mathrm{d}x^2}+\frac{\mathrm{d}y}{\mathrm{d}x}+xy=0 \tag{6.4.567}$$

we have:

$$xu''+u'+xu=0 \quad \text{and} \quad xv''+v'+xv=0 \tag{6.4.568}$$

Multiplying the first relation by v and the second by u and after subtracting, we get:

$$x(u''v-uv'')+u'v-uv'=0 \tag{6.4.569}$$

we therefore also have:

$$\frac{\mathrm{d}}{\mathrm{d}x}(u'v-uv')=u''v+u'v'-u'v'-uv''=u''v-uv'' \tag{6.4.570}$$

we can therefore write:

$$\frac{\mathrm{d}}{\mathrm{d}x}[x(u'v-uv')]=0 \tag{6.4.571}$$

Indeed, because if we develop, we find:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}x}[x(u'v-uv')]&=1\cdot u'v+xu''v+xu'v'-1\cdot uv'-xu'v'-xuv''\\&=x(u''v+u'v'-u'v'-uv'')+u'v-uv'\\&=x(u''v-uv'')+u'v-uv'=0\end{aligned} \tag{6.4.572}$$

For the equality:

$$\frac{\mathrm{d}}{\mathrm{d}x}[x(u'v-uv')]=0 \tag{6.4.573}$$

is satisfied, we have:

$$x(u'v-uv')=c^{te}=B \tag{6.4.574}$$

Dividing by xv^2, we have:

$$\frac{(u'v-uv')}{v^2}=\frac{B}{xv^2} \tag{6.4.575}$$

which is equivalent to:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{u}{v}\right)=\frac{B}{xv^2} \tag{6.4.576}$$

immediately, by integrating it comes:

$$\frac{u}{v}=A+B\int\frac{1}{xv^2}\mathrm{d}x \tag{6.4.577}$$

where A is a constant. Consecutively we have since $v=J_0(x)$:

$$u=AJ_0(x)+BJ_0(x)\int\frac{1}{xJ_0^2(x)}\mathrm{d}x \tag{6.4.578}$$

where we recall, A and B are constants, and $B\neq 0$ if u is not a multiple of $J_0(x)$ by definition!

If in the last relation, $J_0(x)$ is replaced by its expression in terms of series we have:

$$\frac{1}{xJ_0^2(x)}=\frac{1}{x}+\frac{x}{2}+\frac{5x^3}{32}+\ldots \tag{6.4.579}$$

For those who want to check this last relation (I do not like this kind of algebraic calculations) in Maple™ 4.00b just write:

```
>1/x*taylor(1/(series(BesselJ(0,x),x))^2,x=0,5);
```

Therefore:

$$\begin{aligned}J_0(x)\int\frac{1}{xJ_0^2(x)}\mathrm{d}x&=J_0(x)\left[\log(x)+\frac{x^2}{4}+\frac{5x^4}{128}+\ldots\right]\\&=J_0(x)\log(x)+\left(1-\frac{x^2}{2^2}+\ldots\right)\left(\frac{x^2}{4}+\frac{5x^4}{128}+\ldots\right)\\&=J_0(x)\log(x)+\frac{x^2}{4}-\frac{3x^4}{128}+\ldots\end{aligned} \tag{6.4.580}$$

consecutively if we put:

$$\boxed{Y_0(x)=J_0(x)\log(x)+\frac{x^2}{4}-\frac{3x^4}{128}+\ldots} \tag{6.4.581}$$

where $Y_0(x)$ is a particular Bessel function of the second type named "Bessel-Neumann function of the second kind of zero order".

Identically to the fact that when $J_0(x) \to 0$ when $x \to 0$, the expression $Y_0(x)$ because of the term $\log(x)$ when x is small approaches $Y_0(x) \to -\infty$ when $x \to +0$.

Finally, it comes from what we have seen that $J_0(x)$ and $Y_0(x)$ are independent solutions of the differential equation:

$$\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} + \frac{1}{x}\frac{\mathrm{d}y}{\mathrm{d}x} + y = 0 \tag{6.4.582}$$

The general solution being therefore:

$$y = AJ_0(x) + BY_0(x) \tag{6.4.583}$$

where A, B are arbitrary constants and $x > 0$ so that $Y_0(x)$ is real.

If we replace x by kx, where k is a constant, the differential equation becomes:

$$\frac{1}{k^2}\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} + \frac{1}{kx}\frac{\mathrm{d}y}{k\mathrm{d}x} + y = 0 \tag{6.4.584}$$

by multiplying the whole by k^2 we find the general form of the differential equation:

$$\boxed{\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} + \frac{1}{x}\frac{\mathrm{d}y}{\mathrm{d}x} + k^2 y = 0} \tag{6.4.585}$$

whose general solution is:

$$\boxed{y = AJ_0(kx) + BY_0(kx)} \tag{6.4.586}$$

where $k > 0$ such that $Y_0(kx)$ is real when $x > 0$.

In fact, the Bessel functions are solutions of the differential equation previously studied and solved by the "Frobenius method". Indeed, let us write:

$$L_y \equiv \left(x\frac{\mathrm{d}^2}{\mathrm{d}x^2} + \frac{\mathrm{d}}{\mathrm{d}x} + x \right) y \tag{6.4.587}$$

and let us make the substitution:

$$y = x^\rho \sum_{k=0}^{+\infty} c_k x^k = x^\rho + c_1 x^{\rho+1} + c_2 x^{\rho+2} + c_3 x^{\rho+3} + \ldots \tag{6.4.588}$$

substituting in Ly, we get:

$$Ly = \rho^2 x^{\rho-1} + (\rho+1)^2 c_1 x^\rho + \left[(\rho+2)^2 c_2 + 1\right] x^{\rho+1} + \left[(\rho+3)^2 c_3 + c_1\right] x^{\rho+1} \tag{6.4.589}$$

Now let us choose the c_i to satisfy the differential equation such as:

$$\begin{aligned} (\rho+1)^2 c_1 &= 0 \\ (\rho+2)^2 c_2 + 1 &= 0 \\ (\rho+3)^2 c_3 + c_1 &= 0 \\ &\ldots \end{aligned} \tag{6.4.590}$$

Therefore, unless ρ is a negative integer, we have:

$$\begin{aligned}
&c_1 = c_3 = c_5 = c_7 = \ldots = 0\\
&c_2 = -\frac{1}{(\rho+2)^2}\\
&c_4 = -\frac{c_2}{(\rho+4)^2} = \frac{1}{(\rho+2)^2(\rho+4)^2}\\
&\ldots
\end{aligned} \tag{6.4.591}$$

By substituting these values in the relation:

$$y = x^\rho + c_1 x^{\rho+1} + c_2 x^{\rho+2} + c_3 x^{\rho+3} + \ldots \tag{6.4.592}$$

we get:

$$\boxed{y = x^\rho \left(1 - \frac{x^2}{(\rho+2)^2} + \frac{1}{(\rho+2)^2(\rho+4)^2} - \cdots\right)} \tag{6.4.593}$$

Therefore:

$$x\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} + \frac{\mathrm{d}y}{\mathrm{d}x} + xy = Ly = \rho^2 x^{\rho-1} \tag{6.4.594}$$

If we put $\rho =$ in the prior-previous relation, we get:

$$y = x^\rho \left(1 - \frac{x^2}{(\rho+2)^2} + \frac{1}{(\rho+2)^2(\rho+4)^2} - \cdots\right) = J_0(x) \tag{6.4.595}$$

6.4.2.8.3 Bessel's Differential Equations of order n

We have defined the Bessel series as:

$$J_n(x) = \frac{x^n}{2^n n!}\left(1 - \frac{x^2}{2(2n+2)} + \frac{x^4}{2\cdot 4\cdot(2n+2)(2n+4)} - \cdots\right) \tag{6.4.596}$$

Let us put:

$$y = J_n(x)2^n n! = x^n - \frac{x^{n+2}}{2(2n+2)} + \frac{x^{n+4}}{2\cdot 4(2n+2)(2n+4)} - \cdots \tag{6.4.597}$$

and let us derivate as follows:

$$x\frac{\mathrm{d}}{\mathrm{d}x}\left(x\frac{\mathrm{d}y}{\mathrm{d}x}\right) = n^2 x^n - \frac{(n+2)^2 x^{n+2}}{2(2n+2)} + \frac{(n+4)^2 x^{n+4}}{2\cdot 4(2n+2)(2n+4)} - \cdots \tag{6.4.598}$$

But we also have:

$$n^2 y = n^2 x^n - \frac{n^2 x^{n+2}}{2(2n+2)} + \frac{n^2 x^{n+4}}{2\cdot 4(2n+2)(2n+4)} - \cdots \tag{6.4.599}$$

By subtraction:

$$x\frac{\mathrm{d}}{\mathrm{d}x}\left(x\frac{\mathrm{d}y}{\mathrm{d}x}\right) - n^2 y = -x^{n+2} + \frac{x^{n+4}}{2(2n+2)} - \cdots = -x^2 y \tag{6.4.600}$$

Which finally gives:

$$x\frac{\mathrm{d}}{\mathrm{d}x}\left(x\frac{\mathrm{d}y}{\mathrm{d}x}\right)+(x^2-n^2)y=0 \tag{6.4.601}$$

This is also written:

$$\boxed{x^2\frac{\mathrm{d}^2y}{\mathrm{d}x}+x\frac{\mathrm{d}y}{\mathrm{d}x}+(x^2-n^2)y=0} \tag{6.4.602}$$

which is named the "Bessel differential equation of order n" or more simply "Bessel equation". In fact, most schools or Internet sites give this differential equation as a definition but now it is clear that there is rigorous reasoning behind this equation.

The solution is therefore of the type:

$$y=2^n n!J_n(x) \tag{6.4.603}$$

which is still sometimes written using the gamma Euler function (see section Differential and Integral Calculus page 1574):

$$y=2^n\Gamma_0(n)J_n(x)=c^{te}J_n(x) \tag{6.4.604}$$

It follows that:

$$x^2\frac{\mathrm{d}^2J_n(x)}{\mathrm{d}x^2}+x\frac{\mathrm{d}J_n(x)}{\mathrm{d}x}+(x^2-n^2)J_n(x)=0 \tag{6.4.605}$$

and therefore that $y=J_n(x)$ is the solution of this differential equation.

We will fall back on such a differential equation during our study of the wave equation of a circular drum (see section Wave Mechanics page 3500), during our study of the physics of nuclear reactors (see section Nuclear Physics) and finally during our study of self-buckling (see section Mechanical Engineering page 8415).

6.4.3 Convergence Criteria

When we study a series, one of the fundamental questions is that of the convergence or divergence of this series.

If a series converges, its general term approaches zero as n approaches infinity:

$$\lim_{n\to+\infty} a_n=0 \tag{6.4.606}$$

or obviously generally:

$$\lim_{n\to+\infty} a_n=c^{te} \tag{6.4.607}$$

This criterion is necessary but insufficient to establish the convergence of a series. By cons, if this criterion is not met, we are absolutely sure that the series does not converge (so it diverges!).

Three methods are proposed to deepen the convergence criteria:

1. The integral test
2. The d'Alembert rule
3. The Cauchy rule

In the following paragraphs, we will assume the series with positive terms. The case of alternating series will be seen later.

6.4.3.1 Integral Test

The integral test for convergence is a method used to test infinite series of non-negative terms for convergence. It was developed by Colin Maclaurin and Augustin-Louis Cauchy and is sometimes known as the "Maclaurin–Cauchy test".

Given the series with decreasing positive (monotone decreasing) terms:

$$a_1+a_2+a_3+\cdots+a_n+\cdots \tag{6.4.608}$$

That is to say:

$$a_1\geq a_2\geq a_3\geq\cdots\geq a_n\geq\cdots \tag{6.4.609}$$

and given a continuous decreasing function such that:

$$f(1)=a_1,f(2)=a_2,\ldots,f(n)=a_n \tag{6.4.610}$$

Then the infinite series:

$$\sum_{n=1}^{+\infty} f(n) \tag{6.4.611}$$

converges to a real number if and only if the improper integral:

$$\int\limits_1^{+\infty} f(x)\mathrm{d}x \tag{6.4.612}$$

is finite. In other words, if the integral diverges, then the series diverges as well.

Remark

In no case does the integral gives the value of the sum of the series! The full test only gives an indication of the convergence of the series. Before making the test of the integral, it is important to check that the terms of the series are strictly decreasing to fill the condition $a_1\geq a_2\geq a_3\geq\cdots\geq a_n\geq\cdots$.

✍**Example:**

The harmonic series:

$$\sum_{n=1}^{+\infty}\frac{1}{n} \tag{6.4.613}$$

diverges because (see section Differential and Integral Calculus page 1534):

$$\int\limits_{1}^{+\infty}\frac{1}{n}\mathrm{d}n=\ln(n)\Big|_{1}^{+\infty}=\ln(+\infty)\rightarrow+\infty \tag{6.4.614}$$

So this harmonic series does not converge.

6.4.3.2 D'Alembert Rule

The "ratio test" is also a test (or "criterion") for the convergence of a series of the type:

$$\sum_{n=1}^{+\infty}a_n \tag{6.4.615}$$

where each term is a real or complex number and a_n is non-zero when n is large. The test was first published by Jean le Rond d'Alembert and is sometimes known as "d'Alembert's ratio test" or as the "Cauchy ratio test".

The usual form of the test makes use of the limit:

$$L=\lim_{n\rightarrow+\infty}\left|\frac{a_{n+1}}{a_n}\right| \tag{6.4.616}$$

The ratio test states that:

1. if $L<1$ then the series converges absolutely;
2. if $L>1$ then the series does not converge;
3. if $L=1$ or the limit fails to exist, then the test is inconclusive, because there exist both convergent and divergent series that satisfy this case

and we define the "radius of convergence" by:

$$R=\frac{1}{L} \tag{6.4.617}$$

For the proof suppose that:

$$L=\lim_{n\rightarrow+\infty}\left|\frac{a_{n+1}}{a_n}\right|<1 \tag{6.4.618}$$

Remark

In reality this rule is normally without the absolute value. The case with the absolute value as above is named the "absolute convergence test" and applied for the more general case of an alternate series such that:

$$a_1+|-a_2|+a_3+|-a_4|+\ldots+|-a_n|+\ldots \qquad (a_n>0) \tag{6.4.619}$$

If an alternating series of terms is absolutely convergent, the absolute series that follows also converge.

Therefore the absolute convergence test is a generalization of the d'Alembert rule but most of time we don't make any distinctions between the both.

We can then show that the series converges absolutely by showing that its terms will eventually become less than those of a certain convergent geometric series. To do this, let:

$$r=\frac{L+1}{2} \tag{6.4.620}$$

Then r is strictly between L and 1, and:

$$|a_{n+1}|<r|a_n| \tag{6.4.621}$$

for sufficiently large n (say, n greater than N).

Hence:

$$|a_{n+i}|<r^i|a_n| \tag{6.4.622}$$

for each $n>N$ and $i>0$, and so:

$$\sum_{i=N+1}^{+\infty}|a_i|=\sum_{i=1}^{+\infty}|a_{N+i}|<\sum_{i=1}^{+\infty}r^i|a_{N+1}|=|a_{N+1}|\sum_{i=1}^{+\infty}r^i=|a_{N+1}|\frac{r}{1-r}<+\infty \tag{6.4.623}$$

That is, the series converges absolutely.

On the other hand, if $L>1$, then:

$$|a_{n+1}|>|a_n| \tag{6.4.624}$$

for sufficiently large n, so that the limit of the sum is non-zero. Hence the series diverges.

✍**Example:**

Given the following geometric series:

$$\sum_{n=1}^{+\infty}\left(\frac{1}{2}\right)^n=\frac{1}{2}+\frac{1}{4}+\frac{1}{8}+\cdots \tag{6.4.625}$$

We get the quotient:

$$L=\frac{a_{n+1}}{a_n}=\frac{0.5^{n+1}}{0.5^n}=0.5 \tag{6.4.626}$$

Therefore the series converge!

Obviously some practical applications will (can) give for example:

$$L=\lim_{n\rightarrow+\infty}\sqrt[n]{a_n} \tag{6.4.627}$$

and some practitioners name this the "Cauchy convergence rule"... (do not confuse with the Cauchy convergence test that will be study in the section Fractals at page 7038).

✍**Example:**

Let us do now a last important example. We studied earlier above Bessel series. But it can be not obvious that these series converge. Let us prove that this is indeed the case for J_0, that is to say for:

$$J_0=\sum_{k=0}^{+\infty}\frac{(-1)^k}{k!(n+k)!}\left(\frac{x}{2}\right)^{2k+n}=\sum_{k=0}^{+\infty}\frac{(-1)^k x^{2k}}{2^{2k}k!^2} \tag{6.4.628}$$

Therefore:

$$\begin{aligned}L&=\lim_{k\rightarrow+\infty}\left|\frac{a_{n+1}}{a_n}\right|=\lim_{k\rightarrow+\infty}\left|\frac{(-1)^{k+1}x^{2(k+1)}}{2^{2(k+1)}[(k+1)!]^2}\cdot\frac{2^{2k}k!^2}{(-1)^k x^{2k}}\right|\\&=\lim_{k\rightarrow+\infty}\left|\frac{x^{2k+2}}{2^{2k+2}[(k+1)!]^2}\cdot\frac{2^{2k}(k!)^2}{x^{2k}}\right|\\&=\lim_{k\rightarrow+\infty}\left|\frac{x^{2k}x^2}{2^{2k}2^2(k+1)!(k+1)!}\cdot\frac{2^{2k}k!k!}{x^{2k}}\right|=\lim_{n\rightarrow+\infty}\left|\frac{x^2k!k!}{4(k+1)k!(k+1)k!}\right|\\&=\lim_{k\rightarrow+\infty}\left|\frac{x^2}{4(k+1)(k+1)}\right|=\lim_{k\rightarrow+\infty}\frac{1}{(k+1)^2}\left|\frac{x^2}{4}\right|=\lim_{n\rightarrow+\infty}\frac{x^2}{4(k+1)^2}\\&=0\end{aligned} \tag{6.4.629}$$

6.4.3.3 Alternating Series Test

The alternating series test is a method used to prove that an alternating series with terms that decrease in absolute value is a convergent series. The test was used by Gottfried Leibniz and is sometimes known as "Leibniz's test", "Leibniz's rule, or the "Leibniz criterion".

A series of the form:

$$\sum_{n=0}^{+\infty}(-1)^n a_n = a_0 - a_1 + a_2 - a_3 + \cdots \tag{6.4.630}$$

where either all a_n are positive or all a_n are negative, is named an "alternating series".

The alternating series test then says: if a_n decreases monotonically and that:

$$\lim_{n\rightarrow+\infty} a_n = 0 \tag{6.4.631}$$

then the alternating series converges!

There's a lot of other tests of the same kind as the Raabe's test, the Bertrand's test, the Gauss's test, the Kummer's test, etc.

6.4.3.4 Fixed Point Theorem

The fixed point theorem is not really useful in physics and for the engineers (but implicitly it is essential but physicists and engineers often use math tools whose properties have already been approved in advance by mathematicians), however we find it in Chaos Theory and in Theoretical Computing (see the section on Fractals at page 7038 especially the topic on the Sierpinski triangle). We can therefore only recommend the reader to take the time to read and understand the explanations and developments that follow.

Let (X,d), be a complete metric space (see sections Topology page 2447 or Fractals page 7054) and $T:X\mapsto X$ an application strictly contracting of constant L (see the Lipschitz functions in the section Topology page 2457), then there exists a unique point $\omega\in X$ such that:

$$T(\omega)=\omega \tag{6.4.632}$$

ω is then named the "fixed point" of T (think to the case $\cos(x)=x$). Furthermore, if denote by:

$$T^n(x)=\underbrace{T(T(T\ldots T}_{n \text{ times}}(x)\ldots)) \tag{6.4.633}$$

the image of x by the n-th iterate of T, then we have:

$$\omega=\lim_{t\rightarrow\infty}\left(T^n(x)\right) \quad \forall x\in X \tag{6.4.634}$$

and the convergence speed can also be estimated by:

$$\mathrm{d}\left(\omega,T^n(x)\right)\leq \mathrm{d}\left(x,T(x)\right)\frac{L^n}{1-L} \tag{6.4.635}$$

By the fact that we restrict our study to iterating a function, we speak of "Banach fixed-point theorem" that gives a general criterion guaranteeing that, if it is satisfied, the procedure of iterating a function yields a fixed point.

Remark

You can have fun with your pocket calculator or your operating system by choosing a random number and taking the cosine iteratively. You will find you will tend to 0.74 and therefore it is verbatim the solution of $\cos(x)=x$.

Proof 6.25.2. Given $x\in X$. We consider the following sequence $(T^n(x))_{n\in\mathbb{N}}$ as defined above. First we will prove that this sequence is a Cauchy sequence (see above what is a Cauchy sequence).

Applying the triangle inequality (see section Vector Calculus page 1828) several times we have:

$$\begin{aligned}\mathrm{d}\big(T^{n+k}(x),T^n(x)\big) \leq &\mathrm{d}\big(T^{n+k}(x),T^{n+k-1}(x)\big)+\mathrm{d}\big(T^{n+k-1}(x),T^{n+k-2}(x)\big)\\ &+\cdots+\mathrm{d}\big(T^{n+1}(x),T^n(x)\big)\end{aligned}\tag{6.4.636}$$

But:

$$\mathrm{d}\big(T^{n+1}(x),T^n(x)\big)\leq L\cdot\mathrm{d}\big(T^n(x),T^{n-1}(x)\big)\leq\cdots\leq L^n\cdot\mathrm{d}\big(T(x),x\big)\tag{6.4.637}$$

Therefore:

$$\mathrm{d}\big(T^{n+k}(x),T^n(x)\big)\leq(L^{n+k-1}+L^{n+k-2}+\cdots+L^n)\cdot\mathrm{d}\big(T(x),x\big)=L^n\cdot d\big(T(x),x\big)\cdot(1+L+L^2+\ldots+L^{k-1})\tag{6.4.638}$$

and as:

$$(1+L+L^2+\ldots+L^{k-1})\leq\frac{1-L^k}{1-L}\leq\frac{1}{1-L}\tag{6.4.639}$$

Therefore:

$$\mathrm{d}\big(T^{n+k}(x),T^n(x)\big)\leq\frac{L^n}{1-L}\cdot\mathrm{d}\big(T(x),x\big)\tag{6.4.640}$$

To finish:

$$0\leq L\leq 1\Rightarrow\lim_{n\rightarrow+\infty}\frac{L^n}{1-L}=0\tag{6.4.641}$$

that is to say, that in a first time $(T^n(x))_{n\in\mathbb{N}}$ converge, and we put:

$$\omega=\lim_{n\rightarrow+\infty}T^n(x)\tag{6.4.642}$$

Now we check that ω is a fixed point of T. Indeed T is uniformly continuous (as Lipschitz - see section Topology page 2457) therefore a fortiori continue:

$$\omega=\lim_{n\rightarrow+\infty}T^n(x)=\lim_{n\rightarrow+\infty}T\big(T^{n-1}(x)\big)\underbrace{=}_{\text{as }T\text{ is continuous}}T\left(\lim_{n\rightarrow+\infty}T^{n-1}(x)\right)=T(\omega)\tag{6.4.643}$$

It remains to check that ω is the only fixed point (therefore we will have proved that ω does not depend on the choice of x). Suppose that we also have $T(y)=y$ then:

$$\mathrm{d}(y,\omega)=\big(T(y),T(\omega)\big)\leq L\cdot\mathrm{d}(y,\omega)\Rightarrow\mathrm{d}(y,\omega)=0\Rightarrow y=\omega \tag{6.4.644}$$

An estimate of the speed of convergence is given by:

$$\mathrm{d}\big(T^{n+k}(x),T^n(x)\big)\leq\frac{L^n}{1-L}\cdot\mathrm{d}\big(T(x),x\big) \tag{6.4.645}$$

$\mathrm{d}(,)$ is continuous with respect to each variable so:

$$\lim_{k\rightarrow+\infty}\mathrm{d}\big(T^{n+k}(x),T^n(x)\big)=\mathrm{d}\left(\lim_{k\rightarrow\infty}T^{n+k}(x),T^n(x)\right)=\mathrm{d}\big(\omega,T^n(x)\big) \tag{6.4.646}$$

and the limits preserve the inequalities (not strict one) thus:

$$\mathrm{d}\big(\omega,T^n(x)\big)\leq\frac{L^n}{1-L}\mathrm{d}\big(T(x),x\big) \tag{6.4.647}$$

■ Q.E.D.

6.4.4 Generating Functions

For some mathematical financial risk management models (see section Economy page 7485) and also integration transformation of Bessel functions (see section Differential and Integral Calculus page 1564) we will need in this textbook a gentle introduction to generating functions.

6.4.4.1 Ordinary Generating Functions (transformation of a sequence into a series)

Remember first that we have proved earlier above that the general Maclaurin expansion of a function was given by:

$$f(x)=\sum_{k=0}^{+\infty}\frac{f^{(n)}(0)}{n!}x^n \tag{6.4.648}$$

That is for $x\cong 0$:

$$f(x)=f(0)+f'(0)x+\frac{f''(0)}{2}x^2+\frac{f'''(0)}{6}x^3+\ldots \tag{6.4.649}$$

In the case of our study, let us write the latter relation as:

$$\boxed{G(x)=a_0+a_1x+a_2x^2+a_3x^3+\ldots=\sum_k a_kx^k} \tag{6.4.650}$$

We say then that the above relation is the "ordinary generating function" of the sequences of numbers $a_0,a_1,a_2,a_3,\ldots$ in the formal parameter x. And we don't care if it diverges or not!

Because the generating function is an algebraic expression that encodes the sequence and allows us to manipulate it in ways that are not possible in other forms. Many times if the sequence you are looking at is "interesting" (and this word has lots of interpretations), the generating function has a short simple form.

The generating function allows us to derive formulas for the sequence, identities involving the sequence, estimate the values and so much more as we will see further below.

One thing to never forget: The generating function is not the sequence and the sequence is not the generating function. They are not the same thing. One is a sequence, the other is an algebraic expression!

If you have a sequence you can say "the generating function of the sequence" to refer to the algebraic object. If you have a generating function you might say "the sequence of coefficients of the generating function" in order to refer to the sequence.

Let us try now a companion example, the sequence consisting of all 1:

$$1,1,1,1,1,1,1,\ldots \tag{6.4.651}$$

The generating function is therefore the geometric series that we have proved earlier above implicitly (explicitly you can see the proof at page 2419):

$$1+1x+1x^2+1x^3+\ldots=1+x+x^2+x^3+\ldots=\frac{1}{1-x} \tag{6.4.652}$$

The next simple companion example would be the positive integers:

$$1,2,3,4,5,\ldots \tag{6.4.653}$$

This has for generating function:

$$1+2x+3x^2+4x^3+\ldots \tag{6.4.654}$$

Now we observe that the derivative of this generating function is the generating function itself:

$$1+x+x^2+x^3+\ldots=\frac{1}{1-x} \tag{6.4.655}$$

Indeed:

$$\frac{\mathrm{d}}{\mathrm{d}x}(1+x+x^2+x^3+\ldots)=1+2x+3x^2+4x^3+\ldots \tag{6.4.656}$$

That is we have therefore:

$$\frac{\mathrm{d}}{\mathrm{d}x}\frac{1}{1-x}=1+2x+3x^2+4x^3+\ldots \tag{6.4.657}$$

We conclude that:

$$\frac{1}{(1-x)^2}=1+2x+3x^2+4x^3+\ldots=\sum_{k=0}^{+\infty}(k+1)x^k \tag{6.4.658}$$

We can't use the exactly same trick to figure out the generating function for the sequence:

$$1,4,9,16,25 \tag{6.4.659}$$

because if we take the derivative of:

$$1+2x+3x^2+4x^3+\ldots \tag{6.4.660}$$

then we do not quite have the square integers. But the attentive reader will notice that if we first multiply the latter relation by x and then take the derivative then we have:

$$\begin{aligned}1+4x+9x^2+16x^3+\ldots&=1^2+2^2x+3^2x+4^2x^3+\ldots\\&=\frac{\mathrm{d}}{\mathrm{d}x}(x+2x^2+3x^3+4x^4+\ldots)\\&=\frac{\mathrm{d}}{\mathrm{d}x}(x(1+2x+3x^2+4x^3+\ldots))\\&=\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{x}{(1-x)^2}\right)\end{aligned} \tag{6.4.661}$$

Therefore:

$$\sum_{k=0}^{+\infty}(k+1)^2x^k=\frac{1+x}{(1-x)^3} \tag{6.4.662}$$

It is easy with a software like Maple™ to control that the Maclaurin series of $(1+x)/(1-x)^3$ is equal to the generating function and therefore gives us the coefficients a_i of the sequence.

Let us see now a non-trivial example... It's the Fibonacci sequence given for recall (see page 1661) by (each term is equal to the sum of the previous two):

$$1,1,2,3,5,8,13,21,34,55,\ldots \tag{6.4.663}$$

We will give the generating function for this sequence a name $F(x)$ so then:

$$F(x)=\sum_{k=0}^{+\infty}=1+x+2x^2+3x^3+5x^4+\ldots \tag{6.4.664}$$

where $F_0=F_1=1$ and $F_k=F_{k-1}+F_{k-2}$ for $k\geq 2$. Then we can see that:

$$\begin{aligned}F(x)&=1+x+\sum_{k=2}^{+\infty}F_kx^k=1+x+\sum_{k=2}^{+\infty}(F_{k-1}+F_{k-2})x^k\\&=1+x+\sum_{k=2}^{+\infty}F_{k-1}x^k+\sum_{k=2}^{+\infty}F_{k-2}x^k\\&=1+x+(x^2+2x^3+3x^4+\ldots)+(x^2+x^3+2x^4+3x^5+\ldots)\\&=1+xF(x)+x^2F(x)\end{aligned} \tag{6.4.665}$$

Since we have figured out that:

$$F(x)=1+xF(x)+x^2F(x) \tag{6.4.666}$$

then:

$$F(x)-xF(x)-x^2F(x)=1 \tag{6.4.667}$$

and this can be rewritten as:

$$F(x)(1-x-x^2)=1 \tag{6.4.668}$$

and hence:

$$F(x)=\frac{1}{1-x-x^2} \tag{6.4.669}$$

It is always surprising that the generating function for the Fibonacci numbers has such a compact formula. But once again, using for example a software like Maple™ and doing the Maclaurin expansion of the above function, you will get a series whose coefficients a_k corresponds to the Fibonacci sequence!

But let us continue to investigate...! We have therefore the denominator:

$$1-x-x^2 \tag{6.4.670}$$

that can be factorized assuming the equation:

$$1-x-x^2=0 \tag{6.4.671}$$

has solutions! We quickly found that the roots are given by:

$$x_{1,2}=-\frac{1\pm\sqrt{5}}{2} \tag{6.4.672}$$

We recognize here the negative values of the Golden ratio φ and its conjugate (see earlier above page 1389).

Therefore the denominator can be written as (using the relation between the Golden ratio and its conjugate):

$$\begin{aligned}1-x-x^2&=(x-(-\varphi_1))(x-(-\varphi_2))=(x+\varphi_1)(x+\varphi_2))=\varphi_1\varphi_2\left(\frac{x}{\varphi_1}+1\right)\left(\frac{x}{\varphi_2}+1\right)\\&=\varphi\left(-\frac{1}{\varphi}\right)\left(\frac{x}{\varphi_1}+1\right)\left(\frac{x}{\varphi_2}+1\right)=-\left(\frac{x}{\varphi_1}+1\right)\left(\frac{x}{\varphi_2}+1\right)\\&=-\left(-x\varphi_2+1\right)\left(-x\varphi_1+1\right)=-\left(1-x\varphi_1\right)\left(1-x\varphi_2\right)\end{aligned}\tag{6.4.673}$$

Thus we can write:

$$F(x)=\frac{1}{1-x-x^2}=-\frac{1}{\left(1-x\varphi_1\right)\left(1-x\varphi_2\right)}\tag{6.4.674}$$

Let us decompose this fraction (the $-$ sign is now the in the constants A and B):

$$F(x)=-\frac{1}{(1-x\varphi_1)(1-x\varphi_2)}=\frac{A}{(1-x\varphi_1)}+\frac{B}{(1-x\varphi_2)}\tag{6.4.675}$$

where A, B need to be found out. Clearly we have:

$$1=A(1-x\varphi_2)+B(1-x\varphi_1)\tag{6.4.676}$$

By identification, we have the following linear system:

$$\begin{aligned}A+B&=1\\-Ax\varphi_2-Bx\varphi_1&=-x(A\varphi_2+B\varphi_1)=0\end{aligned}\tag{6.4.677}$$

Hence:

$$A+B=1\tag{6.4.678}$$
$$A\varphi_2+B\varphi_1=0\tag{6.4.679}$$

Or written explicitly:

$$A+B=1\tag{6.4.680}$$
$$-\frac{A}{\varphi}+B\varphi=0\tag{6.4.681}$$

The solution to this linear system is straightforward and given by:

$$A=\frac{\varphi^2}{\varphi^2+1}=\frac{\varphi_1}{\varphi_1-\varphi_2}\qquad B=\frac{1}{\varphi^2+1}=\frac{-\varphi_2}{\varphi_1-\varphi_2}\tag{6.4.682}$$

Thus we have:

$$\begin{aligned}F(x)&=\frac{A}{(1-x\varphi_1)}+\frac{B}{(1-x\varphi_2)}=\frac{1}{\varphi_1-\varphi_2}\left(\frac{\varphi_1}{(1-x\varphi_1)}-\frac{\varphi_2}{(1-x\varphi_2)}\right)\\&=\frac{1}{\varphi_1-\varphi_2}\left(\varphi_1\frac{1}{(1-x\varphi_1)}-\varphi_2\frac{1}{(1-x\varphi_2)}\right)\end{aligned}\tag{6.4.683}$$

Next we use another quite famous result, the following Taylor development:

$$\frac{1}{1-x}=1+x+x^2+x^3+\ldots \tag{6.4.684}$$

for $|x|<1$. Using this result we can see that:

$$\sum_{k=0}^{+\infty} F_k x^k = F(x) = \frac{1}{\varphi_1-\varphi_2}\left(\sum_{k=0}^{+\infty}(\varphi_1^{k+1}-\varphi_2^{k+1})x^k\right) \tag{6.4.685}$$

Therefore:

$$F_k=\frac{\varphi_1^{k+1}-\varphi_2^{k+1}}{\varphi_1-\varphi_2}=\frac{\varphi_1^{k+1}-\varphi_2^{k+1}}{\sqrt{5}}=\frac{1}{\sqrt{5}}\left[\left(\frac{1+\sqrt{5}}{2}\right)^{k+1}-\left(\frac{1-\sqrt{5}}{2}\right)^{k+1}\right] \tag{6.4.686}$$

Hence:

$$\boxed{F_k=\frac{1}{\sqrt{5}}\left[\left(\frac{1+\sqrt{5}}{2}\right)^{k+1}-\left(\frac{1-\sqrt{5}}{2}\right)^{k+1}\right]} \tag{6.4.687}$$

This result is sometimes named the "Binet's Fibonacci formula".

6.4.4.1.1 Composition of Generating functions

Now if we have two generating functions:

$$G_1(x)=\sum_{k=0}^{+\infty} a_k x^k \qquad \text{and} \qquad G_2(x)=\sum_{k=0}^{+\infty} b_k x^k \tag{6.4.688}$$

for two sequences of integers $a_0,a_1,a_2,a_3,\ldots$ and $b_0,b_1,b_2,b_3,\ldots$ then there are several ways that we can combine these both sequences and get generating functions for the new corresponding sequence.

- Sum: If we add the generating functions we have that:

  $$A(x)+B(x)=\sum_{k=0}^{+\infty}(a_k+b_k)x^k \tag{6.4.689}$$

  is a generating function for the series:

  $$a_0+b_0,a_1+b_1,a_2+b_2,a_3+b_3,\ldots \tag{6.4.690}$$

- Product: However if we multiply the two generating function, we ha that:

$$\begin{aligned}G_1(x)G_2(x)&=(a_0+a_1x+a_2x^2+a_3x^3+\ldots)(b_0+b_1x+b_2x^2+b_3x^3+\ldots)\\&=a_0b_0+(a_1b_0+a_0b_1)x+(a_2b_0+a_1b_1+a_0b_2)x^2+\ldots\\&=\sum_{k=0}^{+\infty}(a_nb_0+a_{n-1}b_1+\ldots+a_0b_n)x^n\end{aligned} \tag{6.4.691}$$

This can be summarized in the expression:

$$G_1(x)G_2(x)=\sum_{k=0}^{+\infty}\left(\sum_{i=0}^{n}a_{k-i}b_i\right) \quad (6.4.692)$$

Another special case of the product of generating function is the product:

$$\frac{1}{1-x}G(x) \quad (6.4.693)$$

It is the product of two generating functions, the first one being the generating function:

$$\frac{1}{1-x}=1+x+x^2+x^3+\ldots \quad (6.4.694)$$

By:

$$G_1(x)G_2(x)=\sum_{k=0}^{+\infty}\left(\sum_{i=0}^{n}a_{k-i}b_i\right) \quad (6.4.695)$$

The product of these is a generating function for the series (as all $a_i=1$):

$$b_0,b_0+b_1,b_0+b_1+b_2,b_0+b_1+b_2+b_3,\ldots \quad (6.4.696)$$

- Derivative: We have already seen a couple examples of the use of the derivative in previous examples.

Remember now that we have proved that:

$$\frac{1}{(1-x)^2}=1+2x+3x^2+4x^3\ldots=\sum_{k=0}^{+\infty}(k+1)x^k \quad (6.4.697)$$

Therefore by the fact that:

$$\frac{1}{1-x}G(x) \quad (6.4.698)$$

has for generating sequence:

$$b_0,b_0+b_1,b_0+b_1+b_2,b_0+b_1+b_2+b_3,\ldots \quad (6.4.699)$$

we have then that:

$$\frac{1}{1-x}\frac{1}{(1-x)^2} \quad (6.4.700)$$

is then a generating function for the sequence of the sum of the first n positive integers:

$$1,1+2,1+2+3,1+2+3+4,\ldots \quad (6.4.701)$$

In particular, the coefficient of x^k is:

$$1+2+3+\ldots+k+(k+1) \quad (6.4.702)$$

We also know by taking the derivative of $1/(1-x)^2$ we have:

$$\frac{\mathrm{d}}{\mathrm{d}x}=\frac{2}{(1-x^2)}=2\cdot 1+3\cdot 2x+4\cdot 3x^2+5\cdot 4x^3+\ldots \tag{6.4.703}$$

Therefore if we divide this equation by two we have:

$$\frac{1}{(1-x)^3}=\sum_{k=0}^{+\infty}\frac{(k+1)(k+1)}{2}x^k \tag{6.4.704}$$

It must be known that the coefficient of x^k in $1/(1-x)^3$ is equal to $(k+1)(k+2)/2$ and it is equal to the sum of the first $k+1$ integers, so:

$$1+2+3+\ldots+n+(n+1)=\frac{(n+1)(n+2)}{2} \tag{6.4.705}$$

6.4.4.2 Multivariate Generating Functions

Remember that in the section of Calculus we have proved that:

$$\begin{aligned}
&(a+b)^0=1\\
&(a+b)^1=1a+1b\\
&(a+b)^2=1a^2+2ab+1b^2\\
&(a+b)^3=1a^3+3a^2b+3ab^2+1b^3\\
&\qquad\ldots
\end{aligned} \tag{6.4.706}$$

can be expressed by a condensed form that involves the binomial coefficient (see page 1364):

$$(a+b)^n=\sum_{p=0}^{n}C_p^n a^{n-p}b^p \tag{6.4.707}$$

then this is what we name a "multivariate generating function". It works just as the other generating functions we have previously worked with except that it has two parameters.

6.4.4.3 Functional Generating Functions

So far we have seen generating functions that gives scalar values. But a more general family are the "functional generating functions" that give functions instead of simple scalars.

A generating function for a sequences of functions $\{f_n(x)\}$ is obviously a power series of the type:

$$\boxed{G(x,t)=\sum_n f_n(x)t^n} \tag{6.4.708}$$

whose coefficient are now functions of x.

Let us see the both examples that will be useful to us in the sections of Economy, Wave Optics and also Differential and Integral Calculus!.

Let us start with the most important example involving probabilities and especially the Poisson distribution as used in the First Boston Credit Risk Metric model in the section Economy!

Let us recall that the Poisson distribution mass, that is, the probability that N is equal to n, is given by (see section Statistics page 686):

$$P(n)=\frac{\mu^n e^{-\mu}}{n!} \tag{6.4.709}$$

for $n=0,1,2,\ldots$.

The probability generating function is equal to:

$$P_N(t)=P(n=0)+P(n=1)t+P(n=2)t^2+\ldots=\sum_{n=0}^{+\infty}\frac{\mu^n e^{-\mu}}{n!}t^n \tag{6.4.710}$$

We know also the following Maclaurin infinite series expansion:

$$e^u=1+u+\frac{u^2}{2!}+\frac{u^3}{3!}+u\frac{u^4}{4!}+\ldots= \tag{6.4.711}$$

And if we rewrite:

$$P_N(t)=\sum_{n=0}^{+\infty}\frac{\mu^n e^{-\mu}}{n!}t^n \tag{6.4.712}$$

in the following way:

$$P_N(t)=e^{-\mu}\sum_{n=0}^{+\infty}\frac{(\mu t)^n}{n!} \tag{6.4.713}$$

And further assuming the above Maclaurin expansion we can write:

$$\sum_{n=0}^{+\infty}\frac{(\mu t)^n}{n!}=e^{\mu t} \tag{6.4.714}$$

Which implies:

$$\boxed{P_N(t)=e^{-\mu}\sum_{n=0}^{+\infty}\frac{(\mu t)^n}{n!}=e^{-mu}e^{\mu t}=e^{\mu(t-1)}} \tag{6.4.715}$$

This is the probability generating function of a Poisson distribution that we will use for our study of the CreditRisk model.

And now for our study of Wave Optics (especially the Fresnel diffraction for a circular aperture!) let us found the functional generating function of the first kind Bessel functions!

Theorem 6.26. The generating function for the sequence of Bessel function of first kind, on integer order, is:

$$G(x,t)=e^{(x/2)(t-1/t)}=\sum_{n=-\infty}^{+\infty}J_n(x)t^n \tag{6.4.716}$$

Proof 6.26.1. To get an expression for $J_n(x)$, we use the Maclaurin series for e^x to get:

$$\begin{aligned}G(x,t)=e^{xt/2}e^{-x/(2t)}&=\sum_{r=0}^{+\infty}\frac{1}{r!}\left(\frac{x}{2}\right)^r t^r\sum_{s=0}^{+\infty}\frac{(-1)^s}{s!}\left(\frac{x}{2t}\right)^s=\sum_{r=0}^{+\infty}\frac{1}{r!}\left(\frac{x}{2}\right)^r t^r\sum_{s=0}^{+\infty}\frac{(-1)^s}{s!}\left(\frac{x}{2}\right)^s t^{-s}\\&=\sum_{r=0}^{+\infty}\sum_{s=0}^{+\infty}\frac{(-1)^2}{r!s!}\left(\frac{x}{2}\right)^{r+s}t^{r-s}\end{aligned} \tag{6.4.717}$$

Now let us make the change of variable: $n=r-s$.

Therefore the expression in the sum becomes:

$$\frac{(-1)^s}{(n+s)!s!}\left(\frac{x}{2}\right)^{n+2s}t^n \tag{6.4.718}$$

Then it is obvious that as the range of r and s is $]-\infty,+\infty[$ we have for the range of n also: $]-\infty,+\infty[$. So the first sum is easy to determine:

$$\sum_{n=-\infty}^{+\infty}\frac{(-1)^s}{(n+s)!s!}\left(\frac{x}{2}\right)^{n+2s}t^n \tag{6.4.719}$$

But as we can see in the expression in the sum above, we don't get rid of the summation variable s. So there is obviously a second missing sum on the variable s! The interval of summation for s is not obvious at a first glance...

What is sure is that s is still in the range $[0,+\infty]$ (positive values) if we look at the term $s!$ in the denominator. But what makes problem is the lower bound of the sum. So if we look closely to the relation in the sum above we have a term $(n+s)!$. Obviously $n+s$ must never be negative! It comes therefore that if $n<0$, we must have $n+s\geq 0$, that is when $n<0$, s must start $-n$. Finally:

$$G(x,t)=\sum_{n=-\infty}^{+\infty}\sum_{s=\max(0,-n)}^{+\infty}\frac{(-1)^s}{(n+s)!s!}\left(\frac{x}{2}\right)^{n+2s}t^n=\sum_{n=-\infty}^{+\infty}\left[\sum_{s=\max(0,-n)}^{+\infty}\frac{(-1)^s}{(n+s)!s!}\left(\frac{x}{2}\right)^{n+2s}\right]t^n \tag{6.4.720}$$

That is:

$$G(x,t)=\sum_{n=-\infty}^{+\infty}J_n(x)t^n \tag{6.4.721}$$

where the J_n are the Bessel function of the first kind.

■ Q.E.D.

Therefore, for $n \geq 0$:

$$J_n(x)=\sum_{s=\max(0,-n)}^{+\infty} \frac{(-1)^s}{(n+s)!s!}\left(\frac{x}{2}\right)^{n+2s} \tag{6.4.722}$$

And for $n<0$:

$$J_{-n}(x)=\sum_{s=n}^{+\infty} \frac{(-1)^s}{((-n)+s)!s!}\left(\frac{x}{2}\right)^{(-n)+2s}=\sum_{s=n}^{+\infty} \frac{(-1)^s}{(s-n)!s!}\left(\frac{x}{2}\right)^{-n+2s} \tag{6.4.723}$$

Using an index shift, we get:

$$J_{-n}(x)=\sum_{s=0}^{+\infty} \frac{(-1)^{s+n}}{((s+n)-n)!(s+n)!}\left(\frac{x}{2}\right)^{-n+2(s+n)}=\sum_{s=0}^{+\infty} \frac{(-1)^{s+n}}{s!(s+n)!}\left(\frac{x}{2}\right)^{n+2s}=(-1)^n J_n(x) \tag{6.4.724}$$

There is also a very useful recursive relationship when implementing first kind Bessel functions in computer code that we can derive thanks to the generating function!

First, let us remind that we have just seen that from Generating Function for Bessel Function of the First Kind of Order n of x we have:

$$\exp\left(\frac{x}{2}\left(t-\frac{1}{t}\right)\right)=\sum_{n=-\infty}^{+\infty} J_n(x)t^n \tag{6.4.725}$$

Differentiating both sides of the equation with respect to t we get:

$$\frac{x}{2}\left(1+\frac{1}{t^2}\right)\exp\left(\frac{x}{2}\left(t-\frac{1}{t}\right)\right)=\sum_{n=-\infty}^{+\infty} nJ_n(x)t^{n-1} \tag{6.4.726}$$

That can be obviously rewritten as:

$$\frac{x}{2}\left(1+\frac{1}{t^2}\right)\sum_{n=-\infty}^{+\infty} J_n(x)t^n=\sum_{n=-\infty}^{+\infty} nJ_n(x)t^{n-1} \tag{6.4.727}$$

Distributing:

$$\frac{x}{2}\left(1\cdot\sum_{n=-\infty}^{+\infty} J_n(x)t^n+\frac{1}{t^2}\cdot\sum_{n=-\infty}^{+\infty} J_n(x)t^n\right)=\sum_{n=-\infty}^{+} +\infty nJ_n(x)t^{n-1} \tag{6.4.728}$$

and simplifying:

$$\frac{x}{2}\left(\sum_{n=-\infty}^{+\infty} J_n(x)t^n+\sum_{n=-\infty}^{+\infty} J_n(x)t^{n-2}\right)=\sum_{n=-\infty}^{+\infty} nJ_n(x)t^{n-1} \tag{6.4.729}$$

Translating the index variable of summation we can write:

$$\frac{x}{2}\left(\sum_{n=-\infty}^{+\infty} J_{n-1}(x)t^{n-1}+\sum_{n=-\infty}^{+\infty} J_{n+1}(x)t^{n-1}\right)=\sum_{n=-\infty}^{+\infty} nJ_n(x)t^{n-1} \tag{6.4.730}$$

By comparing coefficients we that we have for each n:

$$\frac{x}{2}\left(J_{n-1}(x)+J_{n+1}(x)\right)=nJ_n(x) \tag{6.4.731}$$

Rearranging:

$$J_{n-1}(x)+J_{n+1}(x)=\frac{2n}{x}J_n(x) \tag{6.4.732}$$

Finally we get the useful result we were looking for:

$$J_{n+1}(x)=\frac{2n}{x}J_n(x)-J_{n-1}(x) \tag{6.4.733}$$

Where for reminder:

$$\begin{aligned}J_0(x)&=\sum_{k=0}^{\infty}\frac{(-1)^k}{(k!)^2}\left(\frac{x}{2}\right)^{2k}\\&=1-\frac{x^2}{2^2}+\frac{x^4}{2^2\cdot 4^2}-\frac{x^6}{2^2\cdot 4^2\cdot 6^2}+\cdots\end{aligned} \tag{6.4.734}$$

6.5. Vector Calculus

VECTOR CALCULUS or "vector analysis" is a branch of mathematics that studies the scalar or vector fields that are sufficiently regular of Euclidean spaces (see definition further below).

The importance of vector calculus comes from its extensive use in physics and in the engineering sciences. It is from this perspective that we will present it, and this is why we limit ourselves mostly to the case of the usual three-dimensional spaces. In this context, a vector field associates to each point of the space a vector (with three real components), while a scalar field associates just a unique real number to such a point.

✍**Example:**

For example, imagine the water from a lake. The temperature data at each point forms a scalar field, that of his speed at each point, a vector field (see definition further below).

Physical concepts such as strength or speed are characterized by a direction, an orientation and an intensity. This triple character is highlighted by arrows. These are the source of the concept of vector and are the most suggestive example. Although their nature is essentially geometric, it is their ability to bind to each other, so their algebraic behaviour, which mostly retain our attention. Split into equivalence classes their set represents the classic model of a "vector space" (see section Set Theory page 686). One of our primary goals here is the detailed description of this model.

Remarks

R1. Before reading what follows, the reader is advised to have at least read diagonally the section on Set Theory in the Arithmetic chapter. We define there what is a "vector space" using the tools of Set Theory. Even if this concept is although not absolutely essential it is still interesting to see how two areas of mathematics fit together and also just for the reason... of introducing vector stuffs with a least a little bit rigour.

R2. Vectorial analysis contains many terms and definitions that must be learned by heart. This work is hard but unfortunately necessary...

6.5.1 Concept of Arrow

Definition (#6.5.225): We denote by U the ordinary space of elementary geometry and $P, Q, \ldots$ its points. We will name "arrow" all directed line segment (in space). The arrow of origin P (origin point) and extremity Q (terminal point) will be denoted $\overrightarrow{PQ}$ or abbreviated by a single letter (Latin or Greek) arbitrarily chosen as example: $\vec{F}$.

Remark

In the norm ISO 80000-2:2009 *Mathematical signs and symbols to be used in the natural sciences and technology* it is authorized to represent the vectors with a letter in bold.

We will consider as obvious that any arrow is characterized by its direction, its orientation (because of a given direction it can point in both directions), its intensity or magnitude (length) and its origin.

In vector (or multivariable) calculus, we will deal with functions of two or three variables (usually x, y or x, y, z, respectively). The graph of the arrow of coordinates (x, y), lies in Euclidean space, which in the Cartesian coordinate system consists of all ordered doublets of real numbers (a, b). Since the Euclidean space can be 3-dimensional (and more or less for sure!), we denote it by $\mathbb{R}^3$.

The graph of the arrow consists of the points (a, b, c) in $\mathbb{R}^3$. The 3-dimensional coordinate system of Euclidean space can be represented on a flat surface, such as this page or a blackboard, only by giving the illusion of three dimensions, in the manner shown in the figure below:

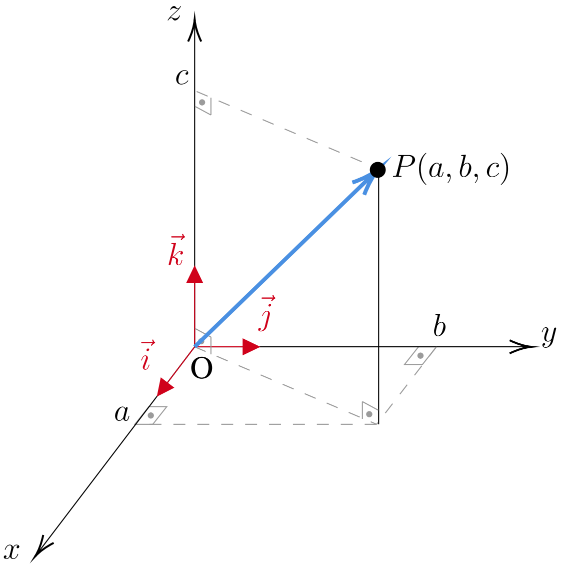

Figure 6.95: Example of arrow in $\mathbb{R}^3$ euclidean space

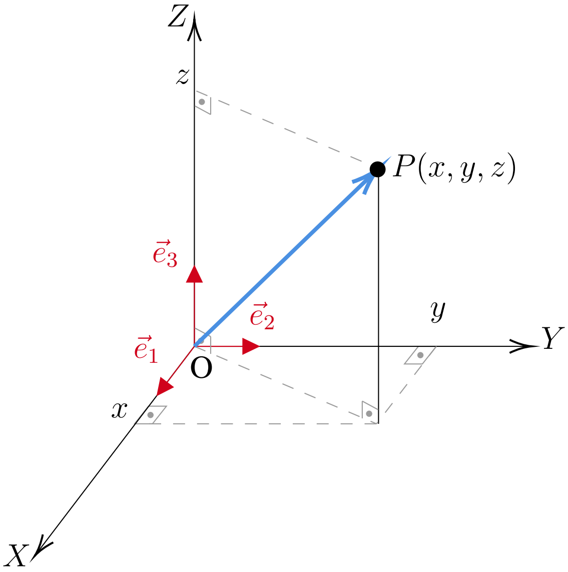
Or the same with another quite common notation:



Euclidean space has three mutually perpendicular coordinate axes (x, y and z), and three mutually perpendicular coordinate planes: the xy-plane, yz-plane and xz-plane:

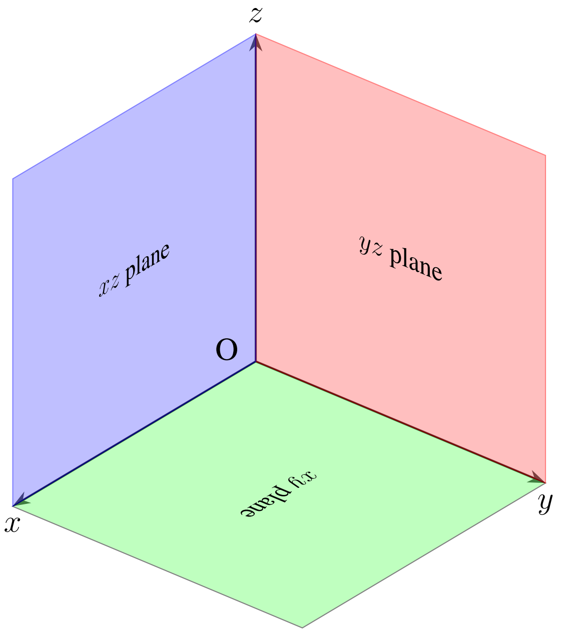


Figure 6.96: **Mutually perpendicular planes in $\mathbb{R}^3$**

The coordinate system shown above is also sometimes stupidly known as a "right-handed coordinate system" (...), because it is possible, using the right hand, to point the index finger in the positive direction of the x-axis, the middle finger in the positive direction of the y-axis, and the thumb in the positive direction of the z-axis, as below:

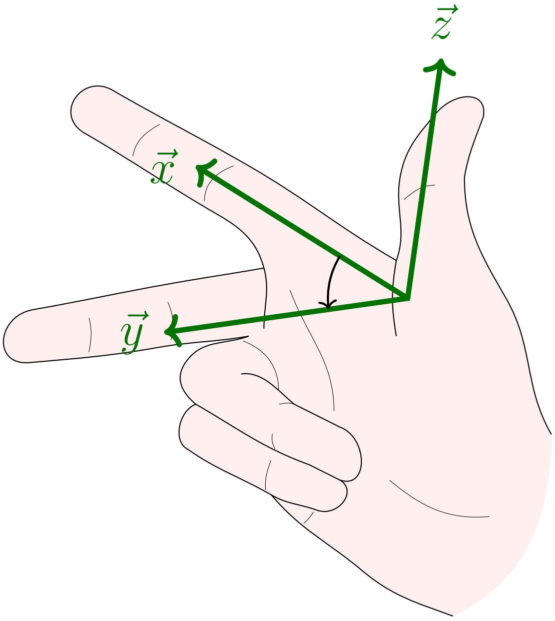

Figure 6.97: **Right-handed coordinate system (author: Izaak Neutelings)**

6.5.2 Set of Vectors

Definitions (#6.5.226):

D1. We say that two arrows are "equivalent arrows" if they have the same direction, the same orientation and the same intensity.

D2. We say that two arrows are "colinear arrows" only if they have the same direction.

Let us now split the set of all arrows in equivalence classes: two arrows belong to the same class if and only if they are equivalent.

So:

Definitions (#6.5.227):

D1. Each equivalence class of arrows whose origin point and terminal point are distinct is a "vector"" or rather a "free vector" because its origin is not taken into account (if its origin is well defined, then we have a "bounded vector").

D2. Degenerated arrows (that is to say of the form $\overrightarrow{PP}$) are named "zero vector" and written $\vec{0}$ when they have an undefined direction and orientation and zero intensity (origin and terminal point are not distinct).

The set of vectors will be commonly referred by $\mathbb{V}$. Note that the elements of $\mathbb{V}$ are (equivalence) classes arrows and not individual arrows. It is however clear that any arrow is sufficient to determine the class of equivalence to which it belongs and it is natural to name the corresponding class: "representative class" of the vector.

Let us now draw a representative of a vector $\vec{y}$ from the end of a representative vector $\vec{x}$. The arrow whose origin is that of the representative $\vec{x}$ and the end of representative $\vec{y}$ determines a new vector which we write: $\vec{x}+\vec{y}$. The operation that combines any two vectors by their sum is named "vector addition".

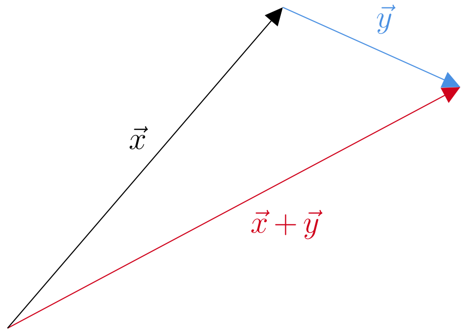

Figure 6.98: **Example of a sum of two vectors**

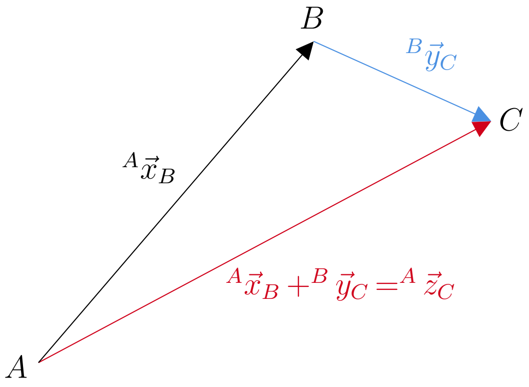

Figure 6.99: **Example of a sum of two vectors with robot dynamics notation**

Using a figure, it is easy to show that the operation of vector addition is associative and commutative, i.e. that:

$$(\vec{x}+\vec{y})+\vec{z}=\vec{x}+(\vec{y}+\vec{z}) \tag{6.5.1}$$

and:

$$\vec{x}+\vec{y}=\vec{y}+\vec{x} \tag{6.5.2}$$

It is also evident that the zero vector $\vec{0}$ is the neutral element of the vector addition. Formally:

$$\vec{x}+\vec{0}=\vec{x} \quad \text{and} \quad \vec{x}+(-\vec{x})=\vec{0} \tag{6.5.3}$$

where $-\vec{x}$ means the opposite of vector $\vec{x}$, that is to say the vector whose representatives have the same direction and the same intensity as those of $\vec{x}$, but the opposite orientation.

Definitions (#6.5.228):

D1. Two vectors whose sum is zero are then named "opposed vectors" since the only thing that differentiates them is their orientation...

D2. It follows that if two or more vectors have the same direction, the same intensity and the same orientation then we say that they are "equal vectors".

As we can see the reverse operation of vector addition is the vector subtraction. Subtract a vector is equivalent to adding the opposite vector.

Remarks

R1. The addition extends, by induction, to the case of any finite family of vectors. Under associativity, these successive additions can be performed in any order, which justifies the writing without brackets.

R2. The multiplication between two vectors is a concept that does not exist. But, as we shall see it a little further, we can multiply the vectors by some other vector properties that which we name the "norm" or simply by scalars and still by some other things...

6.5.2.1 Pseudo-Vectors

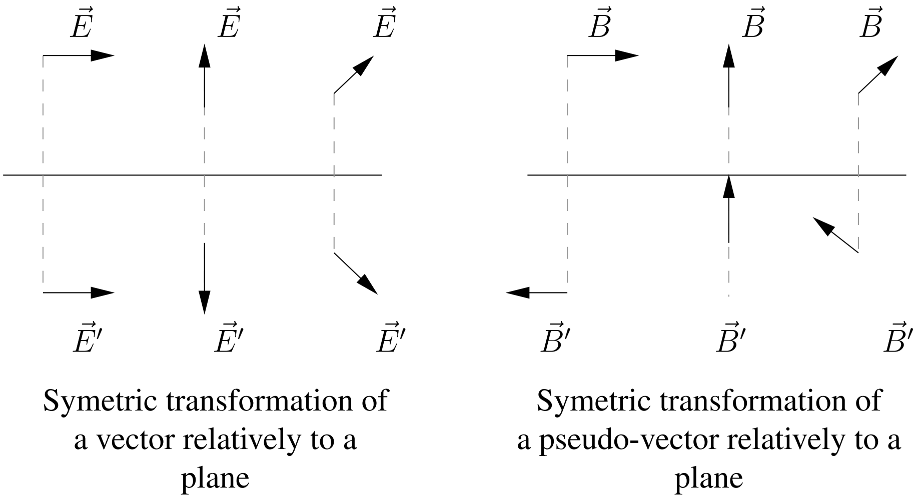
In physics, in the statement named the "Curie's principle" (see section Principia page 3144), physicists mention of what they name "pseudo-vectors". This is the simple vocabulary to talk about something equally trivial but basically only a few people actually do use. But it can still be useful to present what it is.

In fact, vectors and pseudo-vectors are transformed in the same way for a rotation or translation (we will see in our study of Linear Algebra how mathematically perform this type transformations). It is not the same in symmetry with respect to a plane or at one point. In these transformations we have by definition the following properties:

P1. A vector is transformed into its symmetrical.

P2. A pseudo-vector is converted into the opposite of its symmetrical.

Here is a figure with typical examples (the choice of letters representing the vectors and pseudo-vectors is not due to chance; they are a wink to the properties of electric and magnetic fields as studied in the Electromagnetism chapter):



$\vec{E}$
$\vec{E}$
$\vec{E}$
$\vec{B}$
$\vec{B}$
$\vec{B}$
$\vec{E}'$
$\vec{E}'$
$\vec{E}'$
$\vec{B}'$
$\vec{B}'$
$\vec{B}'$
Symetric transformation of a vector relatively to a plane
Symetric transformation of a pseudo-vector relatively to a plane

Figure 6.100: Differences of transformations between a vector and a pseudo-vector

A well known practical example is a pseudo-vector that we will study in detail much further below and resulting of an operation named "cross product" (see page 1830):

$$\vec{x}\times\vec{y}=\begin{pmatrix}x_1\\x_2\\x_3\end{pmatrix}\times\begin{pmatrix}y_1\\y_2\\y_3\end{pmatrix}=\begin{pmatrix}x_2y_3-x_3y_2\\x_3y_1-x_1y_3\\x_1y_2-x_2y_1\end{pmatrix}\tag{6.5.4}$$

And to see why the result is a pseudo-vector, consider the special simple case:

$$\vec{x}\times\vec{y}=\begin{pmatrix}1\\0\\0\end{pmatrix}\times\begin{pmatrix}0\\1\\0\end{pmatrix}=\begin{pmatrix}0\\0\\1\end{pmatrix}\tag{6.5.5}$$

Now if we do a symmetric operation of the XOZ plane we get:

$$\vec{x}\times\vec{y}=\begin{pmatrix}1\\0\\0\end{pmatrix}\times\begin{pmatrix}0\\-1\\0\end{pmatrix}=\begin{pmatrix}0\\0\\-1\end{pmatrix}\tag{6.5.6}$$

So as we can see the vector resulting of the cross product is a pseudo-vector because under transformation of the plane it's orientation change!

A vector resulting of a mathematical operation of symmetry that does not change its orientation is named a "polar vector" but in fact almost everybody say just "vector".

Now that we have an idea of what vectors are, we can start to perform some of the usual algebraic operations on them and this is what we name "vector algebra".

6.5.2.2 Normal vector

The "normal vector", denoted $\vec{N}$ or $\vec{n}$, to a surface is a vector which is perpendicular to the surface or curve at a given point. When normal vectors are considered on closed surfaces or closed curves, the inward-pointing normal (pointing towards the interior of the surface) and outward-pointing normal are usually distinguished.

The unit vector obtained by normalizing the normal vector (i.e., dividing a non-zero normal vector by its vector norm) is the unit normal vector, often known simply as the "unit normal"[13].

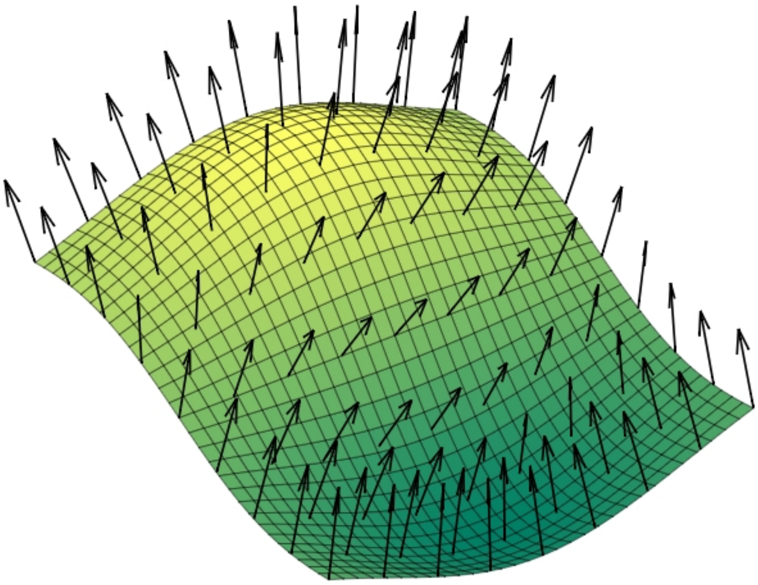


Figure 6.101: A vector field of normals to a surface

In the three-dimensional case a "surface normal", or simply a "normal", to a surface at a point P is a vector that is perpendicular to the tangent plane to that surface at P. The word "normal" is also used as an adjective: a line *normal* to a plane, the *normal* component of a force, the *normal* vector, etc.

We will see and prove in details in this section and many others, how to calculate explicitly various normal vectors to curves and surfaces.

For example that the normal vector to two vectors $\vec{a}$ and $\vec{b}$ is given by the cross product (see further below page 1830):

$$\vec{n}=\vec{a}\times\vec{b} \tag{6.5.7}$$

Or the normal to a parametric curve in Differential Geometry page 2865:

$$\vec{N}=R\frac{\mathrm{d}\vec{T}}{\mathrm{d}s} \tag{6.5.8}$$

---

[13] Care should be taken to not confuse the terms "vector norm" (length of vector), "normal vector" (perpendicular vector) and "normalized vector" (unit-length vector)

Or the normal vector of a plane of equation $ax+by+cz+d=0$ in the section of Analytical Geometry page 2802:

$$\vec{n}=\begin{pmatrix}a\\b\\c\end{pmatrix} \tag{6.5.9}$$

Or the gradient that is perpendicular to the isolines of a surface given by the cartesian function $f(x,y,z)=0$ of smoothness $\mathcal{C}^1$ as we will see further below page 1869:

$$\overrightarrow{\text{grad}}(f)=\begin{pmatrix}\dfrac{\partial f}{\partial x}\\\dfrac{\partial f}{\partial y}\\\dfrac{\partial f}{\partial z}\end{pmatrix} \tag{6.5.10}$$

and so on...

6.5.2.3 Multiplication by a scalar

The vector expression $\alpha\cdot\vec{x}$ named "product of vector $\vec{x}$ by scalar α" is defined as follows:

Definition (#6.5.229): Take a representative arrow $\vec{x}$ and construct a same direction arrow in the same or opposite orientation , depending on whether α (scalar) is positive or negative, and of intensity $|\alpha|$ times the intensity of the initial arrow. The arrow thus obtained is a representative of the vector of relation:

$$\alpha\cdot\vec{x} \tag{6.5.11}$$

If $\alpha=0$ or $\vec{x}=0$ we write:

$$\alpha\cdot\vec{x}=\vec{0} \tag{6.5.12}$$

The operation consisting of performing the product of a scalar by a vector is named "scalar multiplication".

We easily check that the scalar multiplication is associative and distributive with respect to the vector numerical addition, formally:

$$\begin{gathered}\alpha\cdot(\beta\cdot\vec{x})=(\alpha\cdot\beta)\cdot\vec{x}\\(\alpha+\beta)\cdot\vec{x}=\alpha\cdot\vec{x}+\beta\cdot\vec{x}\end{gathered} \tag{6.5.13}$$

The multiplication of a vector by non-null scalar doesn't change its direction if the scalar is positive but if the scalar is negative the vector will still have the same direction but it orientation will be opposite.

From this definition he have that two vectors $\vec{v}$ and $\vec{w}$ are parallel (denoted by $\vec{v}\,||\,\vec{w}$)) if one is a scalar multiple of the other. You can think of scalar multiplication of a vector as stretching or shrinking the vector, and as flipping the vector in the opposite direction if the scalar is a negative number.

Let's see a concrete example worldwide known of use of vectors with scalars (probably also the simplest example):

6.5.2.3.1 Rule of three

Let us go back to the "rule of three" (sometimes also named "rules of ratios and proportions" or "unit reduction method") often define in small classes (middle-school) intuitively but without nice proof. This rule is probably the most widely used algorithm in the world that identifies a fourth number when are given three and the four numbers are linearly dependent.

The rule of three is derived most of time in two versions:

- V1. Simple a direct if the magnitudes are directly proportional.
- V2. Simple and reverse if the quantities are inversely proportional.

and when two variables X and Y are proportional we note for recall:

$$X \propto Y \tag{6.5.14}$$

Theorem 6.27. Suppose now that X can take the values x_1, x_2. Y will take the values linearly dependent y_1, y_2 then the following proportional relation applies:

$$\boxed{\frac{x_1}{x_2}=\frac{y_1}{y_2}=c^{te}} \tag{6.5.15}$$

is named "simple and direct ratio".

Proof 6.27.1. Given two collinear vectors $\vec{x}=(x_1,x_2), \vec{y}=(y_1,y_2)$ and therefore proportional to a given factor λ such that:

$$\vec{x}=\lambda\vec{y} \Leftrightarrow \begin{pmatrix} x_1 \\ x_2 \end{pmatrix}=\lambda\begin{pmatrix} y_1 \\ y_2 \end{pmatrix} \Leftrightarrow \lambda=\frac{x_1}{y_1}=\frac{x_2}{y_2} \Leftrightarrow \frac{y_1}{y_2}=\frac{x_1}{x_2} \tag{6.5.16}$$

This is often denoted in small classes:

$$\begin{gathered} x_1\,(a) \longrightarrow y_1\,(b) \\ x_2\,(c) \longrightarrow y_2\,(d) \end{gathered} \tag{6.5.17}$$

Therefore:

$$y_2=\frac{y_1\cdot x_2}{x_1} \Leftrightarrow d=\frac{b\cdot c}{a} \tag{6.5.18}$$

■ Q.E.D.

Remark

If this ratio is not equal (thus: not proportional), then we must switch to other tools such as simple and inverse ratio, or regression techniques and verbatim: extrapolation.

✍**Example:**

E1. In Lausanne (Switzerland), in 12011 (holocene calendar), garbage bags are taxed and the following rates apply: a bag of 17 [L] is 1.- and the bag of 110 [L] is 3.80.-. Reported to 17 [L] the price of the garbage bag of 110 [L] is thus:

$$\frac{3.80}{110}\cdot 17 \cong 0.58.\text{-} \tag{6.5.19}$$

That is to say approximately 60% of the price of the bag of 17 [L] (then go search for an explanation... ???).

E2. If the Earth has a radius of approximately $6,371$ kilometres and the Moon a radius of approximately $1,737.4$ kilometres and that their distance is actually in average of approximately $384,400$ kilometres, what would be the Earth-Moon distance and the size of the Moon is the Earth was reduce to the radius of a soccer ball of 11.25 centimetres.

The Moon radius would therefore be (everything has been converted into centimetres):

$$\frac{11.25}{6,371\cdot 10^6}\cdot 1,737.4\cdot 10^6 \cong 3[\text{cm}]$$

and the Earth-Moon distance will become:

$$\frac{11.25}{6,371\cdot 10^6}\cdot 384,400\cdot 10^6 \cong 678[\text{cm}]$$

Theorem 6.28. The following proportional relation:

$$\boxed{\frac{x_1}{x_2}=\frac{y_2}{y_1}=c^{te}} \tag{6.5.20}$$

is named "simple and inverse ratio".

Proof 6.28.1. Given two collinear vectors $\vec{x}=(x_1,x_2),\vec{y}=(y_1,y_2)$ and therefore proportional to a given factor λ such that:

$$\vec{x}=\lambda\vec{y}\Leftrightarrow\begin{pmatrix}x_1\\x_2\end{pmatrix}=\lambda\begin{pmatrix}\dfrac{1}{y_1}\\\dfrac{1}{y_2}\end{pmatrix}\Leftrightarrow\lambda=y_1x_1=y_2x_2\Leftrightarrow\frac{x_1}{x_2}=\frac{y_2}{y_1} \tag{6.5.21}$$

■ Q.E.D.

Remark

R1. If this ratio is not equal (thus: not inverse proportional), then we must switch to other tools such as simple and direct ratio, or regression techniques and verbatim: extrapolation.

R2. We also name "simple or inverse joint rule", a series of direct or inverse rule of three.

Basically, it is enough that we knew three of the four variables to solve this simple equation of the first degree.

Conversions of currencies or units of measurement are made using the direct or indirect simple rule of three. Parity calculations (provisional calculation made by an importer of a certain country having his own units of measurement and currency, who searches among several foreign offers - in systems of units of measurement and currencies which differ from the importer - which is the most advantageous or vice versa) are also done with the rule of three.

In such calculations, the agents of the exchange market have noticed that most of the time the ratio values were close to unity. They were thus naturally led to define the "percentage" as the proportion of a quantity or magnitude relative to another, measured with hundred (at least most of time...). Remember (see section Numbers page 234):

- Given a scalar $x\in\mathbb{R}$ then expressed in percentage it will denoted by:

$$x\%=x\cdot 100 \tag{6.5.22}$$

- Given a scalar $x\in\mathbb{R}$ then expressed in per-thousand it will denoted by:

$$x‰=x\cdot 1,000 \tag{6.5.23}$$

6.5.3 Vector Spaces

Definition (#6.5.230): We name "vector space" a set E of elements designated by $\vec{x},\vec{y},\ldots$ and named (as we know) "vectors", with a "vector algebraic structure" defined by the operation of vector addition (and thus vector subtraction) and scalar multiplication. These two operations satisfy the laws of associativity, commutativity, distributivity, neutral element and opposing element as we have already seen in the section of Set Theory.

For more information about what a vector space set is exactly the reader will have therefore to refer to the section of Set Theory at page 1805 where this concept is defined more strictly (it would be redundant to repeat it here an anyway it is not crucial because the properties are intuitive).

For every positive integer n, a_i means all the n-tuples of numbers arranged in a vector column:

$$\vec{v}=\begin{pmatrix}a_1\\a_2\\\vdots\\a_n\end{pmatrix} \tag{6.5.24}$$

or as line vector (vector column that has been **T**ransposed):

$$\vec{v}^T=(a_1\,a_2\,\cdots\,a_n) \tag{6.5.25}$$

and $\mathbb{R}^n$ provides clearly a vector space structure. The vectors of this space will be named as we already know: "vectors". They are often denoted more briefly by:

$$\vec{v}=(a_i)_{1\leq i\leq n} \tag{6.5.26}$$

or even more briefly by:

$$(a_i) \tag{6.5.27}$$

The number a_i is sometimes name "term" or "component of index i" of (a_i).

Now, unless stated otherwise, the vectors will always be the elements of a vector space E.

6.5.3.1 Linear Combinations

Definition (#6.5.231): We name "linear combination" of vectors $\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_n$ any vector relation of the form:

$$\vec{v} = \alpha_1\vec{x}_1 + \alpha_2\vec{x}_2 + \ldots + \alpha_n\vec{x}_n \tag{6.5.28}$$

where $\alpha_1, \alpha_2, \ldots, \alpha_k$ are numbers named "coefficients of the linear combination".

When a vector can be expressed in the above way we say that the vector is in "component form".

The null vector $\vec{0}$ is a linear combination of the $\alpha_1\vec{x}_1 + \alpha_2\vec{x}_2 + \ldots + \alpha_n\vec{x}_n$ with all coefficients equal to zero. We speak therefore of "trivial linear combination".

Definition (#6.5.232): We name "convex combination", any linear combination whose coefficients are non-negative and sum equal to 1. The set of convex combinations of two points P and Q of a punctual space P_0 (with an origin) is the line segment P and Q, traditionally denoted $\overline{PQ}$. To realize this, we just write:

$$\alpha P + (1 - \alpha Q) = Q + \alpha(P - Q) \tag{6.5.29}$$

and we make α vary from 0 to 1 and to find that all the points of the segment are thereby obtained.

If the vector $\vec{v}$ is a linear combination of $\alpha_1\vec{x}_1 + \alpha_2\vec{x}_2 + \ldots + \alpha_n\vec{x}_n$ and each of these vectors $\vec{x}_i$ is a linear combination of a set of independent vectors $\vec{y}_1, \vec{y}_2, \ldots, \vec{y}_k$, then it could be obvious that $\vec{v}$ is also a linear combination of $\vec{y}_1, \vec{y}_2, \ldots, \vec{y}_k$.

Definition (#6.5.233): A number n of non-zero vector are "coplanar" if one of them is a linear combination of the others. For example, three vectors are coplanar if one of them is in the plane defined by the two others.

6.5.3.2 Sub-vector spaces

Definition (#6.5.234): We name "vectorial subspace V of E" any subset of E that is itself a vector space for the operations of addition and scalar multiplication defined in E.

A vectorial sub-space V, as a vectorial space, can not be empty as it includes at least one vector, i.e. its zero vector, this being also necessarily also the zero vector of E. In addition, together with the vectors $\vec{x}$ and $\vec{y}$ (if it contains other vectors than the zero vector), it also includes all their linear combinations $\alpha\vec{x} + \beta\vec{y}$.

Conversely, as soon as we see any subset having these properties is a vectorial subspace. We have thus established the following proposition:

A subset V of E is a subspace of E if and only if V is not empty and $\alpha\vec{x}+\beta\vec{y}$ belongs to V for every pair $(\vec{x},\vec{y})$ of V and all any pair $(\alpha,\beta)\in\mathbb{R}$.

6.5.3.3 Generating families

It follows that if we have a family of vectors $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$ the set of linear combinations of $\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k$ with $k<n$ can be a subspace V of E, more specifically the smallest subspace of E consisting of $\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k$.

The $\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k$ vectors that satisfy the above condition are named "generators" of V and the family $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$ the "generating family" of V. We also say that these vectors or family "generate S".

Remark

The subspace generated by a non-zero vector consists of all multiples of this vector. We name such a subspace a "vector line". A subspace generated by two vector non multiple of each other is named a "vector map" or "vector plane".

6.5.3.4 Linear Dependence or Independence

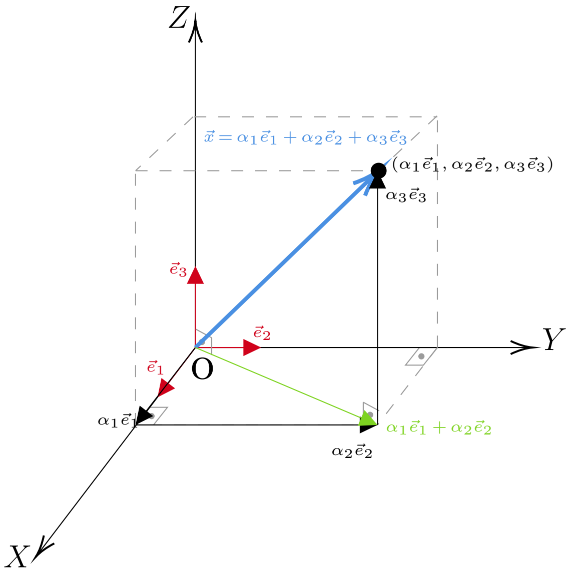
What follows is very important in physics: we advise future physicists or engineer really take the time to read the developments below.

If $(\vec{e}_1,\vec{e}_2,\vec{e}_3)$ are three vectors of E^3 whose representatives are not parallel to the same plane (by convention a zero-vector is parallel to any plane), so any vector $\vec{x}$ of E^3 can be written by the linear combination:

$$\vec{x}=\alpha_1\vec{e}_1+\alpha_2\vec{e}_2+\alpha_3\vec{e}_3 \tag{6.5.30}$$

where $\alpha_1,\alpha_2,\alpha_3$ belongs typically to $\mathbb{R}$.

For example the above vector $\vec{x}$ (but can also be get for different values of α_i!):



Z
$\vec{x}=\alpha_1\vec{e}_1+\alpha_2\vec{e}_2+\alpha_3\vec{e}_3$
$(\alpha_1\vec{e}_1,\alpha_2\vec{e}_2,\alpha_3\vec{e}_3)$
$\alpha_3\vec{e}_3$
$\vec{e}_3$
$\vec{e}_2$
Y
$\vec{e}_1$
O
$\alpha_1\vec{e}_1$
$\alpha_1\vec{e}_1+\alpha_2\vec{e}_2$
$\alpha_2\vec{e}_2$
X

Figure 6.102: **Example of a construction of a vector in a three-dimensional space**

In particular, the only possibility to get the zero vector $\vec{0}$ as a linear combination of $(\vec{e}_1,\vec{e}_2,\vec{e}_3)$ is to assign the trivial value 0 to the coefficients $\alpha_1,\alpha_2,\alpha_3$.

Conversely, if for three vectors $\vec{e}_1,\vec{e}_2,\vec{e}_3$ of E^3 the relation:

$$\vec{x}=\alpha_1\vec{e}_1+\alpha_2\vec{e}_2+\alpha_3\vec{e}_3=\vec{0} \tag{6.5.31}$$

implies $\alpha_1=\alpha_2=\alpha_3=0$, none of the vectors may be linear combination of the other two, in other words, their representatives are not parallel to the same plane.

Based on these observations, we will extend the notion of absence of parallelism to a same plane in the case of any number of vectors of a given vector space E.

We say that the vectors $\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k$ are "linearly independent" if the relation:

$$\alpha_1\vec{e}_1+\alpha_2\vec{e}_2+\ldots+\alpha_k\vec{e}_k=0 \tag{6.5.32}$$

necessarily implies $\alpha_1=\alpha_2=\ldots=\alpha_k=0$, in other words, if the trivial linear combination is the only linear combination of $\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k$ which is zero. Otherwise, we say that the vectors $\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k$ are "linearly dependent".

If the intention is fixed on the family $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$ rather than the terms of which it is made, we say that the latter is a "free family" or "linked family" following that the vectors are linearly independent or dependent.

6.5.3.5 Base of a vectorial space

Definition (#6.5.235): We say that a family of finite vectors is a basis of E if and only if:

1. If it is free.
2. It generates E.

Following this definition, every free family $\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_k$ is a basis of the subspace it generates.

✍**Example:**

If we consider $\mathbb{C}$ as a $\mathbb{R}$-vector space (see section Set Theory page 1805), then since all the elements of $\mathbb{C}$ are written $a + ib$, the elements that generate $\mathbb{C}$ are 1 and i (both are free).

A base of $\mathbb{C}$ (which is 2-dimensional) as a $\mathbb{R}$-vector space is therefore the free finite set $\{1, \mathrm{i}\}$.

For a family of vectors $(\vec{e}_1, \vec{e}_2, \ldots, \vec{e}_n)$ to be a basis of E, then it is necessary and sufficient that every vector $\vec{x}$ of E is expressed uniquely as a linear combination of the vectors $(\vec{e}_1, \vec{e}_2, \ldots, \vec{e}_n)$:

$$\vec{x} = x_1\vec{e}_1 + x_2\vec{e}_2 + \cdots + x_n\vec{e}_n \tag{6.5.33}$$

The above relation is decomposition of $\vec{x}$ following the base $(\vec{e}_1, \vec{e}_2, \ldots, \vec{e}_n)$ where the coefficients $x_1, x_2, \ldots, x_n$ are the components of $\vec{x}$ in this base. In the presence of a base, each vector is determined entirely by its components.

Proposition:

If $x_1, x_2, \ldots, x_n$ are the components of $\vec{x}$ and $y_1, y_2, \ldots, y_n$ those of $\vec{y}$ then:

$$x_1 + y_1, x_2 + y_2, \cdots, x_n + y_n \tag{6.5.34}$$

are the components of $\vec{x} + \vec{y}$.

In other words, add two vectors is equivalent to add their components and multiply a vector by a scalar obviously equivalent to multiplying its components by the same scalar. The basis is an important tool because it allows you to perform operations on vectors through operations on numbers.

✍**Example:**

The following column vectors of $\mathbb{R}^n$:

$$\begin{pmatrix}1\\0\\\cdot\\\cdot\\\cdot\\0\end{pmatrix},\begin{pmatrix}0\\1\\\cdot\\\cdot\\\cdot\\0\end{pmatrix},\ldots,\begin{pmatrix}0\\0\\\cdot\\\cdot\\\cdot\\1\end{pmatrix} \tag{6.5.35}$$

generate a base that we name "canonical basis" of $\mathbb{R}^n$ (we will work in complex spaces in another section of this textbook).

Remark

As part of the three-dimensional space, bases are very often treated as a triad (actually if you connect the ends of the three vectors by features you will get an imaginary triad).

6.5.3.6 Direction Angles

It is clear that only one standard angle cannot describe the direction of a vector in space (in an n-dimensional space, at least $n-1$ angles are required to describe the direction of a vector). We then use the concept of "direction angles". This is to measure the angle of the vector $\vec{U}$ with respect to each of the positive axis of the base:

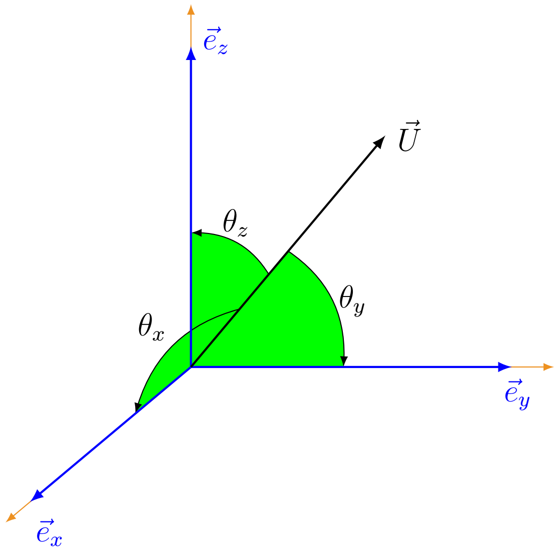


Figure 6.103: Representation of direction angles

If:

$$\vec{U}=(u_1,u_2,u_3)=u_1\vec{i}+u_2\vec{j}+u_3\vec{k} \tag{6.5.36}$$

Then by definition:

$$\begin{aligned}u_1=x&=\|\vec{U}\|\cos(\theta_x)\\u_2=y&=\|\vec{U}\|\cos(\theta_y)\\u_3=z&=\|\vec{U}\|\cos(\theta_z)\end{aligned} \tag{6.5.37}$$

The values:

$$\begin{aligned}\cos(\theta_x)&=\frac{x}{\sqrt{x^2+y^2+z^2}}\\\cos(\theta_y)&=\frac{y}{\sqrt{x^2+y^2+z^2}}\\\cos(\theta_z)&=\frac{z}{\sqrt{x^2+y^2+z^2}}\end{aligned} \tag{6.5.38}$$

are named the "cosines directions" of $\vec{x}$.

The three angles mentioned are not completely independent. Indeed, two are enough to completely determine the direction of a vector in space, the third can be deduced from the following equality (obtained from the calculation of the sum of squares of previous relations):

$$\cos^2(\theta_x)+\cos^2(\theta_y)+\cos^2(\theta_z)=1 \tag{6.5.39}$$

And it is this natural constraint that means, in reality, that in an n-dimensional space we have $n-1$ angles (degrees of freedom) sufficient to describe the direction of the vector.

Therefore the direction cosines are the scalar components of a unit standard vector $\vec{u}$ having the same direction as $\vec{U}$:

$$\frac{\vec{U}}{\|\vec{U}\|}=\vec{u}=\big(\cos(\theta_x),\cos(\theta_y),\cos(\theta_z)\big) \tag{6.5.40}$$

6.5.3.7 Dimensions of a vector space

We say that a basis E is of "finite size" if it is generated by a finite family of vectors. Otherwise, we say that E is of "infinite dimension" (we'll discuss this type of spaces in another section). Any finite dimensional vector space and not reduced to the zero vector has a basis. In fact, from any generating family of such a vector space we can extract a basis.

The dimension of a vector space is denoted by:

$$\dim(E) \tag{6.5.41}$$

Any vector space E of non-zero finite dimension n can be mapped in one to one correspondence (that is to say in bijection) with $\mathbb{R}^n$. We just need to choose a basis of E and to match to any vector $\vec{x}$ of E the column vector whose terms are the components of $\vec{x}$ in the chosen basis (this is mathematician blah blah but it will be useful when we will discuss more complex spaces):

$$\begin{array}{cc} E & \mathbb{R}^n \\ \vec{x}(x_1,x_2,\ldots,x_n)\Leftrightarrow & \begin{pmatrix}0\\0\\ \cdot\\ \cdot\\ \cdot\\ 1\end{pmatrix}\end{array} \tag{6.5.42}$$

This correspondence preserves the operations of addition and multiplication by a scalar as we have already seen; in other words, it can perform operations on vectors by operations on numbers.

Remark

Then we say that E and $\mathbb{R}^n$ are "isomorphic" or that the correspondence is an isomorphism (see section Set Theory page 443).

6.5.3.8 Extension of a free family

Theorem 6.29. Given $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$ a free family and $(\vec{v}_1,\vec{v}_2,\ldots,\vec{v}_m)$ a generating family of E. If $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$ is not a basis of E, we can extract a subfamily

$$(\vec{v}_{i1},\vec{v}_{i2},\ldots,\vec{v}_{il})$$

of $(\vec{v}_1,\vec{v}_2,\ldots,\vec{v}_m)$ so that the family $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k,\vec{v}_{i1},\vec{v}_{i2},\ldots,\vec{v}_{il})$ is a basis of E.

Remark

Such a theorem is useful when going from a mathematical space passage having given properties to another space with different mathematical properties.

Proof 6.29.1. We assume that at least one of the vectors $\vec{v}_i$ is not a linear combination of vectors $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$, otherwise $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$ would generate E and would therefore be a possible basis of E. Let us note that vector $\vec{v}_{i1}$. The family $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k,\vec{v}_{i1})$ is then a free family. Indeed, the relation:

$$\alpha_1\vec{x}_1+\cdots+\alpha_k\vec{x}_k+\beta_1\vec{v}_{i1}=\vec{0} \tag{6.5.43}$$

then implies first that $\beta_1=0$, otherwise $\vec{v}_{i1}$ would be a linear combination of the vectors $\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k$, and then all $\alpha_i=0$ since the vectors $\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k$ are linearly independent.

If the family $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k,\vec{v}_{i1})$ generates E, it is then a possible base for E and the theorem is proved. Otherwise, the same reasoning ensures the existence of another vector $\vec{v}_{i2}$ .... If the new resulting family is not a basis of E, then the extraction process vectors $\vec{v}_i$ of $(\vec{v}_1,\vec{v}_2,\ldots,\vec{v}_m)$ continues. When it stops, we will get an "extension" of $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$ in a free family generating E, that is to say a base of E.

■ Q.E.D.

It returns a corollary:

Every finite dimensional vector space and not reduced to zero vector has a basis! In fact, from any generating family of such a space, we can extract a base.

6.5.3.9 Rank of a finite family

Definition (#6.5.236): We name "rank of a family of vectors" and denote by rk(S) the dimension of the subspace S of E it generates.

Theorem 6.30. The rank of a family of vector $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$ is less than or equal to k and is equal to k if and only if the family is free.

Proof 6.30.1. Let us set aside the trivial first case where the rank of the family $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$ is zero. By the previous corollary, then we can extract from this family a base of the subspace it generates. The rank is than less or equal to k following that $(\vec{x}_1,\vec{x}_2,\ldots,\vec{x}_k)$ is a linked family or not.

■ Q.E.D.

6.5.3.10 Direct Sums

Definition (#6.5.237): We say that the sum $S+T$ of two subspaces S and T of E is a "direct sum" if (special case applied to a 2 dimensional space!):

$$S \cap T = \left\{\vec{0}\right\} \tag{6.5.44}$$

In this case, we note it:

$$S \oplus T \tag{6.5.45}$$

In other words, the sum of two vector subspaces S and T of E is direct if the decomposition of all element $S+T$ into a sum of an element of S and of T is unique.

✍**Example:**

For example, the XY-plane, a two-dimensional vector space, can be thought of as the direct sum of two one-dimensional vector spaces, namely the X and Y axes. In this direct sum, the x and y axes intersect only at the origin (the zero vector). Addition is defined coordinate-wise, that is:

$$(x_1, y_1) + (x_2, y_2) = (x_1 + x_2, y_1 + y_2) \tag{6.5.46}$$

which is the same as vector addition.

This concept of trivial decomposition will be very useful in some theorems, the most important in this textbook is definitely the spectral theorem (see section of Linear Algebra page 2004) that has important implications in statistics!!!

From the direct sum we can introduce the concept of "complementary subspace" also named "subspace" (depending on countries ...):

Theorem 6.31. Suppose that E is of finite dimensions. For any subspace S of E, there exists a subspace T (not unique) of E such that E is the direct sum of S and T. We say then that T is a "supplementary subspace" of S into E.

Proof 6.31.1. First let us set aside the trivial case where $S = \left\{\vec{0}\right\}$ and $S = E$. The subspace S admits a basis $(\vec{e}_1, \vec{e}_2, \ldots, \vec{e}_k)$, where k is less than the dimension n of E. By the theorem of extension of a free family, this basis can be extended in a basis $(\vec{e}_1, \vec{e}_2, \ldots, \vec{e}_k, \vec{e}_{k+1}, \ldots, \vec{e}_n)$ of E. Let T be the subspace vector generated by the family $(\vec{e}_{k+1}, \ldots, \vec{e}_n)$. If $\vec{x}$ is any vector of E, then $\vec{x} = \vec{s} + \vec{t}$, where $\vec{s}$ is a vector of S and $\vec{t}$ a vector of T. In addition $S \cap T = \left\{\vec{0}\right\}$, because no vector, excepted the zero vector may be a linear combination of the vectors $\vec{e}_1, \ldots, \vec{e}_k$ and of the vectors $\vec{e}_{k+1}, \ldots, \vec{e}_n$. We therefore conclude that:

$$E = S \oplus T \tag{6.5.47}$$

■ Q.E.D.

6.5.3.11 Affine spaces

In mathematics, an affine space $G = \mathrm{A}\mathbb{R}^n$ is a geometric structure that is independent of the concepts of distance and measure of angles, keeping only the properties related to parallelism and ratio of lengths for parallel line segments as their is not origin point =$(0,0)$.

The space G of elementary geometry is both common and the source of the concept of "affine space" that we will introduce because when middle-school student begin to learn geometry they learn it (the huge majority of time) without any reference point =$(0,0)$.

In an affine space, there is therefore no distinguished point that serves as an origin. Hence, no vector has a fixed origin and no vector can be uniquely associated to a point. In an affine space, there are instead "displacement vectors", also named "translation vectors" or simply translations, between two points of the space.

This space G is associated with the "geometric vector space" V by the correspondence between vectors and arrows studied so far! The following definition is only to highlight the main common points of this correspondence:

Definition (#6.5.238): Let U be a non-empty set of elements that we name "points" and let us denote them by the letters $P,Q,\ldots$; given also E a vector space. Suppose that to any two points (P,Q) corresponds a vector denoted $\overrightarrow{PQ}$ (typically the point P is chosen as fictive origin). We say then that U is an "affine space" of directed space E if the following conditions are met:

C1. For any fixed point P, the correspondence between pairs (P,Q) and vectors $\vec{x}$ defined by only one point plus the origin point is bijective, i.e., for every vector $\vec{x}$ it exists a point Q such that we can define a vector $\overrightarrow{PQ}$.

C2. For each triple of points (P,Q,R):

$$\overrightarrow{PQ}+\overrightarrow{QR}=\overrightarrow{PR} \tag{6.5.48}$$

This is the famous "Chasles relation" (which we will see later a pseudo-equivalent in the section of Differential and Integral Calculus).

C3. If P is a point and $\vec{x}$ a vector, to express that Q is the unique point such as $\vec{x}=\overrightarrow{PQ}$, we write:

$$Q = P+\vec{x} \tag{6.5.49}$$

Although being a bit excessive, this writing is consistent with the usage and suggests well the idea of the operation it designates.

✍**Example:**

Below an "artistic" example of an affine space $U = \mathbb{AR}^2$ where there is no origin and any extremity of a line can be considered as the origin of a vector:

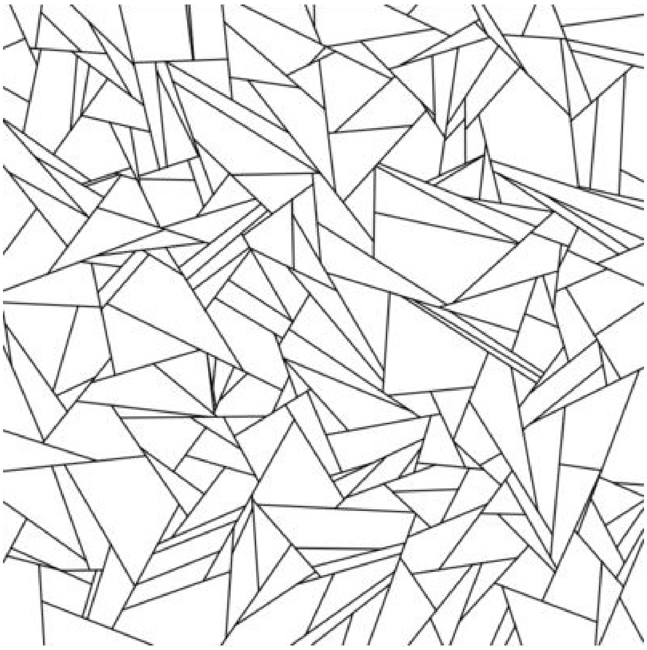

Figure 6.104: **Artistic but real example of an $G = \mathbb{AR}^2$ affine space**

The following properties follow directly from the definition of affine space:

P1. For any point P, $P + (\vec{x} + \vec{y}) = (P + \vec{x}) + \vec{y}$

P2. For any point P, $\overrightarrow{PP} = \vec{0}$. This results from the $\overrightarrow{PQ} + \overrightarrow{QR} = \overrightarrow{PR}$ provided in the case where we have $P = Q = R$.

P3. $\overrightarrow{PQ} = -\overrightarrow{QP}$. Just put $R = P$ in the De Chasles relation $\overrightarrow{PQ} + \overrightarrow{QR} = \overrightarrow{PR}$.

P4. Parallelogram rule:

Given the polygon with the vertices (clockwise) P, P', Q, Q' and edges $\overrightarrow{PP'}, \overrightarrow{P'Q'}, \overrightarrow{QQ'}, \overrightarrow{PQ}$:

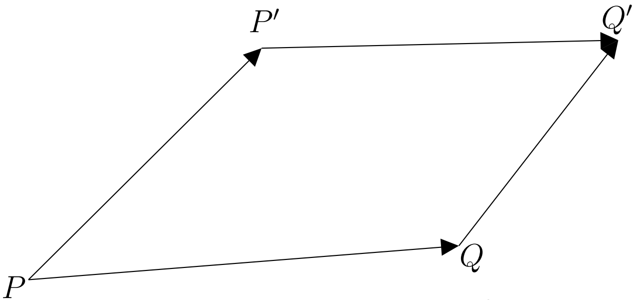

Figure 6.105: **Vectorial polygon in $\mathbb{AR}^2$**

We have:

$$\overrightarrow{PP'} = \overline{QQ'} \tag{6.5.50}$$

if and only if:

$$\overrightarrow{P'Q'} = \overline{PQ} \tag{6.5.51}$$

which would then give a parallelogram!

Indeed, replacing R with Q' in the Chasles relation we have:

$$\overrightarrow{PQ} + \overrightarrow{QQ'} = \overrightarrow{PQ'} \tag{6.5.52}$$

and by doing the same but replacing R by Q' and Q by P' we get:

$$\overrightarrow{PP'} + \overrightarrow{P'Q'} = \overrightarrow{PQ'} \tag{6.5.53}$$

We then have by equating the last two relations:

$$\overrightarrow{PQ} + \overrightarrow{QQ'} = \overrightarrow{PP'} + \overrightarrow{P'Q'} \tag{6.5.54}$$

Which forces the aforementioned equality that we wanted to prove.

Earlier we saw what made that a space G could be provided with a vector space structure (we saw then that it was therefore "vectorialized"). In the general case of an affine space G, the process is the same:

We choose any point O of G. The correspondence between pairs (O, P) and vectors of director space E being therefore biunivocal we define then the addition of points and multiplication of a point by a scalar by the corresponding operations on the vectors of E. Armed with these two operations, G becomes a vector space, named "vectorialized space G regarding to O". We denote this space by V and we name the point O "origin".

Given how operations have been defined, it follows that V is isomorphic to the space vector E:

$$P \overset{V}{=} \text{O} + \vec{x} \leftrightarrow \overset{E}{\vec{x}} \tag{6.5.55}$$

However, this isomorphism depends on the choice of the origin O and in practice this origin is selected on the basis of the data inherent to the studied problem. For example, if an affine transformation allows an invariant point (which does not move), it is advantageous to select that point as the origin.

Remarks

R1. When we talk about dimension of an affine space, we talk about the size of its director space.

R2. The space G of elementary geometry is an affine space of type $\text{A}\mathbb{R}^2$. Indeed, its direction is the geometrical space G and the conditions of definition of affine space are met.

R3. An affine space is a set of elements with a difference function. This difference is a binary function, which takes two points P and Q (both in G) and yields an element (a vector) $\vec{v}$ of a vector space E. We write $\vec{v}=P-Q$. Additionally, this difference function must ensure that, for any point P in E, it holds $P-P=\vec{0}$, where $\vec{0}$ is the null vector of E.

For the people who want to learn more about affine spaces (and related subjects), we recommend the lecture of the following excellent french textbook [8].

6.5.4 Euclidean Vector Spaces

Before defining what is an Euclidean vector space, let us first define some mathematical tools and some concepts.

We can, by choosing a unit length, measure the intensity of each arrow, in other words, determine its length. We can also measure the angular distance of two arrows (or vectors) of any common origin (not necessarily distinct) taking as the unit of angle measurement for example the radian (see section Trigonometry page 2503). The measurement of this difference is then a number between 0 and π named "angle" of the two arrows (see the section of Euclidean Geometry for more details). If both arrows have same direction and orientation, their angle is zero and if they have same direction and the opposite orientation, this same angle is π.

The representing arrows of a same vector $\vec{x}$ all have the same length. We denote this length (distance), named also "norm" or "module", by the notation[14]:

$$\boxed{\|\vec{x}\|} \tag{6.5.56}$$

given in the three-dimensional case explicitly by the following Euclidean distance if the origin of the vector coincides with the origin O of the vector basis:

$$\|\vec{x}\|=\left\|\begin{pmatrix}x\\y\\z\end{pmatrix}\right\|=\sqrt{x^2+y^2+z^2} \tag{6.5.57}$$

---

[14] This is actually a simplified notation because, as we will see much later in this textbook, there are several types of standards!

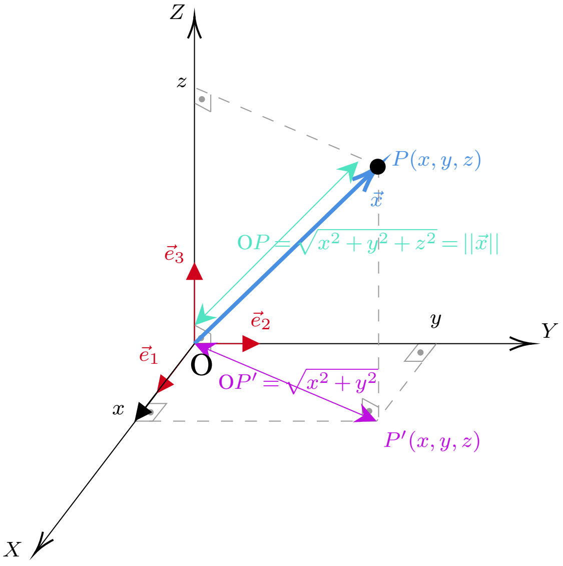

Figure 6.106: **Details of the calculation of the norm in an orthogonal coordinate system $\mathbb{R}^3$**

If $\vec{x}$ is a non-zero vector we can build an unit norm vector $\vec{u}$ of same direction and orientation (colinear) by the following operation that is used a lot in physics:

$$\boxed{\vec{u}=\frac{\vec{x}}{\|\vec{x}\|}} \tag{6.5.58}$$

We will name "non-zero angle of vectors $\vec{x}$ and $\vec{y}$" the angle of two arrows of common origin representing one being $\vec{x}$ and the other $\vec{y}$.

However, more strictly speaking a "norm" is defined on a real vector space (or complex) E, so that we speak then of "normalized vector space" is an application:

$$f\,(\|\;\|):\mathbb{R}^n\mapsto\mathbb{R}^+ \tag{6.5.59}$$

satisfying the following properties:

P1. Positivity:

$$\forall\vec{x}\in E\quad\|\vec{x}\|\geq 0 \tag{6.5.60}$$

P2. Linearity:

$$\forall\lambda\in\mathbb{R},\forall\vec{x}\in E\quad\|\lambda\vec{x}\|=|\lambda|\cdot\|\vec{x}\| \tag{6.5.61}$$

where we take the modulus of the constant if this is not in the set of real numbers $\mathbb{R}$ but in the set of complex numbers $\mathbb{C}$.

P3. Nullity (often associated with the property P1):

$$\forall\vec{x}\in E\quad\|\vec{x}\|=0\Leftrightarrow\vec{x}=0 \tag{6.5.62}$$

P4. Minkowski inequality (triangle inequality):

$$\forall\vec{x},\vec{y}\in E\quad\|\vec{x}+\vec{y}\|\leq\|\vec{x}\|+\|\vec{y}\| \tag{6.5.63}$$

That we will prove further below.

Remarks

R1. These properties are mainly imposed by our intuitive approach of Euclidean space (vector space of finite dimension over the field of real number $\mathbb{R}$ and with a scalar product that we will see later) and its geometric interpretation (through the fact that it is also an affine space $\mathrm{A}\mathbb{R}^n$).

R2. We will prove a little further below the property P4 under the name of "triangle inequality" and we will do a little more general study of this inequality under the name "Minkowski inequality" in the section Topology.

6.5.4.1 Scalar Product (Dot Product)

Definition (#6.5.239): An "Euclidean vector space" of dimension n is a vector space (real and of finite dimensional for the purists) with a specific operation, the "scalar product" also named "dot product" which we denote (notation specific to this textbook) regarding to the special case of vectors:

$$\|\vec{x}\| \cdot \|\vec{y}\| \cos(\theta) = \vec{x} \circ \vec{y} = x_1 y_1 + x_2 y_2 + \ldots + x_n y_n \tag{6.5.64}$$

Remarks

R1. We find in some books (for information) the notation $(\vec{x}|\vec{y})$ or $\langle\vec{x}|\vec{y}\rangle$ in the generalization of this definition as we shall see a little further below. According to the standard ISO 80000-2:2009 *Mathematical signs and symbols to be used in the natural sciences and technology* we should write the dot product as $a \cdot b$. Using the Linear Algebra notation that we will see later, the dot product will be written: $\vec{x}^T\vec{y}$.

R2. The scalar product has a huge importance in the whole field of mathematics and physics; and we will see it again in all following chapters of this textbook. It is therefore necessary to carefully understand what follows.

R3. The scalar product may be viewed as a projection of the length of a vector along the length of another one as we will see later.

This scalar product has the following properties (most of which stem from the definition itself) in a Euclidean space:

P1. Commutativity: $\vec{x} \circ \vec{y} = \vec{y} \circ \vec{x}$

P2. Associativity: $\alpha(\vec{x} \circ \vec{y}) = (\alpha\vec{x}) \circ \vec{y} = \vec{x} \circ (\alpha\vec{y})$

P3. Distributivity: $\vec{x} \circ (\vec{y} + \vec{z}) = \vec{x} \circ \vec{y} + \vec{x} \circ \vec{z}$

P4. Non-degenerated: $\vec{x} \circ \vec{y} = 0$ then $\forall\vec{x} \neq \vec{0} \Rightarrow \vec{y} = \vec{0}$

P5. Squared scalar: $\|\vec{x}\|^2 = \vec{x} \circ \vec{x}$ and $\vec{x} \circ \vec{x} > 0$ if $\vec{x} \neq \vec{0}$

P6. Bi-linearity: $(\alpha\vec{x} + \beta\vec{y}) \circ \vec{z} = \alpha(\vec{x} \circ \vec{z}) + \beta(\vec{y} \circ \vec{z})$

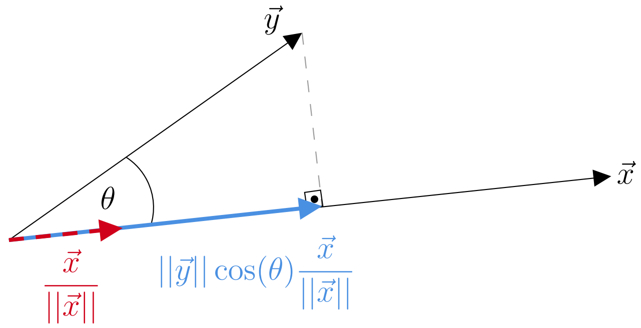
Only the latter property requires perhaps a proof (and one of the results of the proof will be useful to us later to prove another very important property of the scalar product):

Proof 6.31.2. Given:

$$\text{proj}_x\vec{y} = \|\vec{y}\| \cos(\theta) \frac{\vec{x}}{\|\vec{x}\|} = \cos(\theta) \left(\frac{\|\vec{y}\| \cdot \|\vec{x}\|}{\|\vec{x}\|^2}\right) \vec{x} = \cos(\theta) \left(\frac{\|\vec{y}\| \cdot \|\vec{x}\|}{\vec{x} \circ \vec{x}}\right) \vec{x} \tag{6.5.65}$$

which is the "orthogonal projection vector" (the x on index of project meaning "the vector $\vec{x}$") of the vector $\vec{y}$ of standardization at the unit of vector $\vec{x}$.

Using the scalar (dot) product, the vector $\text{proj}_x\vec{y}$ can be expressed otherwise, we just need to take the relation that we have seen above:



$\vec{y}$
$\vec{x}$
θ
$\dfrac{\vec{x}}{||\vec{x}||}$
$||\vec{y}||\cos(\theta)\dfrac{\vec{x}}{||\vec{x}||}$

Figure 6.107: **Geometrical representation of the dot product (projection)**

$$\|\vec{x}\|\cdot\|\vec{y}\|\cos(\theta)=\vec{x}\circ\vec{y}\Leftrightarrow\|\vec{x}\|\cdot\|\vec{y}\|\cos(\theta)=\vec{x}\circ\vec{y} \tag{6.5.66}$$

and introduce it into $\text{proj}_x\vec{y}$ to get:

$$\text{proj}_x\vec{y}=\cos(\theta)\left(\frac{\|\vec{y}\|\cdot\|\vec{x}\|}{\vec{x}\circ\vec{x}}\right)\vec{x}=\frac{\vec{x}\circ\vec{y}}{\vec{x}\circ\vec{x}}\vec{x} \tag{6.5.67}$$

The norm of $\text{proj}_x\vec{y}$ is written:

$$\|\text{proj}_x\vec{y}\|=\frac{|\vec{x}\circ\vec{y}|}{\|\vec{x}\|\cdot\|\vec{x}\|}\|\vec{x}\|=\frac{|\vec{x}\circ\vec{y}|}{\|\vec{x}\|} \tag{6.5.68}$$

If $\vec{x}$ has a unit norm, the relations of previous projections are simplified and become obviously:

$$\text{proj}_x\vec{y}=(\vec{x}\circ\vec{y})\vec{x}\quad\text{and}\quad\|\text{proj}_x\vec{y}\|=|\vec{x}\circ\vec{y}| \tag{6.5.69}$$

By elementary geometric considerations (distributivity of the scalar product), it is easy to realize that:

$$\text{proj}_v(\vec{x}+\vec{y})=\text{proj}_v\vec{x}+\text{proj}_v\vec{y}\quad\text{and}\quad\text{proj}_v\alpha\vec{x}=\alpha\text{proj}_v\vec{x} \tag{6.5.70}$$

If we now return to the proof of the bi-linearity property:

$$(\alpha\vec{x}+\beta\vec{y})\circ\vec{z}=\alpha(\vec{x}\circ\vec{z})+\beta(\vec{y}\circ\vec{z}) \tag{6.5.71}$$

We have in a first time:

$$\text{proj}_v((\alpha\vec{x}+\beta\vec{y}))=\text{proj}_v\alpha\vec{x}+\text{proj}_v\beta\vec{y}=\alpha\text{proj}_v\vec{x}+\beta\text{proj}_v\vec{y} \tag{6.5.72}$$

and, from the definition of the property of the orthogonal projection, it comes immediately by a one-to-one correspondence:

$$\begin{gathered}\text{proj}_v(\alpha\vec{x}+\beta\vec{y})=\text{proj}_v\alpha\vec{x}+\text{proj}_v\beta\vec{y}=\alpha\text{proj}_v\vec{x}+\beta proj_v\vec{y}\\ \frac{(\alpha\vec{x}+\beta\vec{y})\circ\vec{z}}{\vec{z}\circ\vec{z}}\vec{z}=\alpha\frac{\vec{x}\circ\vec{z}}{\vec{z}\circ\vec{z}}\vec{z}+\beta\frac{\vec{y}\circ\vec{z}}{\vec{z}\circ\vec{z}}\vec{z}\end{gathered} \tag{6.5.73}$$

hence the property P6 that follows by multiplying the two members of equality by $\vec{z}\circ\vec{z}$ and after by simplification by $\vec{z}$.

■ Q.E.D.

Definitions (#6.5.240):

D1. A vector space E is said to be an "proper Euclidean vector space" if $\forall \vec{x} \in E \qquad \|\vec{x}\| > 0$.

D2. We say that the vectors $\vec{x}$ and $\vec{y}$ are "orthogonal vectors" if they are non-null and that their scalar product is equal to zero (their angle is equal to $\pi/2$).

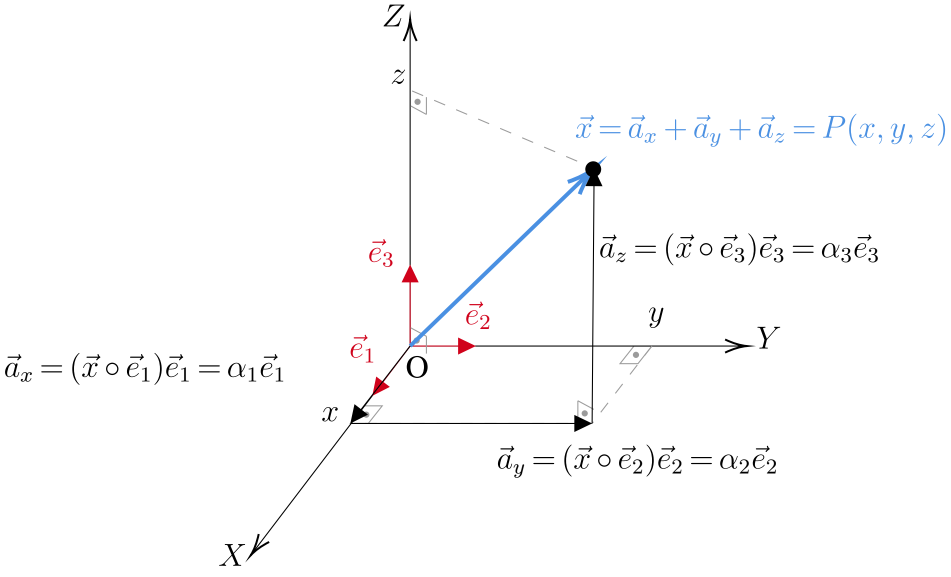
D3. A basis of vectors $(\vec{e}_1, \vec{e}_2, \ldots, \vec{e}_n)$ is said to be an "orthonormal basis" if all the vectors $\vec{e}_1, \vec{e}_2, \ldots, \vec{e}_n$ are pairwise orthogonal and their norm is equal to the unit (thus constituting a: free family).

Remark

We will see in the section Tensor Calculus (we could have done here too but we don't use it for a practical case in this section therefore...) how from a set of independent vectors build an orthogonal basis. This is what the reader will find under the name "(Gram-)Schmidt orthogonalization method" (see page 2062).

By a simple geometric argument, we see that every vector is the sum of its orthogonal projections on the vectors of an orthonormal basis, that is, if $(\vec{e}_1, \vec{e}_2, \vec{e}_2) = (\vec{u}, \vec{v}, \vec{w})$ is an orthonormal basis in $\mathbb{R}^3$ for example:

$$\vec{x} = (\vec{x} \circ \vec{e}_1)\vec{e}_1 + (\vec{x} \circ \vec{e}_2)\vec{e}_2 + (\vec{x} \circ \vec{e}_3)\vec{e}_3 = \alpha_1 \vec{e}_1 + \alpha_2 \vec{2} + \alpha_3 \vec{e}_3 = \vec{a}_x + \vec{a}_y + \vec{a}_z \tag{6.5.74}$$



Z
z
$\vec{x} = \vec{a}_x + \vec{a}_y + \vec{a}_z = P(x, y, z)$
$\vec{e}_3$
$\vec{a}_z = (\vec{x} \circ \vec{e}_3)\vec{e}_3 = \alpha_3 \vec{e}_3$
$\vec{e}_2$
y
Y
$\vec{a}_x = (\vec{x} \circ \vec{e}_1)\vec{e}_1 = \alpha_1 \vec{e}_1$
$\vec{e}_1$
O
x
$\vec{a}_y = (\vec{x} \circ \vec{e}_2)\vec{e}_2 = \alpha_2 \vec{e}_2$
X

Figure 6.108: Orthonormal basis projection example

This decomposition is also obtained by the P6 property of the scalar product. Indeed, consider the components $(\vec{x}_1, \vec{x}_2, \vec{x}_3)$ of a vector $\vec{x}$ in our orthonormal basis:

$$\begin{aligned}\vec{x} \circ \vec{e}_1 &= (x_1 \circ \vec{e}_1 + x_2 \circ \vec{e}_2 + x_3 \circ \vec{e}_3) \circ \vec{e}_1 \\ &= x_1(\vec{e}_1 \circ \vec{e}_1) + x_2(\vec{e}_2 \circ \vec{e}_1) + x_3(\vec{e}_3 \circ \vec{e}_1) \\ &= x_1\end{aligned} \tag{6.5.75}$$

since $\vec{e}_1 \circ \vec{e}_1 = 1$ and $\vec{e}_1 \circ \vec{e}_2 = 0$. Therefore we get immediately:

$$\vec{x} \circ \vec{e}_2 = x_2 \qquad \text{and} \qquad \vec{x} \circ \vec{e}_3 = x_3 \tag{6.5.76}$$

hence the decomposition.

Given the respective components (x_1, x_2, x_3) and (y_1, y_2, y_3) of the vectors $\vec{x}$ and $\vec{y}$ in a canonical orthonormal basis $(\vec{e}_1, \vec{e}_2, \vec{e}_3)$ we know now that we can write the scalar product in the form:

$$\vec{x} \circ \vec{y} = (x_1\vec{e}_1 + x_2\vec{e}_2 + x_3\vec{e}_3) \circ (y_1\vec{e}_1 + y_2\vec{e}_2 + y_3\vec{e}_3) \tag{6.5.77}$$

by the property P6 of the scalar product:

$$\vec{x} \circ \vec{y} = x_1\vec{e}_1 \circ (y_1\vec{e}_1 + y_2\vec{e}_2 + y_3\vec{e}_3) + x_2\vec{e}_2 \circ (y_1\vec{e}_1 + y_2\vec{e}_2 + y_3\vec{e}_3) + x_3\vec{e}_3 \circ (y_1\vec{e}_1 + y_2\vec{e}_2 + y_3\vec{e}_3) \tag{6.5.78}$$

using the properties P1 and P6 again:

$$\begin{gathered}\vec{x} \circ \vec{y} = x_1(y_1\vec{e}_1 + y_2\vec{e}_2 + y_3\vec{e}_3) \circ \vec{e}_1 + x_2(y_1\vec{e}_1 + y_2\vec{e}_2 + y_3\vec{e}_3) \circ \vec{e}_2 + x_3(y_1\vec{e}_1 + y_2\vec{e}_2 + y_3\vec{e}_3) \circ \vec{e}_3 \\ \Rightarrow \\ (y_1\vec{e}_1 + y_2\vec{e}_2 + y_3\vec{e}_3) \circ \vec{e}_1 = y_1\vec{e}_1 \circ \vec{e}_1 + y_2\vec{e}_2 \circ \vec{e}_1 + y_3\vec{e}_3 \circ \vec{e}_1 = y_1\|\vec{e}_1\|^2 = y_1 \\ (y_1\vec{e}_1 + y_2\vec{e}_2 + y_3\vec{e}_3) \circ \vec{e}_2 = y_1\vec{e}_1 \circ \vec{e}_2 + y_2\vec{e}_2 \circ \vec{e}_2 + y_3\vec{e}_3 \circ \vec{e}_2 = y_2\|\vec{e}_2\|^2 = y_2 \\ (y_1\vec{e}_1 + y_2\vec{e}_2 + y_3\vec{e}_3) \circ \vec{e}_3 = y_1\vec{e}_1 \circ \vec{e}_3 + y_2\vec{e}_2 \circ \vec{e}_3 + y_3\vec{e}_3 \circ \vec{e}_3 = y_3\|\vec{e}_3\|^2 = y_3\end{gathered} \tag{6.5.79}$$

Which finally gives us the very famous and important decomposition:

$$\boxed{\vec{x} \circ \vec{y} = x_1y_1 + x_2y_2 + x_3y_3} \tag{6.5.80}$$

This is one of the most important relation in the field of vector calculus, which we name "canonical scalar product" or "canonical dot product".

Remark

The angle θ of the dot product is sometimes denoted by:

$$\theta = \angle(\vec{x}, \vec{y}) \tag{6.5.81}$$

Now let us prove with a simple two dimensional case a property that physicist like a lot to characterize an orthogonal linear application (see section Linear Algebra page 1954): that the dot product is invariant under any orthogonal transformation (then abusively said "invariant under basis change...").

For this let us consider a vector $\vec{x} = (x_1, x_2)$ and the 2D rotation matrix (see section Numbers page 2648):

$$\begin{bmatrix} \cos(\theta) & -\sin(\theta) \\ \sin(\theta) & \cos(\theta) \end{bmatrix} \tag{6.5.82}$$

Now let us calculate:

$$\begin{bmatrix} \cos(\theta) & -\sin(\theta) \\ \sin(\theta) & \cos(\theta) \end{bmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} x_1\cos(\theta) - x_2\sin(\theta) \\ x_1\sin(\theta) + x_2\cos(\theta) \end{pmatrix} \tag{6.5.83}$$

So now let us consider two vectors $\vec{a}$ and $\vec{b}$ we have proved just above that their dot product is given by:

$$\vec{a}\circ\vec{b}=a_1b_1+a_2b_2+a_3b_3 \tag{6.5.84}$$

And after the chosen orthogonal transformation we get:

$$\begin{aligned}\vec{a}'\circ\vec{b}'=&\begin{pmatrix}a_1\cos(\theta)-a_2\sin(\theta)\\a_1\sin(\theta)+a_2\cos(\theta)\end{pmatrix}\circ\begin{pmatrix}b_1\cos(\theta)-b_2\sin(\theta)\\b_1\sin(\theta)+b_2\cos(\theta)\end{pmatrix}\\&=(a_1\cos(\theta)-a_2\sin(\theta))\,(b_1\cos(\theta)-b_2\sin(\theta))\\&+(a_1\sin(\theta)+a_2\cos(\theta))\,(b_1\sin(\theta)+b_2\cos(\theta))\\&=a_1b_1\cos^2(\theta)-a_2b_1\sin(\theta)\cos(\theta)-a_1b_2\cos(\theta)\sin(\theta)+a_2b_2\sin^2(\theta)\\&+a_1b_1\sin^2(\theta)+a_2b_1\cos(\theta)\sin(\theta)+a_1b_2\sin(\theta)\cos(\theta)+a_2b_2\cos^2(\theta)\\&=a_1b_1+a_2b_2=\vec{a}\circ\vec{b}\end{aligned} \tag{6.5.85}$$

So the dot product is indeed invariant under this rotation that is a special 2D case of orthogonal transformation and in fact under any other orthogonal transformation.

Remark

The dot product, must not be confused with the "element-wise multiplication" of two vectors defined by:

$$\boxed{\vec{x}\diamond\vec{y}=\begin{pmatrix}x_1y_1\\x_2y_2\\\vdots\\x_ny_n\end{pmatrix}} \tag{6.5.86}$$

6.5.4.1.1 Cauchy–Schwarz inequality

In mathematics, the Cauchy–Schwarz inequality is a useful inequality encountered in many different settings, such as linear algebra, analysis, probabilities, statistics and other areas (just read this textbook entirely to have an idea...). It is considered to be one of the most important inequalities in all of mathematics!!!

The relation:

$$(\vec{x}\circ\vec{y})\circ(\vec{x}\circ\vec{y})=\vec{x}\circ\vec{x}+\vec{x}\circ\vec{y}+\vec{y}\circ\vec{x}+\vec{y}\circ\vec{y}=\vec{x}\circ\vec{x}+\vec{y}\circ\vec{y}+2\vec{x}\circ\vec{y} \tag{6.5.87}$$

can also be trivially written as follows if we use the concept of the norm and the definition of the scalar product:

$$(\vec{x}\circ\vec{y})\circ(\vec{x}\circ\vec{y})=\|\vec{x}+\vec{y}\|^2=\|\vec{x}\|^2+\|\vec{y}\|^2+2\vec{x}\circ\vec{y} \tag{6.5.88}$$

It is interesting to notice that if both $\vec{x}$ and $\vec{y}$ are orthogonal vectors, we fall back on the result of a famous theorem: the Pythagorean theorem!

Indeed, therefore we have if the two vectors are orthogonal:

$$\vec{x}\circ\vec{y}=0 \tag{6.5.89}$$

This gives us:

$$\boxed{\|\vec{x}+\vec{y}\|^2=\|\vec{x}\|^2+\|\vec{y}\|^2} \tag{6.5.90}$$

This relations is very important in physics and mathematics. It must be remembered!

Theorem 6.32. We name "Cauchy-Schwarz inequality", the inequality, valid for any choice of the vectors $\vec{x}$ and $\vec{y}$, the relation:

$$\boxed{|\vec{x}\circ\vec{y}|\leq\|\vec{x}\|\|\vec{y}\|} \tag{6.5.91}$$

Which can also be written as:

$$|\vec{x}\circ\vec{y}|^2\leq(\vec{x}\circ\vec{x})\cdot(\vec{y}\circ\vec{y}) \tag{6.5.92}$$

First we will consider as obvious that equality only occurs when the two vectors are collinear.

Proof 6.32.1. We put ourself in the case where $\vec{x},\vec{y}\neq\vec{0}$. So then $\lambda\in\mathbb{R}$ we have obviously according to the properties of the scalar product:

$$(\vec{x}+\lambda\vec{y})\circ(\vec{x}+\lambda\vec{y})=\vec{x}\circ\vec{x}+2\lambda\vec{x}\circ\vec{y}+\lambda^2\vec{y}\circ\vec{y}\geq 0 \tag{6.5.93}$$

So this is a simple equation of the second degree where variable is λ. Remembering what we saw in our study of polynomials of second degree (see section Calculus page 1368), the previous relation (that it is always greater than or equal to zero) is satisfied if the discriminant b^2-4ac is negative or zero. In other words, if:

$$4(\vec{x}\circ\vec{y})^2-4(\vec{x}\circ\vec{x})(\vec{y}\circ\vec{y})\leq 0 \tag{6.5.94}$$

Thus after simplification:

$$(\vec{x}\circ\vec{y})^2-(\vec{x}\circ\vec{x})(\vec{y}\circ\vec{y})\leq 0\Rightarrow(\vec{x}\circ\vec{y})^2\leq(\vec{x}\circ\vec{x})(\vec{y}\circ\vec{y}) \tag{6.5.95}$$

■ Q.E.D.

When E is in $\mathbb{R}^n$, the Cauchy-Schwarz inequality is written with the vector components:

$$\sum_{i=1}^{n} a_i b_i \leq \sqrt{\sum_{i=1}^{n} a_i^2 \sum_{i=1}^{n} b_i^2} \tag{6.5.96}$$

In the particular case where $\forall i, b_i = 1$ it becomes:

$$\left(\sum_{i=1}^{n} a_i\right)^2 \leq n \sum_{i=1}^{n} a_i^2 \tag{6.5.97}$$

or even:

$$\left(\frac{1}{n}\sum_{i=1}^{n} a_i\right)^2 \leq \frac{1}{n} \sum_{i=1}^{n} a_i^2 \tag{6.5.98}$$

which shows that the square of the arithmetic mean is less than or equal to the arithmetic mean of the squares. This result is important for the study of Statistics!

Furthermore, using the property of the cosine and the Cauchy-Schwarz inequality we can write immediately:

$$-1 \leq \frac{\vec{x} \circ \vec{y}}{\|\vec{x}\| \cdot \|\vec{y}\|} \leq 1 \tag{6.5.99}$$

relation that we will see again in the context of the study of Statistics (see section Statistics page 613).

Notice that the Cauchy-Schwarz inequality is a special case of the "Hölder's inequality for sums defined by:

$$\sum_{k=1}^{n} |a_k b_k| \leq \left(\sum_{k=1}^{n} |a_k|^p\right)^{1/p} \left(\sum_{k=1}^{n} |b_k|^q\right)^{1/q} \tag{6.5.100}$$

Indeed, plugging $p = q = 2$ into Holder's inequality we get:

$$\sum_{k=1}^{n} |a_k b_k| \leq \left(\sum_{k=1}^{n} |a_k|^2\right)^{1/2} \left(\sum_{k=1}^{n} |b_k|^2\right)^{1/2} \tag{6.5.101}$$

Squaring either side we get exactly Cauchy's inequality;

$$\left(\sum_{k=1}^{n} |a_k b_k|\right)^2 \leq \left(\sum_{k=1}^{n} |a_k|^2\right) \left(\sum_{k=1}^{n} |b_k|^2\right) \tag{6.5.102}$$

6.5.4.1.2 Triangle Inequalities

By majoring $2\vec{x}\circ\vec{y}$ by $2\|\vec{x}\|\cdot\|\vec{y}\|$ (using the Cauchy-Schwarz inequality!) in the relation already establish previously:

$$\|\vec{x}+\vec{y}\|^2=\|\vec{x}\|^2+\|\vec{y}\|^2+2\vec{x}\circ\vec{y} \tag{6.5.103}$$

we get:

$$\|\vec{x}+\vec{y}\|^2\leq\|\vec{x}\|^2+\|\vec{y}\|^2+2\|\vec{x}\|\cdot\|\vec{y}\|=(\|\vec{x}\|+\|\vec{y}\|)^2 \tag{6.5.104}$$

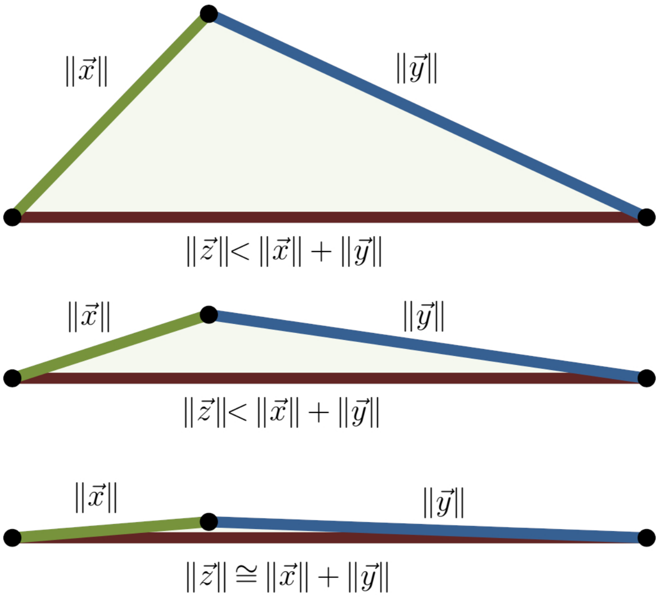
which takes us immediately by taking the root square the "triangle inequality" that is very useful for the study of Sequences and Series and also in Topology:

$$\boxed{\|\vec{x}+\vec{y}\|\leq\|\vec{x}\|+\|\vec{y}\|} \tag{6.5.105}$$

Also sometimes denoted:

$$\|\vec{z}\|\leq\|\vec{x}\|+\|\vec{y}\| \tag{6.5.106}$$

The concept can be illustrated also as following:



$\|\vec{x}\|$
$\|\vec{y}\|$
$\|\vec{z}\|<\|\vec{x}\|+\|\vec{y}\|$
$\|\vec{x}\|$
$\|\vec{y}\|$
$\|\vec{z}\|<\|\vec{x}\|+\|\vec{y}\|$
$\|\vec{x}\|$
$\|\vec{y}\|$
$\|\vec{z}\|\cong\|\vec{x}\|+\|\vec{y}\|$

Figure 6.109: **Illustration of the triangular inequality**

And obviously in the limit case (when all vectors are on the same line) we have: $\|\vec{z}\|=\|\vec{x}\|+\|\vec{y}\|$.

Remark

The generalization of this inequality relatively to the choice of the norm (that is to say: the way we define a distance) as we will see in the section of Topology, gives what we name the "Minkowski inequality".

By applying one time the triangle inequality to the vectors $\vec{x}$ and $(\vec{y}-\vec{x})$ and another time to vectors $(\vec{y})$ and $(\vec{x}-\vec{y})$ we get the variant:

$$\|\vec{x}\|-\|\vec{y}\|\leq\|\vec{x}-\vec{y}\| \tag{6.5.107}$$

6.5.4.1.3 General Scalar/Dot Product

Let us see now another and little more general, formal and abstract way to define the dot product while trying to stay as simple as possible (caution! in the general case the notation of the scalar product changes!).

First the reader must know that, as we will see it in the section of Functional Analysis, all the concepts studied until now in this section can also be applied to a special category of functions! Yeeesss!!! Add, subtract functions like we do it with vectors is obvious but you must know that some more or less complicated functions are colinear or orthogonal (think to affine functions!) and furthermore there are not limited to $\mathbb{R}$ but can be extended to $\mathbb{C}$ easily and hence the scalar product departure set.

To make thinks no too much complicate we will focus here only on a gentle generalization of the dot product to vectors (we will come back on the case of functions in the section of Functional Analysis later).

Definition (#6.5.241): Let E be a real vector space (once again we focus here only on simple vectors for the moment). A "positive symmetric bilinear form" on E also named "inner product", is an application:

$$\phi:\begin{cases}E\times E\mapsto\mathbb{R}\\(x,y)\mapsto\langle x|y\rangle\end{cases}\tag{6.5.108}$$

which satisfies by definition:

P1. Positivity:

$$\forall\vec{x}\in E:\qquad\phi(\vec{x},\vec{x})=\langle\vec{x}|\vec{x}\rangle\geq 0\in\mathbb{R}\tag{6.5.109}$$

P2. Nullity (defined):

$$\forall\vec{x}\in E:\qquad\phi(\vec{x},\vec{x})=\langle\vec{x}|\vec{x}\rangle=0\Rightarrow\vec{x}=0\tag{6.5.110}$$

P3. Symmetry (defined):

$$\forall(\vec{x},\vec{y})\in E^2:\qquad\phi(l\vec{x},\vec{y})=\phi(\vec{y},\vec{x})\Leftrightarrow\langle l\vec{x}|\vec{y}\rangle=\langle\vec{y}|\vec{x}\rangle\tag{6.5.111}$$

P4. The bilinearity (bilinear form) with, in order, the "linearity on the left" and "linearity on the right":

$$\forall(\vec{x},\vec{y},\vec{z})\in E^3,\forall(\lambda,\mu)\in\mathbb{R}^2:\begin{cases}\langle\lambda\vec{x}+\mu\vec{y}|\vec{z}\rangle=\lambda\langle\vec{x}|\vec{z}\rangle+\mu\langle\vec{y}|\vec{z}\rangle\\\langle\vec{x}|\lambda\vec{y}+\mu\vec{z}\rangle=\lambda\langle\vec{x}|\vec{y}\rangle+\mu\langle\vec{x}|\vec{z}\rangle\end{cases}\tag{6.5.112}$$

P... And so on... we have the same six properties as the scalar product as the both are the same if we focus only on vectors in $\mathbb{R}$.

Remark

Again, these properties are mainly imposed by our intuitive approach of the Euclidean space and its geometric interpretation.

Definition (#6.5.242): A space E provided with a scalar product is named in general (with the departure set in $\mathbb{C}$) a "pre-Hilbert space" or "inner product space". If E is of finite dimension, then we speak of "Euclidean space".

Remark

If E is a Euclidean space, then if the determinant $\det(\vec{e}_1,\vec{e}_2,\ldots,\vec{e}_n)$ is equal ± 1 (see section Linear Algebra page 1961) we speak of "oriented Euclidean space".

We will see in our study of Topology (see section of the same name page 2446) that the properties of the scalar product are the foundation bricks to set a norm and therefore a distance in a metric space. This distance will be given according to what we will see in the section of Topology:

$$\forall \vec{x},\vec{y}\in E \quad d(\vec{x},\vec{y}):=\|\vec{x}-\vec{y}\| \tag{6.5.113}$$

Definition (#6.5.243): We say that a space E having a dot product (inner product) $\langle\cdot|\cdot\rangle$ is a "Hilbert space" if this space is complete for the metric defined above.

In other words, having a metric space provided with a distance generated by a scalar product is one thing. Then having a measurable distance is another one!!! A Hilbert space has thus distances measurable in the topological sense because the set we are working on is continuous and any point can be approached indefinitely (imagine having a rule and you can not approach on this rule the points that define the dimensions of your object... it would be embarrassing...). So without complete space a lot of theorems of functional analysis (that is strongly linked to vector calculus) could not be used in the study of vector spaces and this would be very embarrassing in Quantum Wave Physics for example...

Formally, remember that a metric space is complete if all Cauchy sequences (see section Sequences and Series page 1657) of this space are converging (see section Fractals page 7046) in a metric space (see section Topology page 2447).

6.5.4.2 Cross Product

The cross product of two vectors is a proper operation to the dimension 3. To introduce it, it is first necessary to orient the space intended to receive it. The orientation is defined by the concept of "determinant", therefore we will begin with a brief introduction to the study of this concept. This study will be repeated later in more details in the analysis of linear systems in the section of Linear Algebra.

Definition (#6.5.244): We name basically "determinant" of two column vectors of $\mathbb{R}^2$ (for the general form of the determinant see the section of Linear Algebra page 1961):

$$\begin{pmatrix}a_1\\a_2\end{pmatrix},\begin{pmatrix}b_1\\b_2\end{pmatrix} \tag{6.5.114}$$

and we denote it:

$$\det([\vec{a},\vec{b}])=\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} \tag{6.5.115}$$

the number:

$$\det([\vec{a},\vec{b}])=a_1b_2-a_2b_1 \tag{6.5.116}$$

We name determinant of three column vectors of $\mathbb{R}^3$ (once again see the section Linear Algebra for a generalization):

$$\begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix},\begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix},\begin{pmatrix} c_1 \\ c_2 \\ c_3 \end{pmatrix} \tag{6.5.117}$$

and we denote it:

$$\det([\vec{a},\vec{b},\vec{c}])=\begin{vmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{vmatrix} \tag{6.5.118}$$

the number:

$$\begin{aligned}\det([\vec{a},\vec{b},\vec{c}])&=a_1\begin{vmatrix} b_2 & c_2 \\ b_3 & c_3 \end{vmatrix}-a_2\begin{vmatrix} b_1 & c_1 \\ b_3 & c_3 \end{vmatrix}-a_3\begin{vmatrix} b_1 & c_1 \\ b_2 & c_2 \end{vmatrix}\\ &=a_1b_2c_3+a_2b_3c_1+a_3b_1c_2-a_1b_3c_2-a_2b_1c_3-a_3b_2c_1\end{aligned} \tag{6.5.119}$$

Thus, the function that associates to each pair of column vectors of $\mathbb{R}^2$ (or respectively to each triplet of column vectors of $\mathbb{R}^3$) has a determinant named "determinant of order 2" (respectively "determinant of order 3")

As we will prove it in the section of Linear Algebra the determinant has the property of being multiplied by -1 if one of the column vectors is replaced by its opposite or two of its column vectors are exchanged. In addition, the determinant is non-zero if and only if its column vectors are linearly independent (the proof - that has a great importance in Applied Mathematics - is a few lines further below and a generalization can be found in the section of Linear Algebra).

Definition (#6.5.245): Given x_1,x_2,x_3 and y_1,y_2,y_3 the respective components of the vectors $\vec{x}$ and $\vec{y}$ in the orthonormal basis $(\vec{e}_1,\vec{e}_2,\vec{e}_3)$. We name "cross-product" of $\vec{x}$ and $\vec{y}$, and we denote it in most books by:

$$\vec{x}\times\vec{y} \tag{6.5.120}$$

and in a minority of books:

$$\vec{x}\wedge\vec{y} \tag{6.5.121}$$

the vector:

$$\vec{x}\times\vec{y}=(x_2y_3-x_3y_2)\vec{e}_1+(x_3y_1-x_1y_3)\vec{e}_2+(x_1y_2-x_2y_1)\vec{e}_3 \tag{6.5.122}$$

or as components:

$$\boxed{\vec{x}\times\vec{y}=\begin{pmatrix} x_2y_3-x_3y_2 \\ x_3y_1-x_1y_3 \\ x_1y_2-x_2y_1 \end{pmatrix}=\begin{pmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{pmatrix}\begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix}} \tag{6.5.123}$$

The matrix form above will be very useful to us in the section Mechanics for the construction of the Inertial Matrix.

Remarks

R1. The first notation is the international notation due to Gibbs (which we will use throughout this textbook), the second is the French notation due to Burali-Forti (quite annoying because confusing with the notation of the operator AND in Proof Theory or Logical Systems).

R2. It is usually quite annoying to remember by heart the relations that form the cross product. But fortunately there are at least three good mnemonics techniques:

1. The first and probably the fastest method is to remember by heart only one of the expressions of the components of the cross product and after by decrement of the indices (by starting again from 3 when we reaches 0) get all the other components. But we must still find a simple way to remember by heart one of the components... A good way is the following mathematical property of two collinear vectors giving an easy with to find back the third component (the one along the z-axis):

   Given two colinear vectors in the same plane, then:

   $$\vec{x}=\lambda\vec{y}\Leftrightarrow\begin{pmatrix}x_1\\x_2\end{pmatrix}=\lambda\begin{pmatrix}y_1\\y_2\end{pmatrix}\Leftrightarrow\frac{x_1}{y_1}=\frac{x_2}{y_2}\Leftrightarrow x_1y_2-x_2y_1=0 \qquad (6.5.124)$$

   We fall back on the expression of the third component of the cross product of two vectors.

   Or if you want to remember only the first component given in letters by $z_x=x_yy_z-x_zy_y$ the indices gives "xyzzy" (like a name of a person...). The second and third equations can be obtained from the first by simply vertically rotating the subscripts, $x\rightarrow y\rightarrow z\rightarrow x$.

2. The second method that we will see in details during our study of the section of Tensor Calculus is to use the Levi-Civita antisymmetric symbol. This method is certainly the most aesthetic of all but not necessarily the fastest to develop and the easiest to remember. We give here just the expression without explanations at the moment as we will study this later (but t is also useful to get the general expression of the determinant):

   $$(\vec{x}\times\vec{y})_i=\varepsilon_{ijk}x_jy_k \qquad (6.5.125)$$

3. The latter method is quite simple and trivial but it implicitly uses the first method as you must remember how the calculate at least a 2×2 determinant. The idea is the following: the i-th component of $\vec{x}\times\vec{y}$ is the determinant of the two column vectors from which we have removed the i-th term, the second determinant is, however, with a "$-$" sign such that:

   $$\vec{x}\times\vec{y}=\begin{vmatrix}x_2 & y_2\\x_3 & y_3\end{vmatrix}\vec{e}_1-\begin{vmatrix}x_1 & y_1\\x_3 & y_3\end{vmatrix}\vec{e}_2+\begin{vmatrix}x_1 & y_1\\x_2 & y_2\end{vmatrix}\vec{e}_3 \qquad (6.5.126)$$

It is important, even if it is relatively simple to remember, that the different cross products for orthogonal basis vectors are (and especially for the canonical basis) first:

$$\vec{e}_1\times\vec{e}_1=\vec{e}_2\times\vec{e}_2=\vec{e}_3\times\vec{e}_3=\vec{0} \tag{6.5.127}$$

and also:

$$\vec{e}_1\times\vec{e}_2=\vec{e}_3,\quad \vec{e}_2\times\vec{e}_3=\vec{e}_1,\quad \vec{e}_3\times\vec{e}_1=\vec{e}_2 \tag{6.5.128}$$

These relations can be condensed using the Dirac function symbol (see section Tensor Calculus page 2044):

$$\vec{e}_i\times\vec{e}_j=\delta_{ij} \tag{6.5.129}$$

The cross product also has the following properties that we will prove just now:

P1. Antisymmetry:

$$\vec{x}\times\vec{y}=-(\vec{y}\times\vec{x}) \tag{6.5.130}$$

P2. Linearity:

$$(\alpha\vec{x}+\beta\vec{y})\times\vec{z}=\alpha(\vec{x}\times\vec{z})+\beta(\vec{y}\times\vec{z}) \tag{6.5.131}$$

P3. If and only if $\vec{x}$ and $\vec{y}$ are linearly independent (very important!):

$$\vec{x}\times\vec{y}\neq\vec{0} \tag{6.5.132}$$

P4. Non associativity:

$$\vec{x}\times(\vec{y}\times\vec{z})\neq(\vec{x}\times\vec{y})\times\vec{z} \tag{6.5.133}$$

P5. Distributivity over the sum:

$$\vec{x}\times(\vec{a}+\vec{b})=\vec{x}\times\vec{a}+\vec{x}\times\vec{b} \tag{6.5.134}$$

The first two properties directly derived from the definition and the property P4 is easily verified by developing the components and comparing the results.

Then let us prove the third property which is very important in linear algebra (next section) and the fifth one (because requested by a reader).

Theorem 6.33. If and only if $\vec{x}$ and $\vec{y}$ are linearly independent (very important!):

$$\vec{x}\times\vec{y}\neq\vec{0} \tag{6.5.135}$$

Proof 6.33.1. Given two vectors $\vec{x}(x_1,x_2,x_3)$ and $\vec{y}(y_1,y_2,y_3)$. If the two vectors are linearly dependent then there exists an $\alpha\in\mathbb{R}$ such that we can write:

$$\vec{y}=\alpha\vec{x} \tag{6.5.136}$$

If we develop the cross product of the two vectors that are dependent to a given factor α, we get:

$$\begin{aligned}\vec{x}\times\vec{y}&=\vec{x}\times\alpha\vec{x}\\&=(x_2\alpha x_3-x_3\alpha x_2)\vec{e}_1+(x_3\alpha x_1-x_1\alpha x_3)\vec{e}_2+(x_1\alpha x_2-x_2\alpha x_1)\vec{e}_3\end{aligned} \tag{6.5.137}$$

It goes without saying that the above result is equal to the zero vector $\vec{0}$ if indeed the two vectors are linearly dependent.

■ Q.E.D.

Theorem 6.34. The cross product is distributive over the sum.

Proof 6.34.1.

$$\begin{aligned}\begin{pmatrix}x_1\\x_2\\x_3\end{pmatrix}\times\left(\begin{pmatrix}a_1\\a_2\\a_3\end{pmatrix}+\begin{pmatrix}b_1\\b_2\\b_3\end{pmatrix}\right)=\begin{pmatrix}x_1\\x_2\\x_3\end{pmatrix}\times\begin{pmatrix}a_1+b_1\\a_2+b_2\\a_3+b_3\end{pmatrix}&=\begin{pmatrix}x_2(a_3+b_3)-x_3(a_2+b_2)\\x_3(a_1+b_1)-x_1(a_3+b_3)\\x_1(a_2+b_2)-x_2(a_1+b_1)\end{pmatrix}\\&=\begin{pmatrix}x_2a_3-x_3a_2\\x_3a_1-x_1a_3\\x_1a_2-x_2a_1\end{pmatrix}+\begin{pmatrix}x_2b_3-x_3b_2\\x_3b_1-x_1b_3\\x_1b_2-x_2b_1\end{pmatrix}=\vec{x}\times\vec{a}+\vec{x}\times\vec{b}\end{aligned}\tag{6.5.138}$$

■ Q.E.D.

If we now assume that both vector $\vec{x}$ and $\vec{y}$ are linearly independent and non-zero vectors, we must prove that the following two cross product properties:

Theorem 6.35. The resultant of a cross product of two vectors $\vec{x}$ and $\vec{y}$ is a vector orthogonal (perpendicular) to $\vec{x}$ and $\vec{y}$ if they are not null.

Proof 6.35.1. To prove this we simply write the development using the dot product:

$$\vec{x}\circ(\vec{x}\times\vec{y})=x_1\begin{vmatrix}x_2&y_2\\x_3&y_3\end{vmatrix}-x_2\begin{vmatrix}x_1&y_1\\x_3&y_3\end{vmatrix}+x_3\begin{vmatrix}x_1&y_1\\x_2&y_2\end{vmatrix}=\begin{vmatrix}x_1&x_1&y_2\\x_2&x_2&y_2\\x_3&x_3&y_3\end{vmatrix}=0\tag{6.5.139}$$

This equation shows that the vector $\vec{x}$ is perpendicular to the resulting vector of cross product between $\vec{x}$ and $\vec{y}$.

■ Q.E.D.

Theorem 6.36. The cross product has for norm (module):

$$\|\vec{x}\|\cdot\|\vec{y}\|\sin(\theta)\tag{6.5.140}$$

where θ is the angle between $\vec{x}$ and $\vec{y}$.

Proof 6.36.1. To prove this we simply write the development of the norm of the cross product:

$$\begin{aligned}\|\vec{x}\times\vec{y}\|^2&=(x_2y_3-x_3y_2)^2+(x_3y_1-x_1y_3)^2+(x_1y_2-x_2y_1)^2\\&=(x_1^2+x_2^2+x_3^2)(y_1^2+y_2^2+y_3^2)-(x_1y_1+x_2y_2+x_3y_3)^2\\&=\|\vec{x}\|^2\|\vec{y}\|^2-\|\vec{x}\|^2\|\vec{y}\|^2\cos^2(\theta)=\|\vec{x}\|^2\|\vec{y}\|^2(1-\cos^2(\theta))=\|\vec{x}\|^2\|\vec{y}\|^2\sin^2(\theta)\end{aligned}\tag{6.5.141}$$

Finally:

$$\boxed{\|\vec{x}\times\vec{y}\|=\|\vec{x}\|\|\vec{y}\|\sin(\theta)}\tag{6.5.142}$$

■ Q.E.D.

We then notice that in the case where E is the Euclidean vector space, the norm of the cross product is the area (surface) of the parallelogram constructed on representatives of vectors $\vec{x}$ and $\vec{y}$ of common origin:

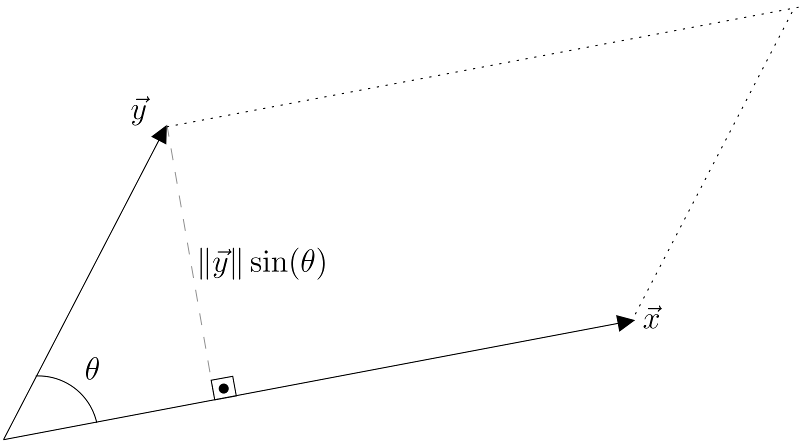


Figure 6.110: Geometrical representation of the cross product

If $\vec{x}$ and $\vec{y}$ are linearly independent, the triplet $(\vec{x},\vec{y},\vec{x}\times\vec{y})$ and also the triplet $(\vec{x},\vec{y},\vec{y}\times\vec{x})$ are direct.

Indeed, $(\vec{z}_1,\vec{z}_2,\vec{z}_3)$ being the components of $\vec{x}\times\vec{y}$ (in the basis $(\vec{e}_1,\vec{e}_2,\vec{e}_3)$), the determinant of passage of $(\vec{e}_1,\vec{e}_2,\vec{e}_3)$ to $(\vec{x}\times\vec{y},\vec{x},\vec{y})$ (for example) will be written:

$$\begin{vmatrix} z_1 & x_1 & y_1 \\ z_2 & x_2 & y_2 \\ z_3 & x_3 & y_3 \end{vmatrix} = z_1^2+z_2^2+z_3^2 \tag{6.5.143}$$

This determinant is positive, as at least one of the z_i is not zero, according to the third property of linear independence of the cross product.

Here are a few very important properties of practical utility of the cross product (particularly in the different sections of physics in this textbook!) that are trivial to check whether the developments with explicit components are done (we can make them on request if needed!):

P1. $\vec{x}\times(\vec{y}\times\vec{z})=(\vec{x}\circ\vec{z})\vec{y}-(\vec{x}\circ\vec{y})\vec{z}$

Remark

The latter relation is sometimes named the "Grassmann rule", or more commonly "dual vector product", or even by physicists "triple cross product", and it is important to note that without the parentheses the result is not unique!

Let us prove this identity! First the left part is equal to:

$$\begin{aligned}\vec{x}\times(\vec{y}\times\vec{z})=\vec{x}\times\left(\begin{pmatrix}y_1\\y_2\\y_3\end{pmatrix}\times\begin{pmatrix}z_1\\z_2\\z_3\end{pmatrix}\right)&=\vec{x}\times\begin{pmatrix}y_2z_3-y_3z_2\\y_3z_1-y_1z_3\\y_1z_2-y_2z_1\end{pmatrix}=\begin{pmatrix}x_1\\x_2\\x_3\end{pmatrix}\times\begin{pmatrix}y_2z_3-y_3z_2\\y_3z_1-y_1z_3\\y_1z_2-y_2z_1\end{pmatrix}\\&=\begin{pmatrix}x_2(y_1z_2-y_2z_1)-x_3(y_3z_1-y_1z_3)\\x_3(y_2z_3-y_3z_2)-x_1(y_1z_2-y_2z_1)\\x_1(y_3z_1-y_1z_3)-x_2(y_2z_3-y_3z_2)\end{pmatrix}\end{aligned}\tag{6.5.144}$$

And for the right part:

$$\begin{aligned}(\vec{x}\circ\vec{z})\vec{y}-(\vec{x}\circ\vec{y})\vec{z}&=(x_1z_1+x_2z_2+x_3z_3)\vec{y}-(x_1y_1+x_2y_2+x_3y_3)\vec{z}\\&=\begin{pmatrix}(x_1z_1+x_2z_2+x_3z_3)y_1\\(x_1z_1+x_2z_2+x_3z_3)y_2\\(x_1z_1+x_2z_2+x_3z_3)y_3\end{pmatrix}-\begin{pmatrix}(x_1y_1+x_2y_2+x_3y_3)z_1\\(x_1y_1+x_2y_2+x_3y_3)z_2\\(x_1y_1+x_2y_2+x_3y_3)z_3\end{pmatrix}\\&=\begin{pmatrix}x_1z_1y_1+x_2z_2y_1+x_3z_3y_1-x_1y_1z_1-x_2y_2z_1-x_3y_3z_1\\x_1z_1y_2+x_2z_2y_2+x_3z_3y_2-x_1y_1z_2-x_2y_2z_2-x_3y_3z_2\\x_1z_1y_3+x_2z_2y_3+x_3z_3y_3-x_1y_1z_3-x_2y_2z_3-x_3y_3z_3\end{pmatrix}\\&=\begin{pmatrix}x_2z_2y_1+x_3z_3y_1-x_2y_2z_1-x_3y_3z_1\\x_1z_1y_2+x_3z_3y_2-x_1y_1z_2-x_3y_3z_2\\x_1z_1y_3+x_2z_2y_3-x_1y_1z_3-x_2y_2z_3\end{pmatrix}\end{aligned}\tag{6.5.145}$$

and then we see that there is indeed equality!

P2. $(\vec{x}\times\vec{y})\circ(\vec{z}\times\vec{v})=(\vec{x}\circ\vec{z})(\vec{y}\circ\vec{v})-(\vec{x}\circ\vec{v})(\vec{y}\circ\vec{z})$

P3. $(\vec{x}\times\vec{y})\circ\vec{z}=-(\vec{x}\times\vec{z})\circ\vec{y}$

P4. $(\vec{x}\times\vec{y})\circ\vec{z}=\vec{x}\circ(\vec{y}\times\vec{z})$

Indeed, let:

$$\vec{x}=(x_1,x_2,x_3)\,,\quad \vec{y}=(y_1,y_2,y_3)\,,\quad \vec{z}=(z_1,z_2,z_3\tag{6.5.146}$$

First compute $\vec{y}\times\vec{z}$:

$$\vec{y}\times\vec{z}=\begin{pmatrix}y_2z_3-y_3z_2\\y_3z_1-y_1z_3\\y_1z_2-y_2z_1\end{pmatrix}\tag{6.5.147}$$

Taking the dot product with $\vec{x}$:

$$\begin{aligned}\vec{x}\circ(\vec{y}\times\vec{z})&=x_1\,(y_2z_3-y_3z_2)+x_2\,(y_3z_1-y_1z_3)+x_3\,(y_1z_2-y_2z_1)\\&=x_1y_2z_3-x_1y_3z_2+x_2y_3z_1-x_2y_1z_3+x_3y_1z_2-x_3y_2z_1\end{aligned}\tag{6.5.148}$$

Now we compute $\vec{x}\times\vec{y}$:

$$\vec{x}\times\vec{y}=\begin{pmatrix}x_2y_3-x_3y_2\\x_3y_1-x_1y_3\\x_1y_2-x_2y_1\end{pmatrix}\tag{6.5.149}$$

Taking the dot product with $\vec{z}$:

$$\begin{aligned}(\vec{x}\times\vec{y})\circ\vec{z} &= (x_2y_3-x_3y_2)\,z_1+(x_3y_1-x_1y_3)\,z_2+(x_1y_2-x_2y_1)\,z_3\\ &= x_2y_3z_1-x_3y_2z_1+x_3y_1z_2-x_1y_3z_2+x_1y_2z_3-x_2y_1z\end{aligned} \tag{6.5.150}$$

Reordering the terms of of both intermediate results above gives exactly the equality:

$$\vec{x}\circ(\vec{y}\times\vec{z})=(\vec{x}\times\vec{y})\circ\vec{z} \tag{6.5.151}$$

P5. $\|\vec{x}\times\vec{y}\|^2=(\vec{x}\circ\vec{x})^2(\vec{y}\circ\vec{y})^2-(\vec{x}\circ\vec{y})^2$

The last identity is related to the Pythagorean theorem (see section Euclidean Geometry page 2609). Indeed, we see it better by rewriting:

$$\|\vec{x}\times\vec{y}\|^2+(\vec{x}\circ\vec{y})^2=\|\vec{x}\|^2\|\vec{y}\|^2 \tag{6.5.152}$$

This can be seen from the definitions of the cross product and dot product, as:

$$\vec{x}\times\vec{y}=ab\vec{n}\sin(\theta) \tag{6.5.153}$$

$$\vec{x}\circ\vec{y}=xy\cos(\theta) \tag{6.5.154}$$

6.5.4.3 Mixed Product (triple product)

We can extend the definition of the cross product to another type of mathematical tool we name the "mixed product".

Definition (#6.5.246): We name "mixed product", also sometimes named "triple scalar product", of vectors $\vec{x},\vec{y},\vec{z}$ the double product:

$$\vec{x}\circ(\vec{y}\times\vec{z}) \tag{6.5.155}$$

often condensed under the following notation:

$$[\vec{x},\vec{y},\vec{z}] \tag{6.5.156}$$

From what we saw in the definition of the dot and cross product, mixed product can also be written:

$$\boxed{\vec{x}\circ(\vec{y}\times\vec{z})=[\vec{x},\vec{y},\vec{z}]=\|\vec{x}\|\cdot\|\vec{y}\times\vec{z}\|\cos(\alpha)=\|\vec{x}\|\cdot\|\vec{y}\|\cdot\|\vec{z}\|\sin(\theta)\cos(\alpha)} \tag{6.5.157}$$

We note that in the case where E is the Euclidean vector space $\mathbb{R}^3$, the absolute value of the mixed product symbolize the oriented volume of the parallelepiped, built on the representatives $\vec{x},\vec{y},\vec{z}$ of common origin:

$$\vec{x}\circ(\vec{y}\times\vec{z})=\underbrace{\|\vec{y}\times\vec{z}\|}_{\text{basis}}\cdot\underbrace{\|\vec{x}\|\cos(\alpha)}_{\text{height}}=V \tag{6.5.158}$$

It is quite trivial that the mixed product is an extension to the three-dimensional case of the cross product. Indeed, in the expression of the mixed product, the cross product is the base surface of the parallelepiped and the scalar product project the vectors on the resulting vector from the cross product which gives the height h of the parallelepiped.

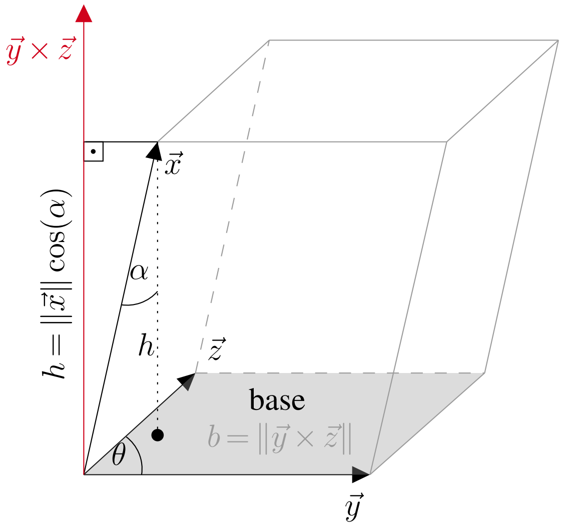

Figure 6.111: **Mixed product illustration**

If we develop:

$$[\vec{x},\vec{y},\vec{z}]=\vec{x}\begin{pmatrix}y_2z_3-y_3z_2\\y_3z_1-y_1z_3\\y_1z_2-y_2z_1\end{pmatrix}=x_1(y_2z_3-y_3z_2)+x_2(y_3z_1-y_1z_3)+x_3(y_1z_2-y_2z_1) \tag{6.5.159}$$

so triple product can also be understood as the determinant of a 3×3 matrix (thus also its inverse) having the three vectors either as its rows or its columns (see section Linear Algebra page 1967):

$$[\vec{x},\vec{y},\vec{z}]=\begin{vmatrix} x_1 & y_1 & z_1 \\ x_2 & y_2 & z_2 \\ x_3 & y_3 & z_3 \end{vmatrix} \qquad (6.5.160)$$

By the commutative properties of the scalar product, we have:

$$(\vec{x}\times\vec{y})\circ\vec{z}=\vec{z}\circ(\vec{x}\times\vec{y}) \qquad (6.5.161)$$

and the reader will check without any trouble (we can write the details on request) that by developing components we have:

$$(\vec{x}\times\vec{y})\circ\vec{z}=\vec{x}\circ(\vec{y}\times\vec{z}) \qquad (6.5.162)$$

The triple product has also the following properties - that we don't use actually anywhere in this textbook - that the reader could be able to check easily by developing just the components of each expression excepted perhaps the third one (we can detailed as always on request if needed):

P1. $[\vec{x},\vec{y},\vec{z}]=[\vec{z},\vec{x},\vec{y}]=[\vec{y},\vec{z},\vec{x}]=-[\vec{y},\vec{x},\vec{z}]=-[\vec{z},\vec{y},\vec{x}]=-[\vec{x},\vec{z},\vec{y}]$

P2. $[\alpha\vec{x}+\beta\vec{y},\vec{z},\vec{v}]=\alpha[\vec{x},\vec{z},\vec{v}]+\beta[\vec{y},\vec{z},\vec{v}]$

P3. $[\vec{x},\vec{y},\vec{z}]\neq 0$ if and only if $\vec{x},\vec{y},\vec{z}$ are independent.

P4. $(\vec{x}\times\vec{y})\times(\vec{z}\times\vec{v})=[\vec{x},\vec{y},\vec{v}]\cdot\vec{z}-[\vec{x},\vec{y},\vec{z}]\cdot\vec{v}$

The first property in named "property of cyclicity" and the second one obviously "property of linearity" of the mixed product. We don't know if the two last properties have a name...

Obviously the third property is quite easy to interpret: The mixed product is zero if any two of the vectors, $\vec{x},\vec{y}$ and $\vec{z}$ are parallel, or if $\vec{x},\vec{y}$ and $\vec{z}$ are coplanar. That is, when the given three vectors are coplanar the altitude of the parallelepiped is zero and thus the mixed product is such that $V=0$.

Remark

We will come back on the triple product during our study on tensor calculus as it gives the opportunity to get a very interesting result concerning a future application in General Relativity.

6.5.5 Vectorial Functional Space

Given $\mathcal{C}^k_{[a,b]}$ the set of real functions that can be k-times derivates (see section Differential and Integral Calculus page 1496) in the closed bounded interval $[a,b]$. We will designate the elements of this set by the letters $\vec{f},\vec{g},\ldots$.

The value of $\vec{f}$ at the point t will be obviously denoted by $\vec{f}(t)$. Say that $\vec{f}=\vec{g}$ is therefore equivalent than to say that:

$$\vec{f}=\vec{g}, \quad \forall t\in[a,b] \tag{6.5.163}$$

In a condensed way some practitioners denote this $\vec{f}(t)\equiv\vec{g}(t)$, the symbol $\equiv$ indicating obviously that the two members are equals for any t in the bounded interval $[a,b]$.

Consider the two following operations:

- $\vec{f}(t)+\vec{g}(t)$ defined by the relation $(\vec{f}+\vec{g})(t)\equiv\vec{f}(t)+\vec{g}(t)$
- $\alpha\vec{f}$ defined by the relation $(\alpha\vec{f})(t)=\alpha\vec{f}(t)$

These two operations satisfy to all conditions of the vectors of a vector space as we have already defined at the beginning of this section (associativity, commutativity, null vector, opposed vector, distributivity, neutral element) and therefore gives us the possibility to assign to $\mathcal{C}^k_{[a,b]}$ of a vector space structure! Le null vector of this space being obviously the null function (equal to zero everywhere) and the opposite of $\vec{f}$ being $-\vec{f}$.

It is interesting to notice that $\mathcal{C}^k_{[a,b]}$ as a vector space is a generalization of $\mathbb{R}^n$ to the continuous case. Indeed, we can consider any vector $\vec{v}=(a_i)$ of $\mathbb{R}^n$ in the form of a real function defined on the set $\{1,2,\ldots,n\}$: the value of this function at the point i is simply a_i.

Remark

The polynomials of order n with one unknown form as an example of functional vector space of dimension $n+1$ such that for each coefficient of the polynomial corresponds a vector component such that:

$$P(x)=a_nx^n+a_{n-1}x^{n-1}+\ldots+a_1x+a_0\mapsto\begin{pmatrix}a_n\\a_{n-1}\\\vdots\\a_1\\a_0\end{pmatrix} \tag{6.5.164}$$

The preferred application field of the abstract theory of the dot product (inner product) is formed by the functional vector spaces. We name therefore "canonical scalar product" in $\mathcal{C}_{[a,b]}(\mathbb{R}^2)$ the operation defined by the relation:

$$\vec{f}\circ\vec{g}=\int\limits_a^b\vec{f}(t)\vec{g}(t)\mathrm{d}t \tag{6.5.165}$$

This operation defines indeed a scalar product, the properties of the latter being verified (on reader request we can add the proof if necessary), and furthermore, the integral:

$$\vec{f}\circ\vec{f}=\|\vec{f}\|^2=\int\limits_a^b \vec{f}^2(t)\mathrm{d}t \tag{6.5.166}$$

is positive if the continuous function $\vec{f}$ is not identically zero.

Technically the latter relation is written when in $\mathbb{R}^2$:

$$\|f\|_{L^2}=\sqrt{\vec{f}\circ\vec{f}}=\int\limits_a^b |f|^2(t)\mathrm{d}t \tag{6.5.167}$$

We will give more precision about this norm and its associated scalar product and with example in the section of Functional Analysis.

6.5.6 Hermitian Vector Space

The purpose of what will follow is, as always in this textbook, not to give a detailed study about vector spaces in $\mathbb{C}$ but just to give the minimal knowledge and vocabulary necessary to the lecture of some theoretical models in physics and especially those presented in this textbook in the section of Wave Quantum Physics.

When the scalars that appears in the definition of vector spaces are complex numbers (in $\mathbb{C}$ as seen in the section Numbers at page 243), and not only real numbers, then we speak obviously about "complex vectorial spaces".

Remark

Rigorously in the common communication, people should always precise if we speak of real vectorial space or complex vectorial space...

Let us give some examples of famous complex vectorial spaces (as many people think they are useless):

✍**Examples:**

E1. The space vector $\mathbb{C}^n$ of column-vectors with n components ($\mathbb{C}^1$ being obviously identified to $\mathbb{C}$). We will meet, among others, such vector space in the section of Relativistic Quantum Physics.

E2. The vectorial space of univariate polynomial with coefficient in $\mathbb{C}$. We will meet such spaces in the section of Wave Quantum Physics or even Quantum Chemistry.

E3. The vectorial space of complex functions of one real or complex variables continuous or not. We will meet such vector spaces frequently in the section of Wave Mechanics and especially in the section of Electrodynamics.

The purpose here is to adapt what we have seen so far to complex vectorial space. The following example, show us that we can transpose as it the previous definitions. Indeed, let us consider the vector space $\mathbb{C}^n$. As for $\mathbb{R}^n$, we could have the tentation to define a dot product (i.e. inner product) on $\mathbb{C}^n$ by:

$$\forall \vec{x},\vec{y}\in\mathbb{C}^n, \vec{x}=\begin{pmatrix}x_1\\ \vdots\\ x_n\end{pmatrix}, \vec{y}=\begin{pmatrix}y_1\\ \vdots\\ y_n\end{pmatrix} : \quad \langle\vec{x}|\vec{y}\rangle = x_1y_1+\ldots+x_ny_n \tag{6.5.168}$$

with $x_i,y_i\in\mathbb{C}$.

Sadly, we see that this definition is not satisfactory because we could have therefore:

$$\langle\vec{x}|\vec{x}\rangle = x_1^2+\ldots+x_n^2 \tag{6.5.169}$$

and this quantity is in general not a real number in a complex vector space (take for example components complex exponentials) and violates the property of positivity of the dot product and therefore prevent us to introduce and use the concept of distance. What is obviously a big problem in our actual perception of the world.

We could therefore not define anymore a norm in $\mathbb{C}^n$ by writing:

$$\|\vec{x}\|=\sqrt{\langle\vec{x}|\vec{x}\rangle}=\sqrt{x_1^2+\ldots+x_n^2} \tag{6.5.170}$$

For $\langle\vec{x}|\vec{x}\rangle$ to be a positive real number we see that it would be better to define the scalar product like this:

$$\boxed{\forall\vec{x},\vec{y}\in\mathbb{C}^n:\quad\langle\vec{x}|\vec{y}\rangle=\vec{x}\circ\bar{\vec{y}}=x_1\bar{y}_1+\ldots+x_n\bar{y}_n} \tag{6.5.171}$$

In this case we have therefore:

$$\langle\vec{x}|\vec{x}\rangle=x_1\bar{x}_1+\ldots+x_n\bar{x}_n=|x_1|^2+\ldots+|x_n|^2 \tag{6.5.172}$$

which is well a positive real number. From there, we can once again define a norm for complex vector space $\mathbb{C}^n$ by putting:

$$\|\vec{x}\|=\sqrt{\langle\vec{x}|\vec{x}\rangle}=\sqrt{|x_1|^2+\ldots+|x_n|^2} \tag{6.5.173}$$

We will now show how to define an inner product on a complex vector space in the general case.

6.5.6.1 Hermitian Inner Product

Definition (#6.5.247): Let $\mathcal{H}$ be a complex vector space (!). We name "scalar product" or more accurately "Hermitian inner product" on $\mathcal{H}$ (that is to say: a dot product in complex space...), an application:

$$\phi:\begin{cases}\mathcal{H}\times\mathcal{H}\to\mathbb{C}\\(\vec{x},\vec{y})\quad\mapsto\langle\vec{x}|\vec{y}\rangle\end{cases} \tag{6.5.174}$$

That satisfies (they are more properties but we will focus only about what we need for practical application in this textbook and especially quantum physics):

P1. Positivity:

$$\forall\vec{x}\in\mathcal{H}:\quad\phi(\vec{x},\vec{x})=\langle\vec{x}|\vec{x}\rangle\geq 0\in\mathbb{R}^+ \tag{6.5.175}$$

P2. Nullity:

$$\forall\vec{x}\in\mathcal{H}:\quad\phi(\vec{x},\vec{x})=\langle\vec{x}|\vec{x}\rangle=0\Leftrightarrow\vec{x}=0 \tag{6.5.176}$$

P3. Hermitian symmetry:

$$\forall(\vec{x},\vec{y})\in\mathcal{H}^2:\quad\phi(\vec{x},\vec{y})=\overline{\phi(\vec{y},\vec{x})}\Leftrightarrow\langle\vec{x}|\vec{y}\rangle=\overline{\langle\vec{y}|\vec{x}\rangle} \tag{6.5.177}$$

P4. Bilinearity (bilinear form) changes a little bit too ... so that we speak now of "sesquilinearity". We speak then, in order, of left anti-linearity and of right linearity such as:

$$\forall(\vec{x},\vec{y},\vec{z})\in\mathcal{H}^3,\forall(\lambda,\mu)\in\mathbb{C}^2\begin{cases}\langle\lambda\vec{x}+\mu\vec{y}|\vec{z}\rangle=\bar{\lambda}\langle\vec{x}|\vec{z}\rangle+\bar{\mu}\langle\vec{y}|\vec{z}\rangle\\\langle\vec{x}|\lambda\vec{y}+\mu\vec{z}\rangle=\lambda\langle\vec{x}|\vec{y}\rangle+\mu\langle\vec{x}|\vec{z}\rangle\end{cases} \tag{6.5.178}$$

Remarks

R1. It seems that some mathematicians put the anti-linearity on the right. It's just a matter of agreement that does not matter and exists because of a lack of international norms in mathematics.

R2. The reader may notice easily that if the elements of the above definitions are all in the set $\mathbb{R}$ then the sesquilinearity is reduced to the bilinearity and the hermitian character to a simple symmetry. So the hermitian inner product reduces to the scalar product.

R3. We want to give for now only the minimum on the vast subject that is complex vector spaces so that the reader can read without too much trouble the beginning of the section of Wave Quantum Physics.

When we join to a complex vector space a scalar product then just as a real vector space becomes an Euclidean vector space or Prehilbertien vector space, the complex vector space becomes what we name a "Hermitian vector space" (term often used in the section of Wave Quantum Physics).

Definition (#6.5.248): Again, we say that a space $\mathcal{H}$ provided with an Hermitian product $\langle\vec{x}|\lambda\vec{y}+\mu\vec{z}\rangle$ is a "Hilbert space" if this space is complete for the metric defined above.

Thus, Hilbert spaces is a generalization of spaces including dot products and Hermitian dot product of Euclidean and Prehilbertien spaces.

6.5.6.2 Hermitian Cauchy-Schwarz inequality

Let us now consider the generalization of the Cauchy-Schwarz inequality that we have already proved only for the special case of real vectors at page 1826.

Consider $\vec{x}$ and $\vec{y}$ two complex vectors. Then for $\vec{y}\neq\vec{0}$ and for any complex number λ, we have by definition of the hermitian inner product (remember that $z\bar{z}=|z|^2$):

$$0\leq\langle\vec{x}-\lambda\vec{y},\vec{x}-\lambda\vec{y}\rangle=\langle\vec{x},\vec{x}\rangle-\lambda\langle\vec{y},\vec{x}\rangle-\bar{\lambda}\langle\vec{x},\vec{y}\rangle+|\lambda|^2\langle\vec{y},\vec{y}\rangle \tag{6.5.179}$$

Now let us take:

$$\lambda=\frac{\langle\vec{x},\vec{y}\rangle}{\langle\vec{y},\vec{y}\rangle} \tag{6.5.180}$$

Then the hermitian Cauchy-Schwarz inequality easily follows from:

$$0\leq\langle\vec{x},\vec{x}\rangle-\frac{\langle\vec{x},\vec{y}\rangle}{\langle\vec{y},\vec{y}\rangle}\langle\vec{y},\vec{x}\rangle-\frac{\langle\vec{y},\vec{x}\rangle}{\langle\vec{y},\vec{y}\rangle}\langle\vec{x},\vec{y}\rangle+\left|\frac{\langle\vec{x},\vec{y}\rangle}{\langle\vec{y},\vec{y}\rangle}\right|^2\langle\vec{y},\vec{y}\rangle \tag{6.5.181}$$

as simplified it gives:

$$0\leq\langle\vec{x},\vec{x}\rangle-\frac{|\langle\vec{x},\vec{y}\rangle|^2}{\langle\vec{y},\vec{y}\rangle} \tag{6.5.182}$$

Hence rearranged:

$$\boxed{|\langle\vec{x},\vec{y}\rangle|^2\leq\langle\vec{x},\vec{y}\rangle\langle\vec{y},\vec{y}\rangle} \tag{6.5.183}$$

Equality is when $\vec{y}=\lambda\vec{x}$ (λ complex). Then trivially:

$$|\langle\vec{x},\vec{y}\rangle|^2=|\lambda|^2\langle\vec{x},\vec{x}\rangle=\langle\vec{x},\vec{x}\rangle\langle\lambda\vec{x},\lambda\vec{x}\rangle=\langle\vec{x},\vec{x}\rangle\langle\vec{y},\vec{y}\rangle \tag{6.5.184}$$

This complex version of the Cauchy-Schwarz inequality will be useful to us to derive the complex version of the Cauchy-Schwarz inequality for integrals (see page 2388) that has an important place in Complex Analysis and therefore in Quantum Physics!

6.5.6.3 Types of Vectors Spaces

To sum it all up:

- We name "pre-Hilbert space" (real or complex) any vector space of finite dimension or not, provided with a dot (scalar) product.
- We name "Hilbert space" (real or complex) any complete prehilbertian space (as space provide with a norm).
- We name "Euclidean space" any real vector space of finite dimension with a dot (scalar) product and denoted by $\mathcal{E}^n$.
- We name Hermitian space any complex vector space of finite dimension with a dot (scalar) product and denote it by $\mathcal{H}^n$.

6.5.7 System of Coordinates

We will address here the aspect of coordinates changes of vector components not from a basis to another one (for that you need to go see the section of Linear Algebra) but from one coordinate system to another. That means that in any case we will stay in an Euclidean space. This type of transformation has strong implication in physical (and a little bit less in pure mathematics) when we want to simplify the study of physical systems whose equations become easier to handle in other coordinate systems.

Definition (#6.5.249): In mathematics, a "coordinate system" is used to match to each point of an n-dimensional space, a m-tuple of scalars.

> **Remark**
>
> In many cases, the considered scalars are real numbers, but it is possible to use complex numbers or elements of any field (see section Set Theory page 429). More generally, coordinates can come from a ring or other related algebraic structure.

Although we are in a chapter and in a section of this textbook that is supposed to be purely maths oriented..., we will allow ourselves in what follows to make a direct connection with physics relatively the terms of the speed and acceleration in different coordinate systems (sorry for the "math skills only" people...). Indeed, our teaching experience has shown us that this helps the readers (most of time students) to better understand the various abstract concepts.

6.5.7.1 Cartesian (rectangular) Coordinate System

We do not want to take too much time on this system as it is well known to everyone usually. However, let us recall that most of the time, in physics, the Cartesian systems in which we are working are in $\mathbb{R}^2$(two real spatial dimensions), or $\mathbb{R}^3$ (three real spatial dimensions) or even $\mathbb{R}^4$ or $\mathbb{C}^4$ (three spatial dimensions and one of time) when we work in relativity. The number of dimensions can be higher as for example with the Kaluza-Klein theory (five dimensions) merging General Relativity and Electromagnetism or much more with String Theory (above 20 dimensions!!!).

In $\mathbb{R}^3$ (the most common case in undergraduate physics), there are three basis vectors traditionally denoted by:

$$\vec{e}_1, \vec{e}_2, \vec{e}_3 \tag{6.5.185}$$

Or more explicitly:

$$\boxed{\vec{e}_x = \begin{pmatrix}1\\0\\0\end{pmatrix}, \vec{e}_y = \begin{pmatrix}0\\1\\0\end{pmatrix}, \vec{e}_z = \begin{pmatrix}0\\0\\1\end{pmatrix}} \tag{6.5.186}$$

In this system, the position of a point P (identifiable by a vector $\vec{x}$ for example) is defined by the three numbers named "coordinates" (more generally "components") denoted (typically in Tensor Calculus):

$$(x_1, x_2, x_3) \tag{6.5.187}$$

and in physics denoted more conventionally by:

$$(x,y,z) \tag{6.5.188}$$

where usually the component (z) represents the height (vertical), the component (x) is the width and the component (y) is the length (obviously these are completely arbitrary choice).

This point P can be spotted by a vector arbitrarily designated $\vec{r}$ in the basis $\vec{e}_i$ by the relation (using Tensor notation):

$$\vec{x}=x^i\vec{e}_i \tag{6.5.189}$$

and if the basis is canonical (orthonormal) such that:

$$(\vec{e}_1,\vec{e}_2,\vec{e}_3)=\left\{\begin{pmatrix}1\\0\\0\end{pmatrix},\begin{pmatrix}0\\1\\0\end{pmatrix},\begin{pmatrix}0\\0\\1\end{pmatrix}\right\} \tag{6.5.190}$$

we write:

$$\vec{r}=x^i\vec{e}_i=x_1\begin{pmatrix}1\\0\\0\end{pmatrix}+x_2\begin{pmatrix}0\\1\\0\end{pmatrix}+x_3\begin{pmatrix}0\\0\\1\end{pmatrix}=\begin{pmatrix}x_1\\x_2\\x_3\end{pmatrix}:=\begin{pmatrix}x\\y\\z\end{pmatrix} \tag{6.5.191}$$

In physics, if we work with coordinates, it's in the purpose to always be able to determine the location of an item as depicted in the figure below:

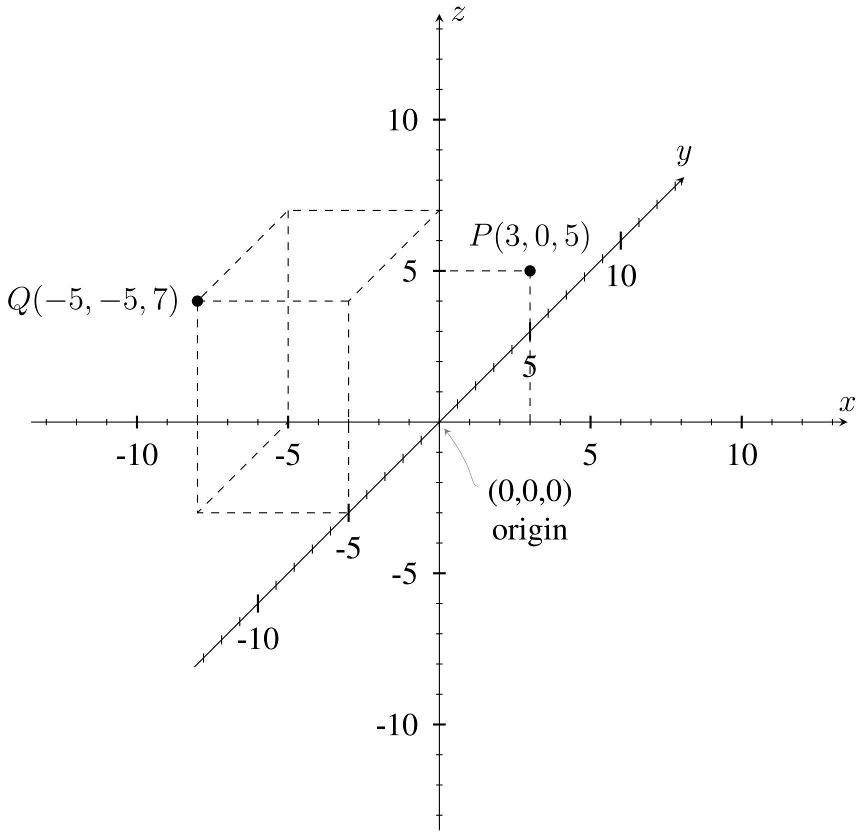

Figure 6.112: **Localisation of a point in a simple 3D coordinate system**

Or, as we shall see it more rigorously in the section of Analytical Mechanics, the physicist works with the following concepts (each element being often time-dependent):

- Position: $\vec{r}=\Big(x(t),y(t),z(t),t\Big)$
- Velocity: $\dfrac{\mathrm{d}\vec{r}}{\mathrm{d}t}=\dot{\vec{r}}=\vec{v}=\Big(\dot{x}(t),\dot{y}(t),\dot{z}(t),t\Big)$
- Acceleration: $\dfrac{\mathrm{d}\vec{v}}{\mathrm{d}t}=\dot{\vec{v}}=\vec{a}=\Big(\ddot{x}(t),\ddot{y}(t),\ddot{z}(t),t\Big)$

Now let us see how the different concepts are expressed in systems such as spherical, cylindrical and polar coordinates (remember that we remains for all of them in a flat Euclidean space!!!).

6.5.7.2 Spherical Coordinate System

The choice to start with this coordinate system is not a coincidence. It has the advantage of being a generalization of cylindrical and polar systems that we will meet thereafter and will help us easier to determine the expressions of position, velocity and acceleration[15].

We traditionally represent (in Switzerland ... and in agreement with the standard ISO 31-11) a spherical coordinate system as follows:

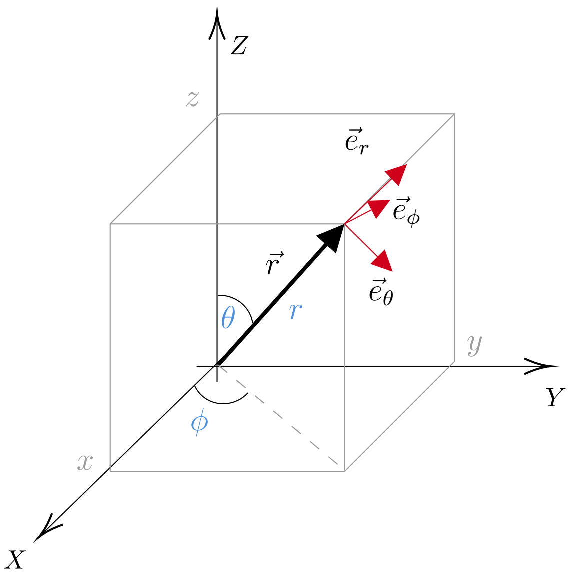

Figure 6.113: **Representation of the spherical coordinate system**

We see very clearly if we know the basic trigonometric relations and identities (see the section of the same name in the Geometry chapter) we have the transformations:

$$\begin{aligned}
&r=\sqrt{x^2+y^2+z^2}, \quad 0\leq r<+\infty\\
&\theta=\arccos\left(\frac{z}{r}\right)=\arccos\left(\frac{z}{\sqrt{x^2+y^2+z^2}}\right), \quad 0\leq\theta<\pi, r\neq 0\\
&\phi=\arccos\left(\frac{x}{\sqrt{x^2+y^2}}\right)=\arccos\left(\frac{x}{r\sin\theta}\right)=\arcsin\left(\frac{y}{r\sin\theta}\right), \quad 0\leq\phi<2\pi, r\neq 0
\end{aligned} \tag{6.5.192}$$

where the two angles θ, ϕ are respectively the colatitude ($\pi/2-\theta$ is the latitude) and longitude:

---

[15] Two commonly-used sets of "orthogonal curvilinear coordinates" are cylindrical polar coordinates and spherical polar coordinates.

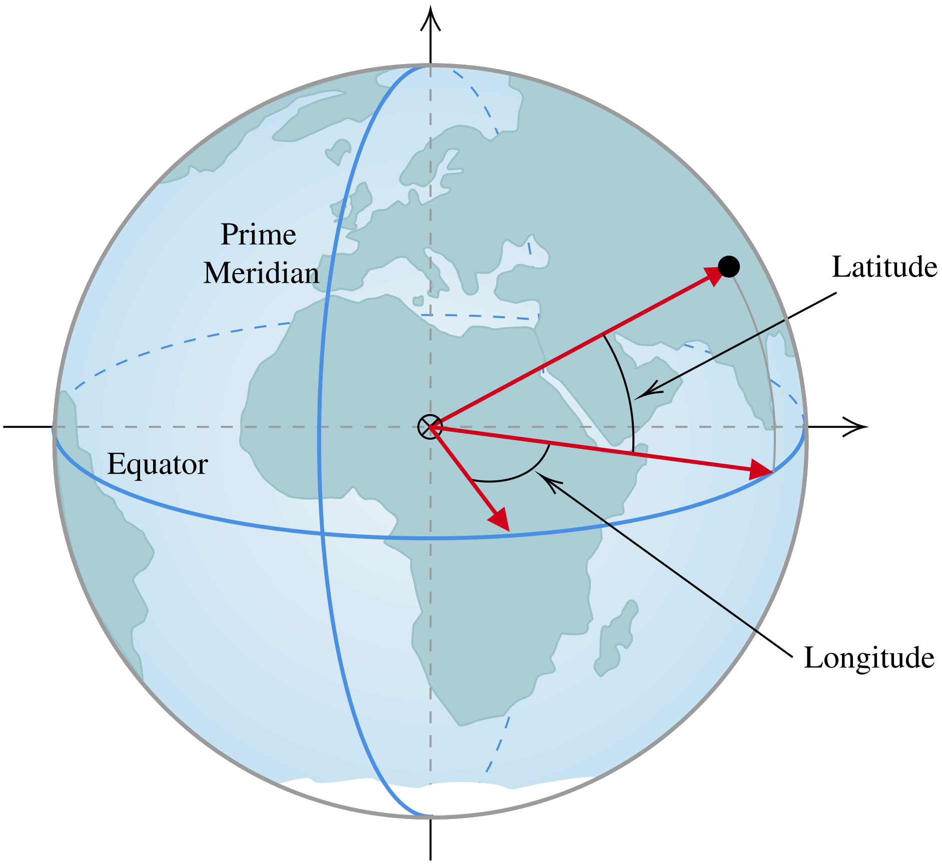

Figure 6.114: **Latitude and Longitude concepts illustrated**

We have inversely:

$$x = r\sin(\theta)\cos(\phi) \quad y = r\sin(\theta)\sin(\phi) \quad z = r\cos(\theta) \tag{6.5.193}$$

Caution! Depending on the angle convention in the prior-previous figure the reader can find different expression for x, y, z in other textbooks. A typical other convention is for example:

$$x = r\cos(\theta)\cos(\phi) \quad y = r\sin(\theta)\cos(\phi) \quad z = r\sin(\phi)$$

Now we must find the expressions that connect the vectors of the spherical basis that we choose to denote by $\vec{e}_r,\vec{e}_\theta,\vec{e}_\phi$ with the vectors of the Cartesian basis $\vec{e}_x,\vec{e}_y,\vec{e}_z$:

$$\begin{aligned}
\vec{e}_r =&\frac{\vec{r}}{r}=\frac{x\vec{e}_x+y\vec{e}_y+z\vec{e}_z}{r}=\frac{r\sin(\theta)\cos(\phi)\vec{e}_x+r\sin(\theta)\sin(\phi)\vec{e}_y+r\cos(\theta)\vec{e}_z}{r}\\
=&\sin(\theta)\cos(\phi)\vec{e}_x+\sin(\theta)\sin(\phi)\vec{e}_y+\cos(\theta)\vec{e}_z\\
\vec{e}_\phi =&\frac{\vec{e}_z\times\vec{e}_r}{\sin(\theta)}=\frac{1}{\sin(\theta)}\begin{pmatrix}0\\0\\1\end{pmatrix}\times\begin{pmatrix}\sin(\theta)\cos(\phi)\\ \sin(\theta)\sin(\phi)\\ \cos(\phi)\end{pmatrix}=\frac{1}{\sin(\theta)}\begin{pmatrix}-\sin(\theta)\sin(\phi)\\ \sin(\theta)\cos(\phi)\\ 0\end{pmatrix}\\
=&\frac{1}{\sin(\theta)}\begin{pmatrix}-\sin(\theta)\sin(\phi)\\0\\0\end{pmatrix}+\frac{1}{\sin(\theta)}\begin{pmatrix}0\\ \sin(\theta)\cos(\phi)\\0\end{pmatrix}=-\vec{e}_x\sin(\phi)+\vec{e}_y\cos(\phi)\\
\vec{e}_\theta =&\vec{e}_\phi\times\vec{e}_r=\begin{pmatrix}-\sin(\phi)\\ \cos(\phi)\\ 0\end{pmatrix}\times\begin{pmatrix}\sin(\theta)\cos(\phi)\\ \sin(\theta)\sin(\phi)\\ \cos(\theta)\end{pmatrix}=\begin{pmatrix}\cos(\phi)\cos(\theta)-0\cdot\sin(\theta)\sin(\phi)\\ 0\cdot\sin(\theta)\cos(\phi)-(-\sin(\phi))\cos(\theta)\\ -\sin(\phi)\sin(\theta)\sin(\phi)-\cos(\phi)\sin(\theta)\cos(\phi)\end{pmatrix}\\
=&\begin{pmatrix}\cos(\phi)\cos(\theta)\\ \sin(\phi)\cos(\theta)\\ -\sin(\phi)\sin(\theta)\sin(\phi)-\cos(\phi)\sin(\theta)\cos(\phi)\end{pmatrix}=\vec{e}_x\cos(\theta)\cos(\phi)+\vec{e}_y\cos(\theta)\sin(\phi)-\vec{e}_z\sin(\theta)
\end{aligned}\tag{6.5.194}$$

Let us indicate that by dividing by $\sin(\theta)$ the second basis vector $\vec{e}_\phi$, we make sure that by the properties of the norm of the cross product that:

$$\|\vec{e}_\phi\|=\|\vec{e}_z\|\cdot\|\vec{e}_r\|\sin(\phi)=1\tag{6.5.195}$$

will be well normalized to unity as expected (as we know from start that as we take a direct orthogonal coordinate system the product of norms of the basis vectors must be equal to 1)!

For later purposes, let us determine the partial differentials of each of these coordinates:

$$\begin{aligned}
&\frac{\partial\vec{e}_r}{\partial r}=\vec{0}\\
&\frac{\partial\vec{e}_r}{\partial\theta}=\vec{e}_x\cos(\theta)\cos(\phi)+\vec{e}_y\cos(\theta)\sin(\phi)-\vec{e}_z\sin(\theta)=\vec{e}_\theta\\
&\frac{\partial\vec{e}_r}{\partial\phi}=-\vec{e}_x\sin(\theta)\sin(\phi)+\vec{e}_y\sin(\theta)\cos(\phi)=(-\vec{e}_x\sin(\theta)+\vec{e}_y\cos(\phi))\sin(\theta)=\vec{e}_\phi\sin(\theta)\\
&\frac{\partial\vec{e}_\phi}{\partial r}=\vec{0}\\
&\frac{\partial\vec{e}_\phi}{\partial\theta}=\vec{0}\\
&\frac{\partial\vec{e}_\phi}{\partial\phi}=-\vec{e}_x\cos(\phi)-\vec{e}_y\sin(\phi)=-(\vec{e}_r\sin(\theta)+\vec{e}_\theta\cos(\theta))\\
&\frac{\partial\vec{e}_\theta}{\partial r}=\vec{0}\\
&\frac{\partial\vec{e}_\theta}{\partial\theta}=-\vec{e}_x\sin(\theta)\cos(\phi)-\vec{e}_y\sin(\theta)\sin(\phi)-\vec{e}_z\cos(\theta)=-\vec{e}_r\\
&\frac{\partial\vec{e}_\theta}{\partial\phi}=-\vec{e}_x\cos(\theta)\sin(\phi)+\vec{e}_y\cos(\theta)\cos(\phi)=\vec{e}_\phi\cos(\theta)
\end{aligned}\tag{6.5.196}$$

We will also use later (for the study of vector operators further below and the geodesic of the sphere in the section of Analytical Mechanics) the variation $\mathrm{d}\vec{r}$ expressed in spherical coordinates:

$$\begin{aligned}\mathrm{d}\vec{r}&=\mathrm{d}(r\vec{e}_r)=\vec{e}_r\mathrm{d}r+r\mathrm{d}\vec{e}_r=\vec{e}_r\mathrm{d}r+r\left(\frac{\partial\vec{e}_r}{\partial r}\mathrm{d}r+\frac{\partial\vec{e}_r}{\partial\theta}\mathrm{d}\theta+\frac{\partial\vec{e}_r}{\partial\phi}\mathrm{d}\phi\right)\\&=\vec{e}_r\mathrm{d}r+\vec{e}_\theta r\mathrm{d}\theta+\vec{e}_\phi r\sin(\theta)\mathrm{d}\phi\end{aligned}\qquad(6.5.197)$$

Or more explicitly:

$$\boxed{\vec{e}_r=\begin{pmatrix}\sin(\theta)\cos(\phi)\\\sin(\theta)\sin(\phi)\\\cos(\theta)\end{pmatrix},\vec{e}_\phi=\begin{pmatrix}-\sin(\phi)\\\cos(\phi)\\0\end{pmatrix},\vec{e}_\theta=\begin{pmatrix}\cos(\theta)\cos(\phi)\\\cos(\theta)\sin(\phi)\\-\sin(\theta)\end{pmatrix}}\qquad(6.5.198)$$

All this can be put in a famous matrix form as (this also applies automatically to the component of the unitary vector):

$$\begin{pmatrix}\vec{e}_r\\\vec{e}_\theta\\\vec{e}_\phi\end{pmatrix}=\begin{bmatrix}\sin(\theta)\cos(\phi)&\sin(\theta)\sin(\phi)&\cos(\theta)\\\cos(\theta)\cos(\phi)&\cos(\theta)\sin(\phi)&-\sin(\theta)\\-\sin(\phi)&\cos(\phi)&0\end{bmatrix}\begin{pmatrix}\vec{e}_x\\\vec{e}_y\\\vec{e}_z\end{pmatrix}\qquad(6.5.199)$$

To express the velocity and acceleration in spherical coordinates, we will also need the derivatives with respect to time:

$$\begin{aligned}\dot{\vec{e}}_r&=\frac{\partial\vec{e}_r}{\partial r}\dot{r}+\frac{\partial\vec{e}_r}{\partial\theta}\dot{\theta}+\frac{\partial\vec{e}_r}{\partial\phi}\dot{\phi}=\vec{e}_\theta\dot{\theta}+\vec{e}_\phi\dot{\phi}\sin(\theta)\\\dot{\vec{e}}_\theta&=\frac{\partial\vec{e}_\theta}{\partial r}\dot{r}+\frac{\partial\vec{e}_\theta}{\partial\theta}\dot{\theta}+\frac{\partial\vec{e}_\theta}{\partial\phi}\dot{\phi}=-\vec{e}_r\dot{\theta}+\vec{e}_\phi\dot{\phi}\cos(\theta)\\\dot{\vec{e}}_\phi&=\frac{\partial\vec{e}_\phi}{\partial r}\dot{r}+\frac{\partial\vec{e}_\phi}{\partial\theta}\dot{\theta}+\frac{\partial\vec{e}_\phi}{\partial\phi}\dot{\phi}=-(\vec{e}_r\sin(\dot{\theta})+\vec{e}_\theta\cos(\dot{\theta}))\dot{\phi}\end{aligned}\qquad(6.5.200)$$

So if we do now a little bit of physics, we have:

$$\begin{aligned}\vec{v}=\dot{\vec{r}}&=\begin{pmatrix}\mathrm{d}_t(r\sin(\theta)\cos(\phi))\\\mathrm{d}_t(r\sin(\theta)\sin(\phi))\\\mathrm{d}_t(r\cos(\theta))\end{pmatrix}=\begin{pmatrix}\dot{r}\sin(\theta)\cos(\phi)+r\cos(\theta)\cos(\phi)\dot{\theta}-r\sin(\theta)\sin(\phi)\dot{\phi}\\\dot{r}\sin(\theta)\sin(\phi)+r\cos(\theta)\sin(\phi)\dot{\theta}+r\sin(\theta)\cos(\phi)\dot{\phi}\\\dot{r}\cos(\theta)-r\sin(\theta)\dot{\theta}\end{pmatrix}\\&=\begin{pmatrix}\sin(\theta)\cos(\phi)\\\sin(\theta)\sin(\phi)\\\cos(\theta)\end{pmatrix}\dot{r}+\begin{pmatrix}r\cos(\theta)\cos(\phi)\\r\cos(\theta)\sin(\phi)\\-r\sin(\theta)\end{pmatrix}\dot{\theta}+\begin{pmatrix}-r\sin(\theta)\sin(\phi)\\r\sin(\theta)\cos(\phi)\\0\end{pmatrix}\dot{\phi}\\&=\vec{e}_r\dot{r}+r\begin{pmatrix}\cos(\theta)\cos(\phi)\\\cos(\theta)\sin(\phi)\\-\sin(\theta)\end{pmatrix}\dot{\theta}+r\sin(\theta)\begin{pmatrix}-\sin(\phi)\\\cos(\phi)\\0\end{pmatrix}\dot{\phi}=\vec{e}_r\dot{r}+r\vec{e}_\theta\dot{\theta}+r\sin(\theta)\vec{e}_\phi\dot{\phi}\end{aligned}\qquad(6.5.201)$$

This brings us to (we will need this relation mainly in the section of Astrophysics):

$$\boxed{\vec{v}=\dot{r}\vec{e}_r+\vec{e}_\theta r\dot{\theta}+\vec{e}_\phi r\dot{\phi}\sin(\theta)}\qquad(6.5.202)$$

It is interesting to notice that we get the same result through the following method that may be less intuitive:

$$\vec{v}=\dot{\vec{r}}=\dot{\vec{e}}r+\dot{r}\vec{e}_r\qquad(6.5.203)$$

and substituting the derivative obtained above:

$$\dot{\vec{e}}_r=\frac{\partial\vec{e}_r}{\partial r}\dot{r}+\frac{\partial\vec{e}_r}{\partial\theta}\dot{\theta}+\frac{\partial\vec{e}_r}{\partial\phi}\dot{\phi}=\vec{e}_\theta\dot{\phi}+\vec{e}_\phi\dot{\phi}\sin(\theta) \tag{6.5.204}$$

Concerning the acceleration we get:

$$\begin{aligned}
\vec{a}=\dot{\vec{v}}=\begin{pmatrix}\ddot{x}\\ \ddot{y}\\ \ddot{z}\end{pmatrix}&=\begin{pmatrix}\mathrm{d}_t\left(\dot{r}\sin(\theta)\cos(\phi)+r\cos(\theta)\cos(\phi)\dot{\theta}-r\sin(\theta)\sin(\phi)\dot{\phi}\right)\\ \mathrm{d}_t\left(\dot{r}sin(\theta)\sin(\phi)+r\cos(\theta)\sin(\phi)\dot{\theta}+r\sin(\theta)\cos(\phi)\dot{\theta}\right)\\ \mathrm{d}_t\left(\dot{r}\cos(\theta)-r\sin(\theta)\dot{\theta}\right)\end{pmatrix}\\
&=\begin{pmatrix}\left(\ddot{r}\sin(\theta)\cos(\phi)+\dot{r}\cos(\theta)\cos(\phi)\dot{\theta}-\dot{r}\sin(\theta)\sin(\phi)\dot{\phi}\right)+\\ \left(\dot{r}\cos(\theta)\cos(\phi)\dot{\theta}-r\sin(\theta)\cos(\phi)\dot{\theta}\dot{\theta}+r\cos(\theta)\cos(\phi)\ddot{\theta}-r\cos(\theta)\sin(\phi)\dot{\theta}\dot{\phi}\right)\\ -\left(\dot{r}\sin(\theta)\sin(\phi)\dot{\phi}+r\cos(\theta)\sin(\phi)\dot{\phi}\dot{\theta}+r\sin(\theta)\cos(\phi)\dot{\phi}\dot{\phi}+r\sin(\theta)\sin(\phi)\ddot{\phi}\right)\\ \\ \left(\ddot{r}\sin(\theta)\sin(\phi)+\dot{r}\cos(\theta)\sin(\phi)\dot{\theta}+\dot{r}\sin(\theta)\sin(\phi)\dot{\phi}\right)\\ +\left(\dot{r}\cos(\theta)\sin(\phi)\dot{\theta}-r\sin(\theta)\sin(\phi)\dot{\theta}\dot{\theta}+r\cos(\theta)\sin(\phi)\ddot{\theta}+r\cos(\theta)\cos(\phi)\dot{\theta}\dot{\phi}\right)\\ +\left(\dot{r}\sin(\theta)\cos(\phi)\dot{\phi}+r\cos(\theta)\cos(\phi)\dot{\phi}\dot{\theta}-r\sin(\theta)\sin(\phi)\dot{\phi}\dot{\phi}+r\sin(\theta)\sin(\phi)\ddot{\phi}\right)\\ \\ \left(\ddot{r}\cos(\theta)-\dot{r}\sin(\theta)\dot{\theta}\right)-\left(\dot{r}\sin(\theta)\dot{\theta}+r\cos(\theta)\dot{\theta}\dot{\theta}+r\sin(\theta)\dot{\theta}\right)\end{pmatrix}\\
&=\left(\ddot{r}-r\dot{\theta}\right)\begin{pmatrix}\sin(\theta)\cos(\phi)\\ \sin(\theta)\sin(\phi)\\ \cos(\theta)\end{pmatrix}+\left(2\dot{r}\dot{\theta}+r\ddot{\theta}\right)\begin{pmatrix}\cos(\theta)\cos(\phi)\\ \cos(\theta)\sin(\phi)\\ -\sin(\theta)\end{pmatrix}\\
&+\left(2\dot{r}\sin(\theta)\dot{\phi}+2r\cos(\theta)\dot{\theta}\dot{\phi}+r\sin(\theta)\ddot{\phi}\right)\begin{pmatrix}-\sin(\phi)\\ \cos(\phi)\\ 0\end{pmatrix}+r\sin(\theta)\dot{\phi}^2\begin{pmatrix}-\cos(\phi)\\ \sin(\phi)\\ 0\end{pmatrix}\\
&=\left(\ddot{r}-r\dot{\theta}\right)\vec{e}_r+\left(2\dot{r}\dot{\theta}+r\ddot{\theta}\right)\vec{e}_\theta+\left(2\dot{r}\sin(\theta)\dot{\phi}+2r\cos(\theta)\dot{\theta}\dot{\phi}+r\sin(\theta)\ddot{\phi}\right)\vec{e}_\phi-r\sin(\theta)\dot{\phi}^2\begin{pmatrix}\cos(\phi)\\ \sin(\phi)\\ 0\end{pmatrix}
\end{aligned} \tag{6.5.205}$$

But we have:

$$\begin{aligned}
\begin{pmatrix}\cos(\phi)\\ \sin(\phi)\\ 0\end{pmatrix}&=\begin{pmatrix}\cos(\phi)\sin^2(\theta)+\cos(\phi)\cos^2(\theta)\\ \sin(\phi)\sin^2(\theta)+\sin(\phi)\cos^2(\theta)\\ 0\end{pmatrix}\\
&=\sin(\theta)\begin{pmatrix}\sin(\theta)\cos(\phi)\\ \sin(\theta)\sin(\phi)\\ \cos(\theta)\end{pmatrix}+\cos(\theta)\begin{pmatrix}\cos(\theta)\cos(\phi)\\ \cos(\theta)\sin(\phi)\\ -\sin(\theta)\end{pmatrix}\\
&=\sin(\theta)\vec{e}_r+\cos(\theta)\vec{e}_\theta
\end{aligned} \tag{6.5.206}$$

Therefore it comes:

$$\begin{aligned}
\vec{a}=&\left(\ddot{r}-r\dot{\theta}^2\right)\vec{e}_r+\left(2\dot{r}\dot{\theta}+r\ddot{\theta}\right)\vec{e}_\theta+\left(2\dot{r}\sin(\theta)\dot{\phi}+2r\cos(\theta)\dot{\theta}\dot{\phi}+r\sin(\theta)\ddot{\phi}\right)\vec{e}_\phi\\
&-r\sin(\theta)\dot{\phi}^2\left(\sin(\theta)\vec{e}_r+\cos(\theta)\vec{e}_\theta\right)
\end{aligned} \tag{6.5.207}$$

Thus finally:

$$\boxed{\begin{aligned}\vec{a} =&\vec{e}_r(\ddot{r}-r\dot{\theta}^2-r\dot{\phi}^2\sin^2(\theta))+\vec{e}_\theta(r\ddot{\theta}+2\dot{r}\dot{\theta}-r\dot{\phi}^2\sin(\theta)\cos(\theta))\\ &+\vec{e}_\phi(r\ddot{\phi}\sin(\theta)+2r\dot{\theta}\dot{\phi}\cos(\theta)+2\dot{r}\dot{\phi}\sin(\theta))\end{aligned}} \tag{6.5.208}$$

6.5.7.2.1 Orthodromic distance

We will now see a powerful and simple application of vector calculus (especially of the dot product with spherical coordinates!). The reader will see later in the section of Analytical Mechanics that the geodesic of the sphere is the equation of the great circles (circles on the sphere whose centers coincide with the center of the sphere).

But without knowing this result, and even without needing it, we want to calculate the "great-circle distance" or "orthodromic distance" that is the shortest distance between two points on the surface of a sphere (to not confuse with the "loxodromic distance" that is the straight line that we draw on a Mercator Earth's projection plane! - a line of constant compass bearing - not the shortest path on a sphere), measured along the surface of the sphere:

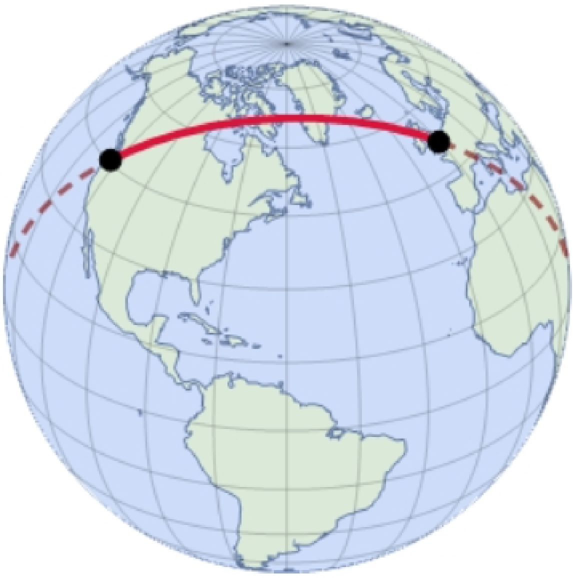

Figure 6.115: Orthodromic distance (great-circle distance)

Through any two points on a sphere that are not directly opposite each other, there is a unique great circle. The two points separate the great circle into two arcs. The length of the shorter arc is the great-circle distance between the points. A great circle endowed with such a distance is named a "Riemannian circle" in Riemannian geometry.

Let us consider two points on the surface of a sphere P_1 and P_2 and their respective latitude and longitude such that they are defined by:

$$P_1=(\text{latitude},\text{longitude})=(\theta_1,\phi_1) \qquad P_2=(\text{latitude},\text{longitude})=(\theta_2,\phi_2) \tag{6.5.209}$$

Therefore in spherical coordinates:

$$\begin{aligned} P_1 &= (R\sin(\theta_1)\cos(\phi_1), R\sin(\theta_1)\sin(\phi_1), R\cos(\theta_1)) \\ P_2 &= (R\sin(\theta_2)\cos(\phi_2), R\sin(\theta_2)\sin(\phi_2), R\cos(\theta_2)) \end{aligned} \quad (6.5.210)$$

Hence taking the vectors having for origin the center of the sphere:

$$\begin{aligned} \vec{P}_1 &= R\sin(\theta_1)\cos(\phi_1)\vec{i} + R\sin(\theta_1)\sin(\phi_1)\vec{j} + R\cos(\theta_1)\vec{k} \\ \vec{P}_2 &= R\sin(\theta_2)\cos(\phi_2)\vec{i} + R\sin(\theta_2)\sin(\phi_2)\vec{j} + R\cos(\theta_2)\vec{k} \end{aligned} \quad (6.5.211)$$

The Earth is nearly spherical, so great-circle distance formulas give the distance between points on the surface of the Earth (as the crow flies) correct to within 0.5% or so.

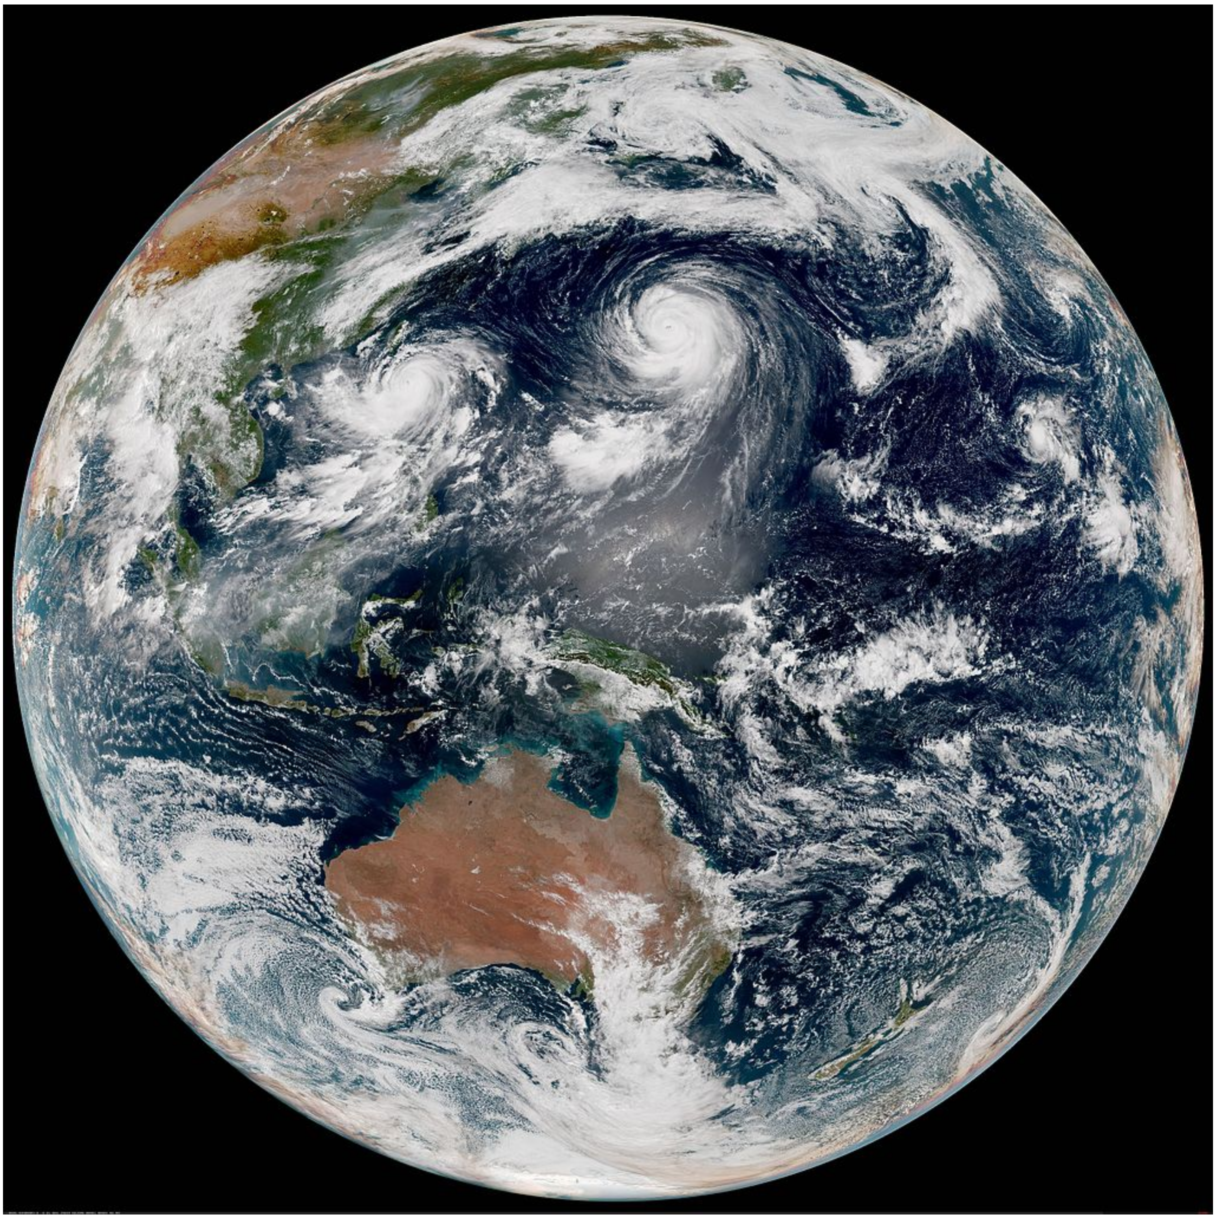

Figure 6.116: Japanese Himawari 8 satellite's Earth, Rayleigh-corrected, true-color image captured from the AHI sensor (year 12015 according to holocene calendar)

We do now the dot product and use trigonometric identity:

$$\begin{aligned}\vec{P}_1 \circ \vec{P}_2 &= RR\left(\sin(\theta_1)\sin(\theta_2)\cos(\phi_1)\cos(\phi_2)+\sin(\theta_1)\sin(\theta_2)\sin(\phi_1)\sin(\phi_2)+\cos(\theta_1)\cos(\theta_2)\right)\\ &= R^2\left[\sin(\theta_1)\sin(\theta_2)\left(\cos(\phi_1)\cos(\phi_2)+\sin(\theta_1)\sin(\theta_2)\right)+\cos(\theta_1)\cos(\theta_2)\right]\\ &= R^2\left[\sin(\theta_1)\sin(\theta_2)\cos(\phi_2-\phi_1)+\cos(\theta_1)\cos(\theta_2)\right]\end{aligned} \tag{6.5.212}$$

In function of the angle that we will denote α we know that the dot product has also for expression:

$$\vec{P}_1 \circ \vec{P}_2 = R^2\cos(\alpha) \tag{6.5.213}$$

By identification of that latter relation with prior-previous one we get:

$$R^2\cos(\alpha) = R^2\left[\sin(\theta_1)\sin(\theta_2)\cos(\phi_2-\phi_1)+\cos(\theta_1)\cos(\theta_2)\right] \tag{6.5.214}$$

Hence after simplification:

$$\alpha = \arccos\left(\sin(\theta_1)\sin(\theta_2)\cos(\phi_2-\phi_1)+\cos(\theta_1)\cos(\theta_2)\right) \tag{6.5.215}$$

As we know that the circumference of circle is given by $P=2\pi R$ then the arc lengths by unit of angle is given by:

$$l = R\alpha \tag{6.5.216}$$

So finally we get the great circle distance relation:

$$\boxed{l = R\arccos\left(\sin(\theta_1)\sin(\theta_2)\cos(\phi_2-\phi_1)+\cos(\theta_1)\cos(\theta_2)\right)} \tag{6.5.217}$$

That can be found in the literature into different forms because of the spherical angles convention as already mentioned during our introduction of spherical coordinates at page 1849.

The relation above works well (we will do a numerical application later!) and we can see many people copying it in spreadsheet softwares or business intelligence softwares to run some kind of geostatistics analytics. However you may encounter another relation in practice (again used in various spreadsheet softwares) that is quite old and gives the same result. The reason both are used is because people copy/paste the first relationship the found thanks to Internet search engines without investigating if there are multiple ways to calculate a same thing. The relation we will see now exist because at a time where computer didn't exist it was easier to be used thanks to tables written by some humans...

Remark

For reasons that are a mixture of valid science and historical accident, there is no one agreed 'latitude and longitude' coordinate system. There are many different meridians of zero longitude (prime meridians) and many different circles of zero latitude (equators), although the former generally pass somewhere near Greenwich, and the latter is always somewhere near the rotational equator.

The result is that different systems of latitude and longitude in common use today can disagree on the coordinates of a point by more than 200 meters! For any application where an error of this size would be significant, it's important to know which system is being used and exactly how it is defined.

The figure below shows three points that all have the same latitude and longitude (approximately N50 56 18, W001 28 11), in three different coordinate systems (OSGB36, WGS84 and ED50). Each one of these coordinate systems is widely used and fit for its purpose, and none of them is wrong. The differences between them are just a result of the fact that any system of 'absolute coordinates' is always arbitrary. Standard conventions ensure only that different coordinate systems tend to agree to within half a kilometer or so, but there is no fundamental reason why they should agree at all.

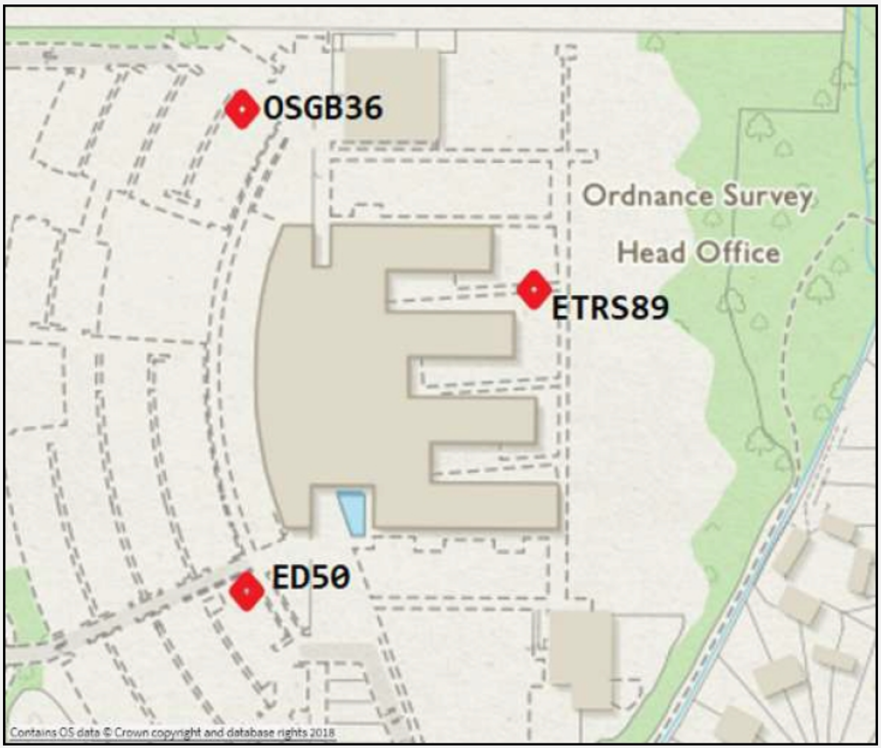

Figure 6.117: **Three points with the same latitude and longitude in three different coordinate systems (the map extract is approximately 300m wide)**

Furthermore, the true coordinates of a ground point do change due to the continuous deforming motions of the Earth. The relative motion of two continents can be 10 centimeters a year, which is significant for mapping because it is constant year after year – after 50 years a region of the earth may have moved by 5 meters relative to a neighbouring continent.

6.5.7.2.2 Haversine distance

The term "haversine" apparently comes from "half versed sine". To derive the haversine distance we assume that we are given two points P_1 and P_2 determined by their respective latitude-longitude pairs: $P_1(\theta_1,\phi_1), P_2(\theta_2,\phi_2)$. In cartesian coordinates we have $P_1=P_1(x_1,y_1,z_1)$ and $P_2=P_2(x_2,y_2,z_2)$, where x,y and z are determined by the spherical coordinates through the other typical convention:

$$\begin{aligned}x&=R\cos(\theta)\cos(\phi)\\y&=R\cos(\theta)\sin(\phi)\\z&=R\sin(\theta)\end{aligned}\tag{6.5.218}$$

The euclidean distance d between P_1 and P_2 is given by the three-dimensional Pythagorean theorem:

$$d^2=(x_1-x_2)^2+(y_1-y_2)^2+(z_1-z_2)^2\tag{6.5.219}$$

The bulk of our work will be in computing this distance in terms of the spherical coordinates. Converting the cartesian coordinates to spherical coordinates, we get:

$$\begin{aligned}d^2&=(R\cos(\theta_1)\cos(\phi_1)-R\cos(\theta_2)\cos(\phi_2)^2+(R\cos(\theta_1)\sin(\phi_1)-R\cos(\theta_2)\sin(\phi_2))^2\\&+(R\sin(\theta_1)-R\sin(\theta_2))^2\\&=R^2\left[\cos^2(\theta_1)\cos^2(\phi_1)-2\cos(\theta_1)\cos(\phi_1)\cos(\theta_2)\cos(\phi_2)+\cos^2(\theta_2)\cos^2(\phi_2)\right.\\&+\cos^2(\theta_1)\sin^2(\phi_1)-2\cos(\theta_1)\sin(\phi_1)\cos(\theta_2)\sin(\phi_2)+\cos^2(\theta_2)\sin^2(\phi_2)\\&\left.+\sin^2(\theta_1)-2\sin(\theta_1)\sin(\theta_2)+\sin^2(\theta_2)\right]\\&=R^2\left(2-2\cos(\theta_1)\cos(\theta_2)\cos(\phi_1-\phi_2)-2\sin(\theta_1)\sin(\theta_2)\right)\end{aligned}\tag{6.5.220}$$

Hence:

$$\frac{d^2}{R^2}=2-2\cos(\theta_1)\cos(\theta_2)\cos(\phi_1-\phi_2)-2\sin(\theta_1)\sin(\theta_2)\tag{6.5.221}$$

The distance is for historical (computational) reasons often represented in therms of the so-named "haversine function" defined by:

$$\text{haversine}(A)=\sin^2\left(\frac{A}{2}\right)=\frac{1-\cos(A)}{2}\tag{6.5.222}$$

This says that $\cos(A)=1-2\text{haversine}(A)$.

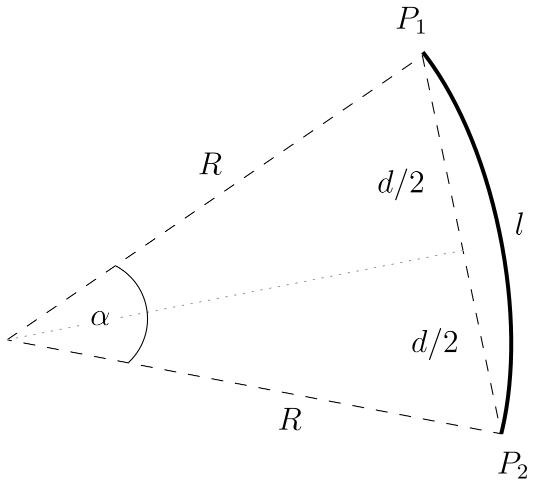
Returning to the relation for d^2/R^2 above, we continue, feeding in the new notation and using trigonometric identities:

$$\begin{aligned}\frac{d^2}{R^2}&=2-2\cos(\theta_1)\cos(\theta_2)\cos(\phi_1-\phi_2)-2\sin(\theta_1)\sin(\theta_2)\\&=2-2\cos(\theta_1)\cos(\theta_2)\left(1-2\text{haversine}(\phi_1-\phi_2)\right)-2\sin(\theta_1)\sin(\theta_2)\\&=2-2\cos(\theta_1-\theta_2)+4\cos(\theta_1)\cos(\theta_2)\text{haversine}(\phi_1-\phi_2)\\&=4\text{haversine}(\theta_1-\theta_2)+4\cos(\theta_1)\cos(\theta_2)\text{haversine}(\phi_1-\phi_2)\end{aligned}\tag{6.5.223}$$

Therefore:

$$\left(\frac{d}{2R}\right)^2=\text{haversine}(\theta_1-\theta_2)+\cos(\theta_1)\cos(\theta_2)\text{haversine}(\phi_1-\phi_2) \tag{6.5.224}$$

Now, based on the figure below:



we have:

$$\sin\left(\frac{\alpha}{2}\right)=\frac{d}{2R}\Leftrightarrow\sin^2\left(\frac{\alpha}{2}\right)=\text{haversine}(\alpha)=\left(\frac{d}{2R}\right)^2 \tag{6.5.225}$$

Therefore:

$$\text{haversine}(\alpha)=\text{haversine}(\theta_1-\theta_2)+\cos(\theta_1)\cos(\theta_2)\text{haversine}(\phi_1-\phi_2) \tag{6.5.226}$$

But remember that we are looking for l in the above figure. So as $l=R\alpha$, and therefore $\alpha=l/R$, we have:

$$\text{haversine}\left(\frac{l}{R}\right)=\text{haversine}(\theta_1-\theta_2)+\cos(\theta_1)\cos(\theta_2)\text{haversine}(\phi_1-\phi_2) \tag{6.5.227}$$

Remark

On Wikipedia, the latter relation is denoted:

$$\text{hav}\left(\frac{d}{r}\right)=\text{hav}(\varphi_2-\varphi_1)+\cos(\varphi_1)\cos(\varphi_2)\,\text{hav}(\lambda_2-\lambda_1)$$

Explicitly:

$$\sin^2\left(\frac{l}{2R}\right)=\text{haversine}(\theta_1-\theta_2)+\cos(\theta_1)\cos(\theta_2)\text{haversine}(\phi_1-\phi_2) \tag{6.5.228}$$

Therefore:

$$l=2R\arcsin\left(\sqrt{\text{haversine}(\theta_1-\theta_2)+\cos(\theta_1)\cos(\theta_2)\text{haversine}(\phi_1-\phi_2)}\right) \tag{6.5.229}$$

Or even more explicitly we have then the "haversine distance":

$$\boxed{l = 2R\arcsin\left(\sqrt{\sin^2\left(\frac{\theta_1-\theta_2}{2}\right)+\cos(\theta_1)\cos(\theta_2)\sin^2\left(\frac{\phi_1-\phi_2}{2}\right)}\right)} \qquad (6.5.230)$$

Working out the great circle distance between two points is so important in navigation that people in the old days produced tables giving the values of the haversine function and also of the inverse of the haversine function. This made seafarers' lives a lot easier. Working out the distance l only involved looking up two cosine values and two haversine values, adding and multiplying them in the correct way, looking up the inverse of the haversine function and multiplying by R— done!

The reason why the haversine function has come out of fashion is that with the help of calculators and computers it's easy enough to work previous calculation methods. That's why you don't find a haversine button on your average calculator.

✍**Example:**

Let us compare the result of the two relations established earlier above! That is:

$$l = 2R\arcsin\left(\sqrt{\sin^2\left(\frac{\theta_1-\theta_2}{2}\right)+\cos(\theta_1)\cos(\theta_2)\sin^2\left(\frac{\phi_1-\phi_2}{2}\right)}\right)$$

and:

$$l = R\arccos\left(\sin(\theta_1)\sin(\theta_2)\cos(\phi_2-\phi_1)+\cos(\theta_1)\cos(\theta_2)\right)$$

Let's give it a go. Liverpool has latitude 53.4° and longitude -3°, and New York has latitude 40.71° and longitude -74°. These are measured in degrees. Converting them into radians (multiplying by $\pi/180$) gives $\theta_\mathrm{L}=0.932^\circ$ and $\phi_\mathrm{L}=-0.052^\circ$ for Liverpool, and $\theta_\mathrm{NY}=0.71^\circ$ and $\phi_\mathrm{NY}=-1.291^\circ$ for New York (rounded to three decimal places).

Plugging these into the haversine relation, with the radius of the Earth $R=6371$, gives:

$$l = 2\cdot 6371\cdot\arcsin\left(\sqrt{\sin^2\left(\frac{0.932-(-0.052)}{2}\right)+\cos(0.932)\cos(0.71)\sin^2\left(\frac{(-0.052)-(-1.291)}{2}\right)}\right)\cong 5323\,[\mathrm{km}]$$

and with the second method we get the same result (remember we establised it using another convention for the definition of spherical coordinates that's why we have to take the complementary angle):

$$l = R\arccos\left(\sin(\pi/2-0.932)\sin(\pi/2-0.71)\cos((-1.291)-(-0.052))+\cos(\theta_1)\cos(\theta_2)\right)\cong 5323\,[\mathrm{km}]$$

6.5.7.3 Cylindrical Coordinate System

The cylindrical coordinate system (very useful in the study of helical motion systems) is quite similar to spherical coordinates as it can be seen as a slice of the sphere.

Given the figure:

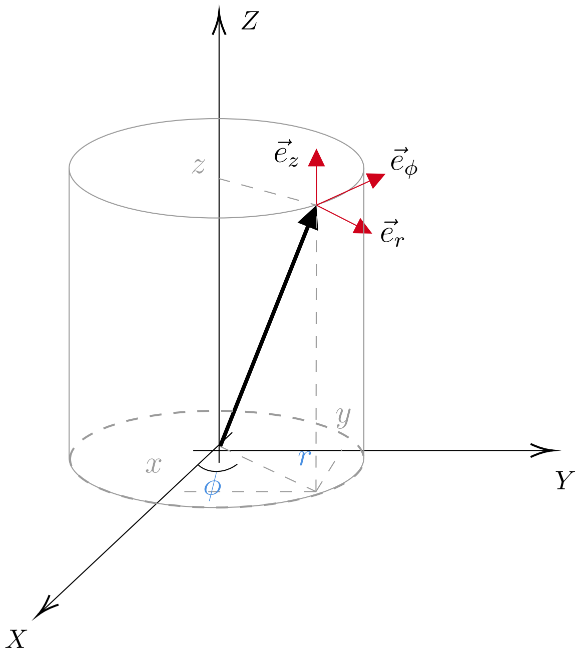


Figure 6.118: **Representation of the cylindrical coordinate system**

Warning!!! The vector $\vec{r}$ is unlike the previous spherical case defined only in the XY plane or a plane which is parallel to it!

It comes easily in cylindrical coordinates for $r>0$:

$$r=\sqrt{x^2+y^2} \quad \phi=\arccos\left(\frac{x}{r}\right) \quad \text{or} \quad \phi=\arcsin\left(\frac{y}{r}\right) \quad \text{or} \quad \phi=\arctan\left(\frac{x}{y}\right) \tag{6.5.231}$$

and vice versa:

$$x=r\cos(\phi) \quad y=r\sin(\phi) \quad z=z \tag{6.5.232}$$

Now we must find the expressions that connect the vectors of the cylindrical base that we choose to denote by $\vec{e}_r, \vec{e}_\phi, \vec{e}_z$ (instead of $\vec{r}, \vec{\phi}, \vec{z}$ as it is done traditionally) with the vectors of the Cartesian base $\vec{e}_x, \vec{e}_y, \vec{e}_z$. We have identically to what we did for the spherical coordinates:

$$\begin{aligned}
\vec{e}_r &= \frac{\vec{r}}{r}=\frac{x\vec{e}_x+y\vec{e}_y}{r}=\vec{e}_x\cos(\phi)+\vec{e}_y\sin(\phi)\\
\vec{e}_\phi &= \frac{\vec{e}_z\times\vec{e}_r}{\sin(\phi)}=-\vec{e}_x\sin(\phi)+\vec{e}_y\cos(\phi)\\
\vec{e}_z &= \vec{e}_z
\end{aligned} \tag{6.5.233}$$

Or more explicitly:

$$\boxed{\vec{e}_r=\begin{pmatrix}\cos(\phi)\\ \sin(\phi)\\ 0\end{pmatrix},\vec{e}_\phi=\begin{pmatrix}-\sin(\phi)\\ \cos(\phi)\\ 0\end{pmatrix},\vec{e}_z=\begin{pmatrix}0\\ 0\\ 1\end{pmatrix}}\tag{6.5.234}$$

All this can be put in a famous matrix form as (this also applies automatically to the component of the unitary vector):

$$\begin{pmatrix}\vec{e}_r\\ \vec{e}_\phi\\ \vec{e}_z\end{pmatrix}=\begin{bmatrix}\cos(\phi) & \sin(\phi) & 0\\ -\sin(\phi) & \cos(\phi) & 0\\ 0 & 0 & 1\end{bmatrix}\begin{pmatrix}\vec{e}_x\\ \vec{e}_y\\ \vec{e}_z\end{pmatrix}\tag{6.5.235}$$

Let us indicate that by dividing by $\sin(\phi)$ the second vector base $\vec{e}_\phi$, we ensure us that by the properties of the norm of the cross product we have:

$$\|\vec{e}_\phi\|=\|\vec{e}_z\|\cdot\|\vec{e}_r\|\sin(\phi)=1\tag{6.5.236}$$

will be well normalized to unity as expected (as we know from start that as we take a direct orthogonal coordinate system the product of norms of the basis vectors must be equal to 1)!! In the case of cylindrical coordinates the angle being anyway right, we would not be obliged to indicate this division, but we have made this choice for consistency with previous developments...

Remark

It is important to notice that the cross product of two basis vectors always gives the third perpendicular basis vector (like the Cartesian and spherical coordinates so!).

For future needs, let us determine the partial differential of each of these coordinates:

$$\begin{gathered}\frac{\partial\vec{e}_r}{\partial r}=0\quad;\quad\frac{\partial\vec{e}_r}{\partial\phi}=-\vec{e}_x\sin(\phi)+\vec{e}_y\cos(\phi)=\vec{e}_\phi\quad;\quad\frac{\partial\vec{e}_r}{\partial z}=0\\ \frac{\partial\vec{e}_\phi}{\partial r}=0\quad;\quad\frac{\partial\vec{e}_\phi}{\partial\phi}=-\vec{e}_x\cos(\phi)-\vec{e}_y\sin(\phi)=-\vec{e}_r\quad;\quad\frac{\partial\vec{e}_\phi}{\partial z}=0\\ \frac{\partial\vec{e}_z}{\partial r}=0\quad;\quad\frac{\partial\vec{e}_z}{\partial\phi}=0\quad;\quad\frac{\partial\vec{e}_z}{\partial z}=0\end{gathered}\tag{6.5.237}$$

We will also use later (for the study of vector operators) the variation $\mathrm{d}\vec{r}$ expressed in cylindrical coordinates:

$$\mathrm{d}\vec{r}=\mathrm{d}(r\vec{e}_r)=\vec{e}_r\mathrm{d}r+r\mathrm{d}\vec{e}_r=\vec{e}_r\mathrm{d}r+r\left(\frac{\partial\vec{e}_r}{\partial r}\mathrm{d}r+\frac{\partial\vec{e}_r}{\partial\phi}\mathrm{d}\phi+\frac{\partial\vec{e}_r}{\partial z}\mathrm{d}z\right)=\vec{e}_r\mathrm{d}r+r\vec{e}_\phi\mathrm{d}\phi\tag{6.5.238}$$

To express the speed and acceleration in cylindrical coordinates, we will also need the derivatives with respect to time:

$$\begin{aligned}\dot{\vec{e}}_r&=\frac{\partial\vec{e}_r}{\partial r}\dot{r}+\frac{\partial\vec{e}_r}{\partial\phi}\dot{\phi}+\frac{\partial\vec{e}_r}{\partial z}\dot{z}=\vec{e}_\phi\dot{\phi}\\ \dot{\vec{e}}_\phi&=\frac{\partial\vec{e}_\phi}{\partial r}\dot{r}+\frac{\partial\vec{e}_\phi}{\partial\phi}\dot{\phi}+\frac{\partial\vec{e}_r}{\partial z}\dot{z}=-\vec{e}_r\dot{\phi}\\ \dot{\vec{e}}_z&=\frac{\partial\vec{e}_z}{\partial r}\dot{r}+\frac{\partial\vec{e}_z}{\partial\phi}\dot{\phi}+\frac{\partial\vec{e}_z}{\partial z}\dot{z}=\vec{0}\end{aligned}\tag{6.5.239}$$

So if we now do a little bit physics, we get (let us recall that the z component is independent of other cylindrical components):

$$\vec{v}=\dot{\vec{r}}+\dot{\vec{z}}=\dot{\vec{e}}_r r+\dot{r}\vec{e}_r+\vec{e}_z\dot{z}+\dot{\vec{e}}_z z \tag{6.5.240}$$

which brings us to:

$$\boxed{\vec{v}=\dot{r}\vec{e}_r+\vec{e}_\phi r\dot{\phi}+\vec{e}_z\dot{z}} \tag{6.5.241}$$

For acceleration we get (exactly the same approach as for the expression of the speed):

$$\boxed{\vec{a}=\vec{e}_r\left(\ddot{r}-r\dot{\phi}^2\right)+\vec{e}_\phi\left(r\ddot{\phi}+2\dot{r}\dot{\phi}\right)+\vec{e}_z\ddot{z}} \tag{6.5.242}$$

6.5.7.4 Polar Coordinate System

The polar coordinate system is very similar to the cylindrical coordinates as it can be seen as an entrenchment of one dimension (the height) of the cylindrical system (we will often encounter this system in the section of Classical Mechanics, Corpuscular Quantum Physics and Astronomy).

Given the figure:

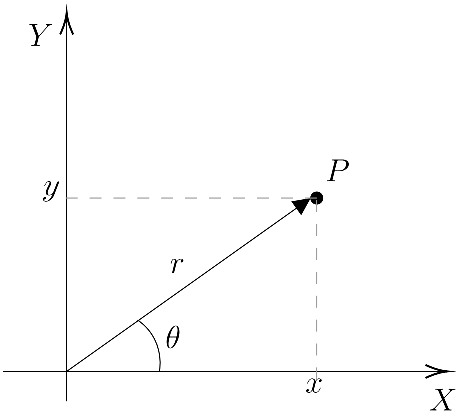

Figure 6.119: **Representation of the polar coordinate system**

Thus, it comes easily in polar coordinates for $r>0$:

$$r=\sqrt{x^2+y^2} \qquad \phi=\arccos\left(\frac{x}{r}\right) \qquad \phi=\arcsin\left(\frac{y}{r}\right) \quad \text{and} \quad \phi=\arctan\left(\frac{y}{x}\right) \tag{6.5.243}$$

and vice versa:

$$x=r\cos(\phi) \qquad y=r\sin(\phi) \tag{6.5.244}$$

Remark

In physics we frequently use the previous parametric equation of the circle in the following way involving time t and pulsation (as a constant) ω:

$$\vec{r}(t)=r\cos(\omega t)\vec{e}_x+r\sin(\omega t)\vec{e}_y \tag{6.5.245}$$

Hence:

$$\|\vec{r}(t)\|=\sqrt{r^2\cos^2(\omega t)+r^2\sin^2(\omega t)} \tag{6.5.246}$$

Now we must find the expressions that connect the vectors of the polar base that we choose to denote by $\vec{e}_r,\vec{e}_\phi$ (instead of $\vec{r},\vec{\phi}$ as it is done traditionally) with the vectors of the Cartesian base $\vec{e}_x,\vec{e}_y$. We have identically to what we did for the spherical coordinates:

$$\begin{aligned}\vec{e}_r&=\frac{\vec{r}}{r}=\frac{x\vec{e}_x+y\vec{e}_y}{r}=\vec{e}_x\cos(\phi)+\vec{e}_y\sin(\phi)\\ \vec{e}_\phi&=\frac{\vec{e}_z\times\vec{e}_r}{\sin(\theta)}=-\vec{e}_x\sin(\phi)+\vec{e}_y\cos(\phi)\end{aligned} \tag{6.5.247}$$

Or more explicitly:

$$\boxed{\vec{e}_r=\begin{pmatrix}\cos(\phi)\\ \sin(\phi)\end{pmatrix},\vec{e}_\phi=\begin{pmatrix}-\sin(\phi)\\ \cos(\phi)\end{pmatrix}} \tag{6.5.248}$$

Once again, dividing by $\sin(\theta)$ the second basis vector $\vec{e}_\phi$, we ensure the properties of the norm of the vector product that:

$$\|\vec{e}_\phi\|=\|\vec{e}_z\|\cdot\|\vec{e}_r\|\sin(\theta)=1 \tag{6.5.249}$$

will be well normalized to unity (as we know from start that as we take a direct orthogonal coordinate system the product of norms of the basis vectors must be equal to 1)!. In the case of polar coordinate the angle being a anyway right, we would not be obliged to indicate this division, but we have made this choice for consistency with the previous developments.

For future needs, Let us determine the partial differential of each of these coordinates:

$$\begin{aligned}\frac{\partial\vec{e}_r}{\partial r}&=\vec{0}\qquad&\frac{\partial\vec{e}_r}{\partial\phi}&=-\vec{e}_x\sin(\phi)+\vec{e}_y\cos(\phi)=\vec{e}_\phi\\ \frac{\partial\vec{e}_\phi}{\partial r}&=0\qquad&\frac{\partial\vec{e}_\phi}{\partial\phi}&=-\vec{e}_x\cos(\phi)-\vec{e}_y\sin(\phi)=-\vec{e}_r\end{aligned} \tag{6.5.250}$$

We will also use later (for the study of vector operators) the variation $\mathrm{d}\vec{r}$ expressed in polar coordinates:

$$\begin{aligned}\mathrm{d}\vec{r}&=\mathrm{d}(r\vec{e}_r)=\vec{e}_r\mathrm{d}r+r\mathrm{d}\mathrm{d}\vec{e}_r=\vec{e}_r\mathrm{d}r+r\left(\frac{\partial\vec{e}_r}{\partial r}\mathrm{d}r+\frac{\partial\vec{e}_r}{\partial\phi}\mathrm{d}\phi\right)\\ &=\vec{e}_r\mathrm{d}r+\vec{e}_\phi r\mathrm{d}\phi\end{aligned} \tag{6.5.251}$$

To express the speed and acceleration in polar coordinates, we will also need the derivatives with respect to time:

$$\begin{aligned}\dot{\vec{e}}_r&=\frac{\partial\vec{e}_r}{\partial r}\dot{r}+\frac{\partial\vec{e}_r}{\partial\phi}\dot{\phi}=\vec{e}_\phi\dot{\phi}\\ \dot{\vec{e}}_\phi&=\frac{\partial\vec{e}_\phi}{\partial r}\dot{r}+\frac{\partial\vec{e}_\phi}{\partial\phi}\dot{\phi}=-\vec{e}_r\dot{\phi}\end{aligned} \tag{6.5.252}$$

So if we now do a little bit physics, we have:

$$\vec{v}=\dot{\vec{r}}=\dot{\vec{e}}_r r+\dot{r}\vec{e}_r \tag{6.5.253}$$

and therefore:

$$\boxed{\vec{v}=\dot{r}\vec{e}_r+\vec{e}_\phi r\dot{\phi}} \tag{6.5.254}$$

where the first term is the radial velocity component and the second term the tangential component of the (angular) velocity. The velocity expression in polar coordinates is very important in astronomy as it allows quite easily calculate the calculation of the kinetic energy:

$$E_c=\frac{1}{2}m\|\vec{v}\|^2=\frac{1}{2}m\left(\sqrt{\dot{r}^2+r^2\dot{\phi}}\right)^2=\frac{1}{2}\left(\dot{r}^2+r^2\dot{\phi}\right) \tag{6.5.255}$$

For the acceleration we get:

$$\boxed{\vec{a}=\vec{e}_r(\ddot{r}-\dot{\phi}^2 r)+\vec{e}_\phi(2\dot{r}\dot{\phi}+r\ddot{\phi})} \tag{6.5.256}$$

where the first term is the radial acceleration, the second term the centripetal acceleration, the third the Coriolis acceleration and finally the fourth one the tangential acceleration.

6.5.8 Differential Operators

Definition (#6.5.250): Define a scalar field, vector field or tensor field in a volume V, it is define an application that for any point $\vec{r}$ of this volume V associates respectively a scalar, a vector or a tensor.

Thus, the application f that at any point $\vec{r}$ of V of spatial coordinates (x,y,z) associates the scalar value $f(\vec{r})=f(x,y,z)$ is a scalar field in V.

At each point of a volume traversed by a moving fluid, the vector that coincides at every moment with the speed of the particle which pass through this point at this same time defines a 3D vector field, optionally variable in time. The fields thus defined are a basic mathematical tool in physics.

Remark

When we plot a scalar field, the set of continuous dots of equal value is so-named "iso-lines" or more commonly "contours".

Vector fields are especially an important tool for describing many physical concepts, such as gravitation and electromagnetism, which affect the behaviour of objects over a large region of a plane or of space. They are also useful for dealing with large-scale behaviour such as atmospheric storms or deep-sea ocean currents.

For example the figure below shows a gravitational field exerted by two astronomical objects, such as a star and a planet or a planet and a moon. At any point in the figure, the vector associated with a point gives the net gravitational force[16] exerted by the two objects on an object of unit mass. The vectors of largest magnitude in the figure are the vectors closest to the larger object. The larger object has greater mass, so it exerts a gravitational force of greater magnitude than the smaller object.

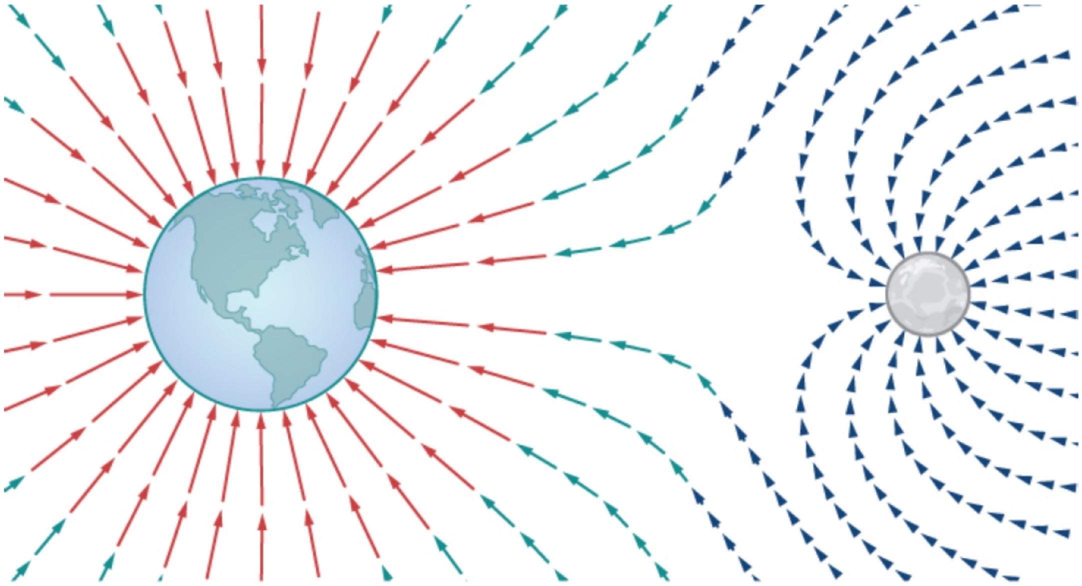

Figure 6.120: **Gravitation vector field example (source: OpenStax)**

---

[16] We will see it during our study of General Relativity that the gravitational force is fictional and we should us the expression "gravitational interaction" instead.

Another example is the figure below that shows the velocity of a river at points on its surface. The vector associated with a given point on the river's surface gives the velocity of the water at that point. Since the vectors to the left of the figure are small in magnitude, the water is flowing slowly on that part of the surface. As the water moves from left to right, it encounters some rapids around a rock. The speed of the water increases, and a whirlpool occurs in part of the rapids.

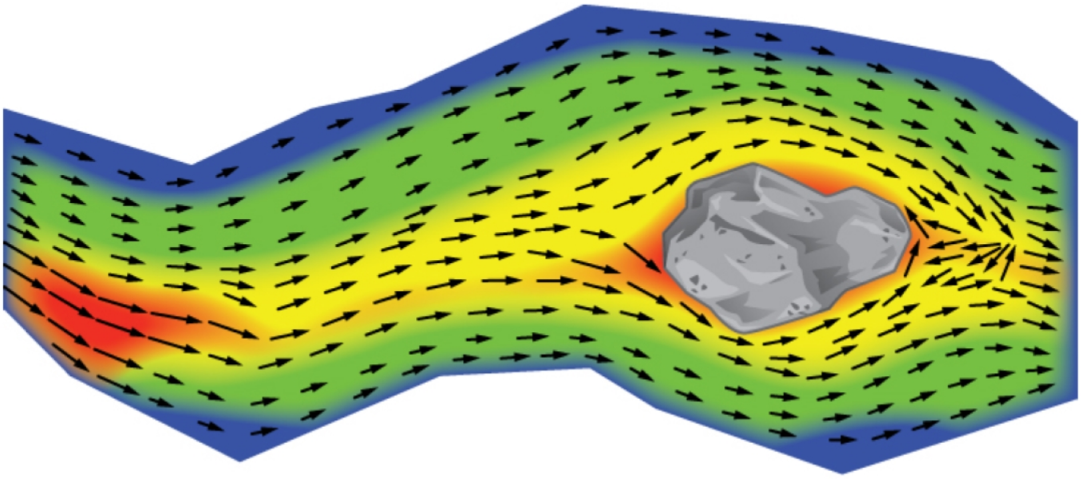

Figure 6.121: **Velocity vector field example (source: OpenStax)**

The gradient, divergence and the rotational are the three main linear differential operators of the first order that will be introduced here. This means they only involve the partial first derivatives (or simply "differentials") of the fields, unlike, for example, the Laplace operator which involves partial derivatives of order 2.

SCALAR, VECTOR, AND TENSOR FIELDS

A COMPARISON OF THEIR MAIN CHARACTERISTICS AND APPLICATIONS

	SCALAR FIELD	VECTOR FIELD	TENSOR FIELD (ORDER 2)
NATURE	Associates a real number with each point in space.	Associates a vector with each point in space.	Associates a second-order tensor (matrix) with each point in space.
TYPICAL SYMBOLS	$\varphi,\ f,\ T,\ \rho,\ \dots$	$\vec{F},\ \vec{v},\ \vec{A},\ \vec{B},\ \dots$	$T,\ \sigma,\ \varepsilon,\ C,\ \dots$
VALUE AT A POINT	A single number (e.g., $\varphi(P) = 3.14$)	A vector (magnitude and direction) (e.g., $\vec{F}(P) = (2, -1, 3)$)	A matrix (tensor) (e.g., $T(P) = \begin{pmatrix} 1 & 2 & 0 \\ 2 & -1 & 3 \\ 0 & 3 & 4 \end{pmatrix}$)
VISUAL REPRESENTATION	Temperature map  	Wind field 	Stress tensor (in 2D) PHYSICAL EXAMPLES	Temperature Pressure Electric potential Density Concentration	Fluid velocity Electric field Magnetic field Acceleration Flux (e.g., heat flux)	Stress tensor (mechanics) Strain tensor (deformations) Inertia tensor Permittivity tensor Conductivity tensor
NUMBER OF INDEPENDENT COMPONENTS IN 3D	**1**	**3** (x, y, z)	**9** in general (6 if symmetric)
BEHAVIOR UNDER COORDINATE TRANSFORMATION	Invariant (the value does not change)	Transforms as a vector (rotation + change of basis)	Transforms according to the law of second-order tensors (rotation + change of basis)
COMMON OPERATIONS	Grad, div, $\nabla\varphi$	div $\vec{F}$, curl $\vec{F}$, $\nabla \cdot \vec{F}$, $\nabla \times \vec{F}$	Contraction, trace, product $\nabla \cdot T,\ T : S,\ \mathrm{tr}(T), \dots$
PRACTICAL APPLICATIONS	**Weather & Climate** Temperature, pressure in atmospheric models. **Electrostatics** Electric potential in devices and materials. **Medical Imaging** Intensity in MRI, CT, ultrasound images.	**Fluid Dynamics** Airflow around aircraft, ocean currents. **Electromagnetism** Electric and magnetic fields in motors, antennas. **Mechanics** Velocity and acceleration of bodies and structures.	**Structural Mechanics** Stress analysis in bridges, buildings, and materials. **Continuum Mechanics** Strain and deformation of materials. **Anisotropic Materials** Modeling of crystals, composites, and tissues.

IN SUMMARY

● **SCALAR FIELD**
A number at each point: intensity without direction.

→

→ **VECTOR FIELD**
A vector at each point: intensity with direction.

→

▦ **TENSOR FIELD**
A tensor at each point: directional relationships with greater complexity.

6.5.8.1 Gradients of Scalar Field

The gradient is an operator that applies to a scalar field and transforms it into a vector field. Intuitively, the gradient indicates the direction of the greater variation of the scalar field, and the intensity of this variation. For example, the gradient of the altitude is directed along the maximum slope line and its norm increases with the slope.

Given a three-dimensional scalar field $f(x,y,z)$, wherein x and y and z are the Cartesian coordinates of a point M in space. When M moves in space according to the $\mathrm{d}\vec{r}$ of components $\mathrm{d}x,\mathrm{d}y$ and $\mathrm{d}z$, the scalar field f varies according to the total differential $\mathrm{d}f$:

$$\mathrm{d}f=\frac{\partial f}{\partial x}\mathrm{d}x+\frac{\partial f}{\partial y}\mathrm{d}y+\frac{\partial f}{\partial z}\mathrm{d}z=\begin{pmatrix}\dfrac{\partial f}{\partial x}\\\dfrac{\partial f}{\partial y}\\\dfrac{\partial f}{\partial z}\end{pmatrix}\circ\begin{pmatrix}\mathrm{d}x & \mathrm{d}y & \mathrm{d}z\end{pmatrix} \tag{6.5.257}$$

From this relation, we can define the "gradient operator", also named "gradient vector", of a scalar field such as:

$$\mathrm{d}f=\overrightarrow{\text{grad}}(f)\circ\mathrm{d}\vec{r}=\vec{\nabla}(f)\circ\mathrm{d}\vec{r} \tag{6.5.258}$$

where:

$$\overrightarrow{\text{grad}}(f) \tag{6.5.259}$$

is a vector operator named "gradient of the scalar field f". To condense the writing, we sometimes use the symbol $\vec{\nabla}$ named the "nabla of the scalar field f".

The vector obtained by the gradient calculation has the following three fundamental properties:

P1. The components of the gradient represent by construction the variation (slope) of the function f in the different directions of space.

P2. The gradient is perpendicular to the isolines of the function f.

P3. The direction of the gradient (and therefore its norm) is the maximum variation of f.

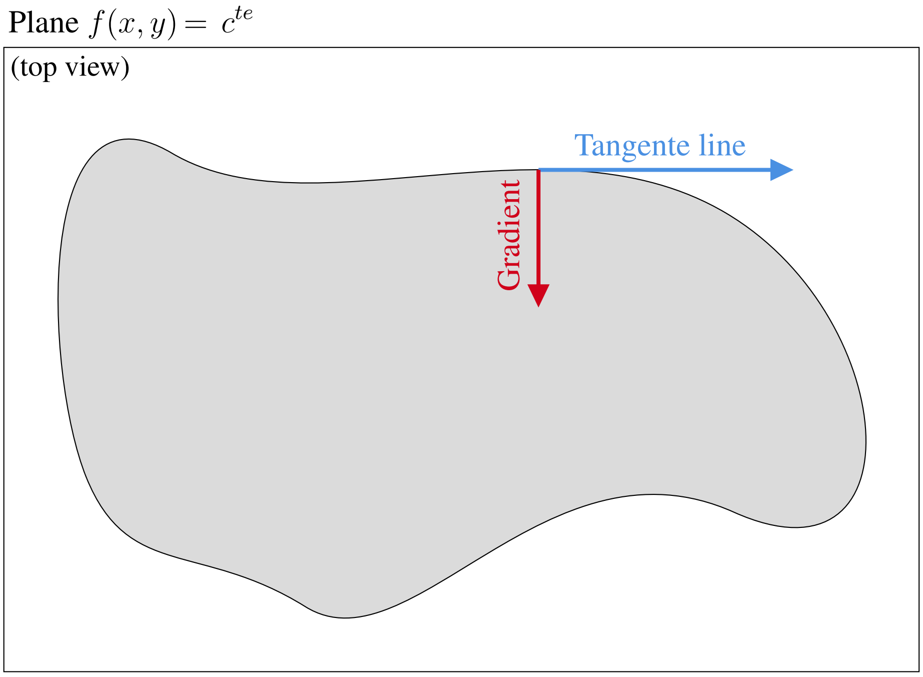
P4. The direction of the gradient shows the values where f increases.

Following the request of some readers let us prove some of these properties.

Given $t\mapsto C(t)$ an isoline. Then $t\mapsto f(c(t))=c^{te}$ and therefore:

$$0=\frac{\mathrm{d}}{\mathrm{d}t}f(c(t))=\vec{\nabla}_{c(t)}\left(f(t)\right)\circ c'(t) \tag{6.5.260}$$

which proves that the gradient is orthogonal to the tangent of the isoline (property P2). This can be illustrated as following:



Remark

In other words: The gradient $\vec{\nabla}_{x_0,y_0}f$ of a function $f(x,y)$ at x_0,y_0 is perpendicular to the tangent of the level-set $f(x,y)=0$ of the function at x_0,y_0.

Let us come back on:

$$\vec{\nabla}(f)\circ\mathrm{d}\vec{r} \tag{6.5.261}$$

That it is tradition to write as:

$$D_uf=\|\vec{\nabla}(f)\|\cdot\|\mathrm{d}\vec{r}\|\cos(\theta) \tag{6.5.262}$$

named the "directional derivative". Its value is maximum obviously if $\theta=0$, that is to say that the gradient is colinear to the variation $\mathrm{d}\vec{r}$. Hence, the direction (and therefore the norm) of greatest increase of f, often named direction of "deepest ascent", is the same direction as the gradient vector!! Thus we proved the property P3.

Obviously the directional derivative takes on its greatest negative value if $\theta=\pi$ (or 180 degrees). Hence, the direction of greatest decrease of f is the direction opposite to the gradient vector and often named direction of "deepest descent".

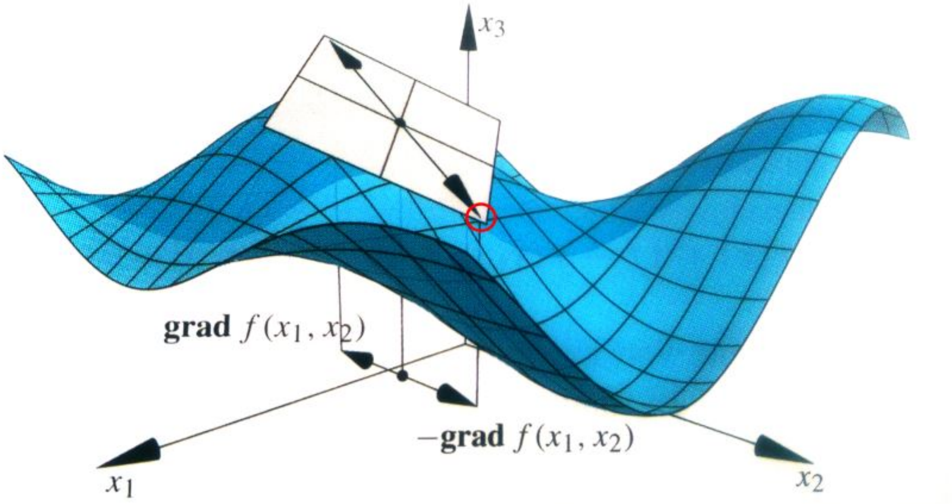


Figure 6.122: Gradient deepest ascent and deepest descent

If $\theta = \pi/2$ then there is no change in altitude in this direction and we are on an "isocline".

The property P4 can be explained without formalism as following:

- If the function is decreasing in one variable, then the partial derivative is negative, so the component vector of the gradient for that variable points in the negative direction - which means increasing function value.
- If the function is increasing in one variable, then the partial derivative is positive, so the component vector of the gradient for that variable points in the positive direction - which means increasing function value.

Then is doesn't matter how the function profile is, the gradient, by definition, points in the increasing direction. Indeed, when $f(x,y)$ is decreasing in x, the function decreases as you move forward in x. But because the partial derivative with respect to x is negative, the x-component of the gradient points towards origin (move backward in x), that is to say in the direction which makes f to increase.

From the definition and from the total differential, we get:

$$\frac{\partial f}{\partial x}\mathrm{d}x+\frac{\partial f}{\partial y}\mathrm{d}y+\frac{\partial f}{\partial z}\mathrm{d}z=\vec{\nabla}(f)_x\circ\mathrm{d}x+\vec{\nabla}(f)_y\mathrm{d}y+\vec{\nabla}(f)_z\mathrm{d}z \tag{6.5.263}$$

This leads us to put that:

$$\vec{\nabla}(f)_x=\frac{\partial f}{\partial x}\mathrm{d}x \qquad \vec{\nabla}(f)_y=\frac{\partial f}{\partial y}\mathrm{d}y \qquad \vec{\nabla}(f)_z=\frac{\partial f}{\partial z}\mathrm{d}z \tag{6.5.264}$$

and so that finally the operator of the "gradient in Cartesian coordinates" is given by:

$$\boxed{\vec{\nabla}=\left(\frac{\partial}{\partial x},\frac{\partial}{\partial y},\frac{\partial}{\partial z}\right)} \tag{6.5.265}$$

Finally we see that the gradient of a scalar field $f(x,y,z)$ is the vector field whose components at each point are the three derivatives of the scalar field f with respect to the three-dimensional coordinates, denoted here by x,y,z and that by its direction, and its norm, the gradient vector of a scalar field at a point therefore includes indications on how the field varies around this point.

Remark

One of the necessary and sufficient conditions for a vector field to be the gradient of a scalar field f is that this vector field is irrotational (see below the rotational operator of a vector field).

✍**Example:**

Let us find the direction for which the directional of:

$$f(x,y,)=3x^2-4xy+2y^2 \tag{6.5.266}$$

at $(-2,3)$ is a maximum and what is its maximum value?

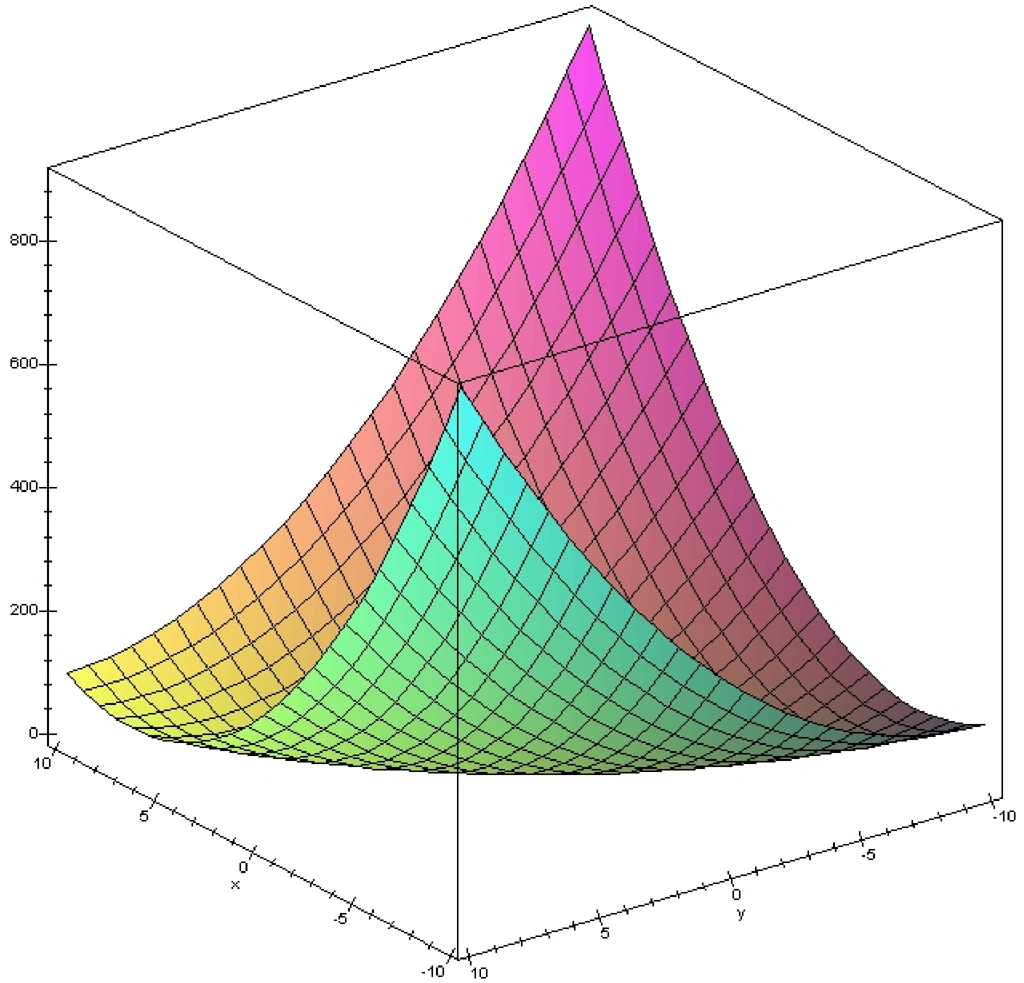

Figure 6.123: **Maple™ plot of** $f(x,y,)=3x^2-4xy+2y^2$

The maximum value of the directional derivative occurs as we have just proved it when

$\vec{\nabla} f$ and the unit vector $\mathrm{d}\vec{r}$ point in the same direction.

Therefore we start by calculating $\vec{\nabla} f(x,y)$:

$$\vec{\nabla} f(x,y) = \begin{pmatrix} \partial_x \\ \partial_y \end{pmatrix} (3x^2 - 4xy + 2y^2) = \begin{pmatrix} 6x - 4y \\ -4x + 4y \end{pmatrix} \tag{6.5.267}$$

Next we evaluate the gradient at $(-2,3)$:

$$\vec{\nabla} f(-2,3) = \begin{pmatrix} 6(-2) - 4(3) \\ -4(-2) + 4(3) \end{pmatrix} = \begin{pmatrix} -24 \\ 20 \end{pmatrix} \tag{6.5.268}$$

We need to find a unit vector that points in the same direction as $\vec{\nabla} f(-2,3)$, so the next step is to divide $\vec{\nabla} f(-2,3)$ by its norm (the value of that norm being also the maximum value of the directional derivative at point $(-2,3)$), which gives:

$$\frac{\vec{\nabla} f(-2,3)}{\|\vec{\nabla} f(-2,3)\|} = \frac{1}{\sqrt{(-24)^2 + (20)^2}} \begin{pmatrix} -24 \\ 20 \end{pmatrix} = \frac{1}{\sqrt{976}} \begin{pmatrix} -24 \\ 20 \end{pmatrix} \cong \begin{pmatrix} -0.768 \\ 0.640 \end{pmatrix} \tag{6.5.269}$$

As the unit vector above is a vector in the plane, nothing prevents us to calculate the angle it does with the axis. By applying elementary trigonometry, we get if we denote this angle by θ:

$$\cos(\theta) = \frac{-0.768}{1} = -0.768 \quad \text{or} \quad \sin(\theta) = \frac{0.640}{1} = 0.640 \tag{6.5.270}$$

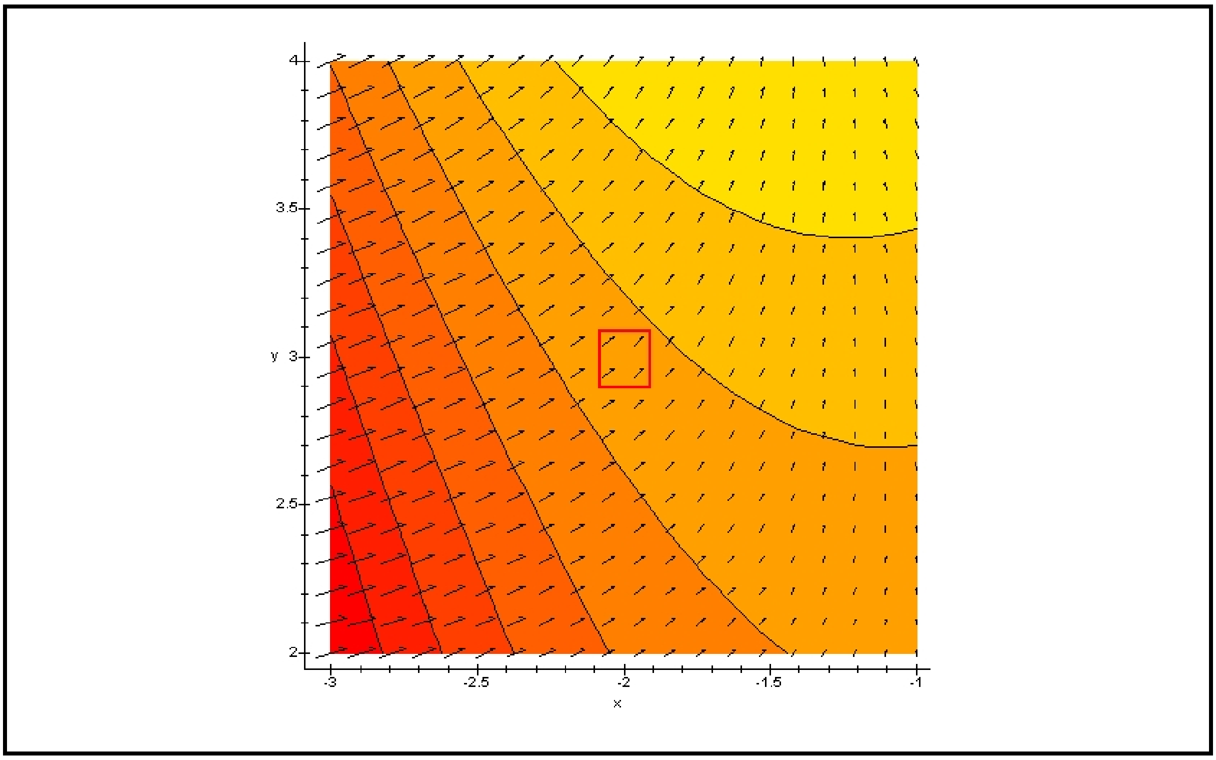
Since cosine is negative and sine is positive, the angle must be in the second quadrant. Therefore:

$$\theta = \pi - \arcsin(0.640) \cong 2.45\,[\text{rad}] \tag{6.5.271}$$

that is to say approximately 114.5916 degrees (or seen from the point of view of the first quadrant: 39.792 degrees).

With Maple™ 4.00b we can have a more detailed and general investigation of the calculation we just did:

```
>with(plots):
>with(linalg):
>Pa:=contourplot(3*x^3-4*x*y+2*y^2,x=-3..-1,y=2..4,filled=true):
>Pb:=fieldplot(grad(3*x^3-4*x*y+2*y^2,vector([x,y])),x=-3..-1,y=2..4):
>display(Pa,Pb);
```



After having defined the gradient in Cartesian coordinates x,y,z we have to address the expression of this operator in other coordinate systems. It is common in physics to have to use cylindrical, polar and spherical coordinates to simplify the formal study of physical systems. So if we refer to the previous study of coordinate systems, we have (recall) first in polar coordinates:

$$\mathrm{d}\vec{r}=\vec{e}_r\mathrm{d}r+\vec{e}_\phi r\mathrm{d}\phi \tag{6.5.272}$$

But, with the definition of gradient in Cartesian coordinates, in polar coordinates we have the following definition:

$$\mathrm{d}f=\vec{\nabla}(f)\circ\mathrm{d}\vec{r} \tag{6.5.273}$$

If we express the total exact differential (see section of Differential and Integral Calculus page 1466) of $\mathrm{d}f$ we get the following relation:

$$\mathrm{d}f=\frac{\partial f}{\partial r}\mathrm{d}r+\frac{\partial f}{\partial \phi}\mathrm{d}\phi=\vec{\nabla}(f)\circ\mathrm{d}\vec{r}=\vec{\nabla}(f)\circ(\vec{e}_r\mathrm{d}r+\vec{e}_\phi r\mathrm{d}\phi) \tag{6.5.274}$$

This allows us to get the relation:

$$\mathrm{d}f=\frac{\partial f}{\partial r}\mathrm{d}r+\frac{\partial f}{\partial \phi}\mathrm{d}\phi=\vec{\nabla}(f)\circ(\vec{e}_r\mathrm{d}r+\vec{e}_\phi r\mathrm{d}\phi)=\vec{\nabla}(f)_r\mathrm{d}r+\vec{\nabla}(f)_\phi r\mathrm{d}\phi \tag{6.5.275}$$

therefore:

$$\mathrm{d}f=\frac{\partial f}{\partial r}\mathrm{d}r+\frac{\partial f}{\partial \phi}\mathrm{d}\phi=\vec{\nabla}(f)_r\mathrm{d}r+\vec{\nabla}(f)_\phi r\mathrm{d}\phi \tag{6.5.276}$$

which bring us to:

$$\vec{\nabla}(f)_r=\frac{\partial f}{\partial r}\quad;\quad\vec{\nabla}(f)_\phi=\frac{1}{r}\frac{\partial f}{\partial \phi} \tag{6.5.277}$$

Thus the "gradient in polar coordinates" is expressed as:

$$\boxed{\vec{\nabla}=\left(\frac{\partial}{\partial r},\frac{1}{r}\frac{\partial f}{\partial \phi}\right)} \tag{6.5.278}$$

Let us now tackle the expression of the gradient in cylindrical coordinates. Let us recall that during our study of different coordinate systems we obtained for cylindrical coordinates:

$$\mathrm{d}\vec{r}=\vec{e}_r\mathrm{d}r+\vec{e}_\phi r\mathrm{d}\phi+\vec{e}_z\mathrm{d}z \tag{6.5.279}$$

So we already know that the expression of the gradient in cylindrical coordinates will be the same in polar coordinates with the exception of the addition of the vertical z component that is independent of other coordinates. Thus we get the "gradient in cylindrical coordinates":

$$\boxed{\vec{\nabla}=\left(\frac{\partial}{\partial r},\frac{1}{r}\frac{\partial f}{\partial \phi},\frac{\partial}{\partial z}\right)} \tag{6.5.280}$$

Let us now tackle on the expression of the gradient in spherical coordinates. Let us recall that during our study of the different coordinate systems we obtained for the spherical coordinates:

$$\mathrm{d}\vec{r}=\vec{e}_r\mathrm{d}r+\vec{e}_\theta r\mathrm{d}\theta+\vec{e}_\phi r\sin(\theta)\mathrm{d}\phi \tag{6.5.281}$$

But, with the definition of gradient in Cartesian coordinates, we have in spherical coordinates the following definition:

$$\mathrm{d}f=\vec{\nabla}(f)\circ\mathrm{d}\vec{r} \tag{6.5.282}$$

If we express the total differential of $\mathrm{d}f$ we get the following relations:

$$\mathrm{d}f=\frac{\partial f}{\partial r}\mathrm{d}r+\frac{\partial f}{\partial \phi}\mathrm{d}\phi+\frac{\partial f}{\partial \theta}\mathrm{d}\theta=\vec{\nabla}(f)\circ\mathrm{d}\vec{r}=\vec{\nabla}(f)\circ\mathrm{d}(\vec{e}_r\mathrm{d}r+\vec{e}_\theta r\mathrm{d}\theta+\vec{e}_\phi r\sin(\theta)\mathrm{d}\phi) \tag{6.5.283}$$

This allows us to get the relation (we now use the notation that uses the operator "nabla"):

$$\begin{aligned}\frac{\partial f}{\partial r}\mathrm{d}r+\frac{\partial f}{\partial \phi}\mathrm{d}\phi+\frac{\partial f}{\partial \theta}\mathrm{d}\theta&=\vec{\nabla}(f)\circ d(\vec{e}_r\mathrm{d}r+\vec{e}_\theta r\mathrm{d}\theta+\vec{e}_\phi r\sin(\theta)\mathrm{d}\phi)\\&=\vec{\nabla}(f)_r\mathrm{d}r+\vec{\nabla}(f)_\theta r\mathrm{d}\theta+\vec{\nabla}(f)_\phi r\sin(\theta)\mathrm{d}\phi\end{aligned} \tag{6.5.284}$$

The relation:

$$\frac{\partial f}{\partial r}\mathrm{d}r+\frac{\partial f}{\partial \phi}\mathrm{d}\phi+\frac{\partial f}{\partial \theta}\mathrm{d}\theta=\vec{\nabla}(f)_r\mathrm{d}r+\vec{\nabla}(f)_\theta r\mathrm{d}\theta+\vec{\nabla}(f)_\phi r\sin(\theta)\mathrm{d}\phi \tag{6.5.285}$$

requires that:

$$\vec{\nabla}(f)_r=\frac{\partial f}{\partial r}\quad;\quad\vec{\nabla}(f)_\theta=\frac{1}{r}\frac{\partial f}{\partial \phi}\quad;\quad\vec{\nabla}(f)_\phi=\frac{1}{r\sin(\theta)}\frac{\partial f}{\partial \theta} \tag{6.5.286}$$

Thus the "gradient in spherical coordinates" is expressed as:

$$\boxed{\vec{\nabla}=\left(\frac{\partial}{\partial r},\frac{1}{r}\frac{\partial f}{\partial \phi},\frac{1}{r\sin(\theta)}\frac{\partial}{\partial \theta}\right)} \tag{6.5.287}$$

So we finally saw all the expressions of the gradient operator in the Cartesian, polar, cylindrical and spherical systems.

✍**Example:**

Let us see now a visual example of the previous developments in Maple™ 4.00 and a special case function $f(x,y)=\sin(x)\sin(y)$.

```
> with(linalg):
> with(plots):
> plot3d(sin(x)*sin(y),x=-3..3,y=-3..3,axes=framed);
```

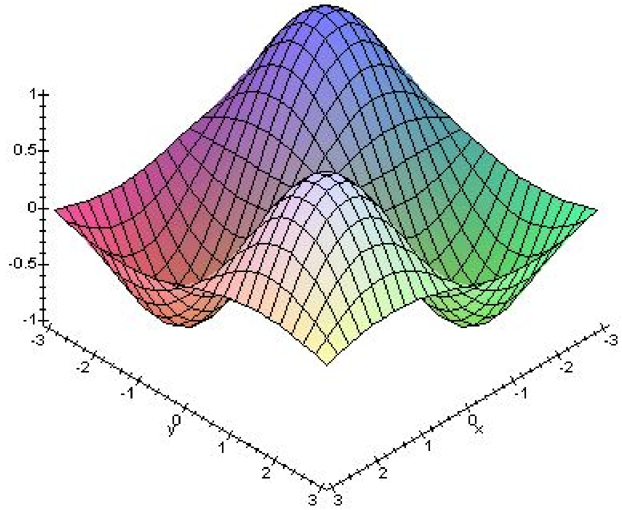


Figure 6.124: **Plot of the function taken as example**

And now we show the isolines:

```
>contourplot3d(sin(x)*sin(y),x=-3..3,y=-3..3,filled=true,
axes=framed,coloring=[red,blue],style=patch);
```

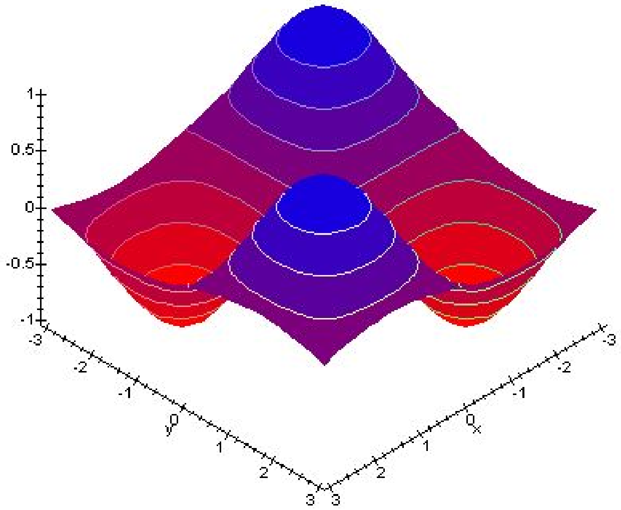

Figure 6.125: **Function with is isolines**

And now we plot the gradient vector with a plane projection and we see they are indeed perpendicular to the isolines:

```
>Pa:=contourplot(sin(x)*sin(y),x=-3..3,y=-3..3,contours=10,
coloring=[red,blue],filled=true):
>Pb:=fieldplot(grad(sin(x)*sin(y),vector([x,y])),x=-3..3,y=-3..3,
arrows=THICK):
>display(Pa,Pb);
```

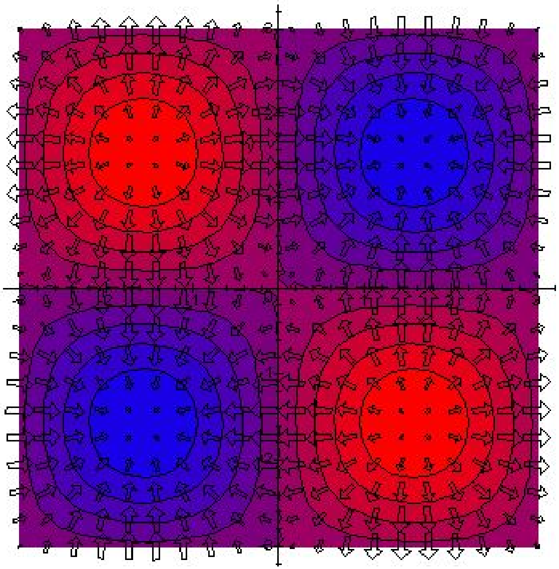

Figure 6.126: Function with its isolines and projected gradient

And with a 3D perspective:

```
>campo:=fieldplot3d([diff(sin(x)*sin(y),x),diff(sin(x)*sin(y),
y),0],x=-3..3,y=-3..3, z=-3..3,axes=framed,arrows=THICK);
>superf:=plot3d(sin(x)*sin(y),x=-3..3,y=-3..3):
> display(campo,superf);
```

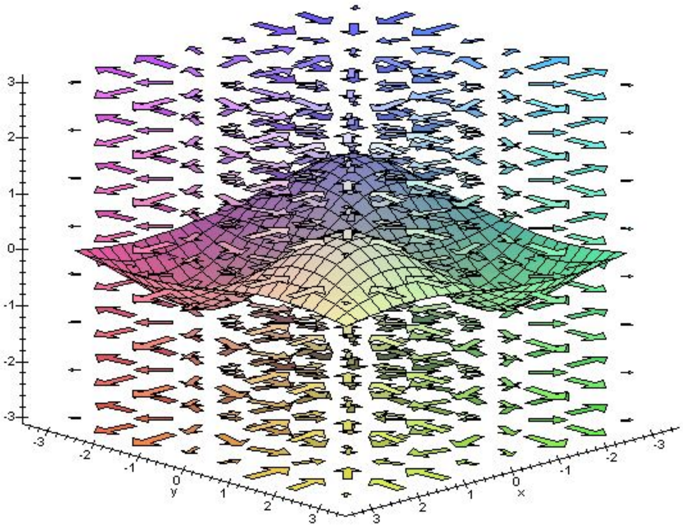

Figure 6.127: Function with its isolines and gradient in 3D

Seen from above with a small rotation:

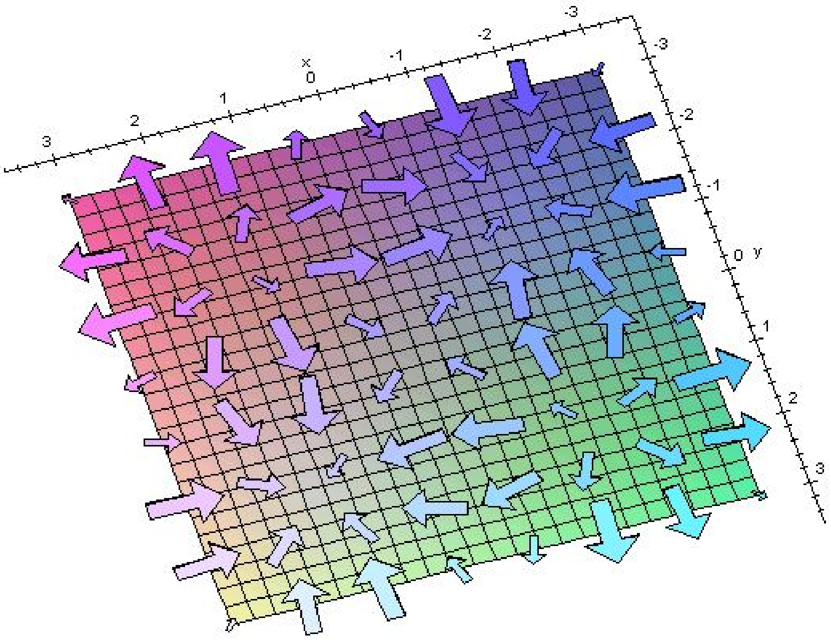

Figure 6.128: **Function rotation with its isolines and gradient**

As we will see during our study of the electromagnetic retarded potentials (see page 4168), if we define $\partial_t \vec{z} = \vec{z}$ then we get two results that may not be very intuitive for some readers. The first result is that:

$$\vec{\nabla}(z) = \frac{\vec{z}}{z}$$

and:

$$\frac{\vec{z}}{z} v = \vec{v}$$

6.5.8.2 Gradients of Vector Field

The gradient of a vector field $\vec{f}(x,y,z) : \mathbb{R}^3 \mapsto \mathbb{R}^3$ is the field named "tensor field" defined by the following nine relations in Cartesian coordinates:

$$\vec{\nabla}(\vec{f}) = \frac{\partial f_i}{\partial x_j} = \begin{bmatrix} \dfrac{\partial f_1}{\partial x} & \dfrac{\partial f_1}{\partial y} & \dfrac{\partial f_1}{\partial z} \\ \dfrac{\partial f_2}{\partial x} & \dfrac{\partial f_2}{\partial y} & \dfrac{\partial f_2}{\partial z} \\ \dfrac{\partial f_3}{\partial x} & \dfrac{\partial f_3}{\partial y} & \dfrac{\partial f_3}{\partial z} \end{bmatrix} \tag{6.5.288}$$

We will use such a gradient in our study in the section of Marine & Weather Engineering of the Papillon effect whose origin comes from the determination of the Navier-Stokes equations of the section of Continuum Mechanics and we will also use this type of gradient in the section of Numerical Methods in our study of the Gauss-Newton optimization method.

We have the following 4 components in polar coordinates:

$$\vec{\nabla}(\vec{f}) = \begin{bmatrix} \dfrac{\partial f_1}{\partial r} & \dfrac{1}{r}\dfrac{\partial f_1}{\partial \phi} \\ \dfrac{\partial f_2}{\partial r} & \dfrac{1}{r}\dfrac{\partial f_2}{\partial \phi} \end{bmatrix} \tag{6.5.289}$$

We have the following 9 components in cylindrical coordinates:

$$\vec{\nabla}(\vec{f})\begin{bmatrix}\dfrac{\partial f_1}{\partial r} & \dfrac{1}{r}\dfrac{\partial f_1}{\partial \phi} & \dfrac{\partial f_1}{\partial z}\\ \dfrac{\partial f_2}{\partial r} & \dfrac{1}{r}\dfrac{\partial f_2}{\partial \phi} & \dfrac{\partial f_2}{\partial z}\\ \dfrac{\partial f_3}{\partial r} & \dfrac{1}{r}\dfrac{\partial f_3}{\partial \phi} & \dfrac{\partial f_3}{\partial z}\end{bmatrix} \tag{6.5.290}$$

We have the following 9 components in spherical coordinates:

$$\vec{\nabla}(\vec{f})\begin{bmatrix}\dfrac{\partial f_1}{\partial r} & \dfrac{1}{r}\dfrac{\partial f_1}{\partial \theta} & \dfrac{1}{r\sin(\theta)}\dfrac{\partial f_1}{\partial \phi}\\ \dfrac{\partial f_2}{\partial r} & \dfrac{1}{r}\dfrac{\partial f_2}{\partial \theta} & \dfrac{1}{r\sin(\theta)}\dfrac{\partial f_2}{\partial \phi}\\ \dfrac{\partial f_3}{\partial r} & \dfrac{1}{r}\dfrac{\partial f_3}{\partial \theta} & \dfrac{1}{r\sin(\theta)}\dfrac{\partial f_3}{\partial \phi}\end{bmatrix} \tag{6.5.291}$$

So we finally saw all the expressions of a gradient vector field in Cartesian , polar, cylindrical and spherical system.

6.5.8.3 Divergences of a Vector Field

The divergence is applied to a vector field and turns it into a scalar field. Therefore it is an application from $\mathbb{R}^3 \mapsto \mathbb{R}$. Intuitively, and in the most common case, the divergence of a vector field expressed its tendency to come from or converge to some points.

Remark

Non-initiated people often confuse the gradient and divergence operator. To make the difference we must remember that the divergence of a vector is a number and that the gradient is a vector! The gradient indicates the direction in which the change is the most important and its amplitude. The divergence simply say what comes in or out from a given point.

However, we must distinguish two contributions to the divergence that we will rigorously define a little further below: one due to the variations named the "directional divergence" and the other due to variations in modules (norm) named the "modular divergence". Thus, for simple fields, we can imagine cases where the divergence would only be modular and others, where it would only be directional. We could also build a field where the two types of divergence coexist, but having adverse effects.

Let us consider for example a vector $\vec{f}$ of space and we make it pass through any surface S. Physicists then assimilate the quantity $\vec{f}$ which moves along the normal vector to the surface as a flow of $\vec{f}$ through S.

To be convinced of this analogy we can imagine a fluid flowing on a flat surface, the flow through the surface is obviously zero in this case, by cons if the fluid flows vertically through a horizontal surface the flow will be maximal. It is then immediate that we want to represent the flow by the scalar product of $\vec{f}$ with the normal $\vec{n}$ to the surface S.

Remark

We must always pay attention to the direction of $\vec{n}$ because at any point of a surface S we have in general two normal vectors $\vec{n}$ that are colinear but of opposite directions.

If the surface is planar then the normal $\vec{n}$ is the same everywhere, but if it changes from place to place, then we will look at a small surface element $\mathrm{d}S$.

If a small flow element is defined by:

$$\mathrm{d}\Phi = (\vec{f} \circ \vec{n})\mathrm{d}S \tag{6.5.292}$$

then the total flow will be given by:

$$\Phi = \int_S (\vec{f} \circ \vec{n})\mathrm{d}S \tag{6.5.293}$$

which is sometimes written (it's a little bit abusive but why not...):

$$\Phi = \int_S \vec{f}\mathrm{d}\vec{S} \tag{6.5.294}$$

Let us now suppose that our vector $\vec{f}$ moves a point $M(x,y,z)$ in space to $M'(x+\mathrm{d}x, y+\mathrm{d}y, z+\mathrm{d}z)$ through a rectangular parallelepiped of sides of $\mathrm{d}x, \mathrm{d}y$ and $\mathrm{d}z$:

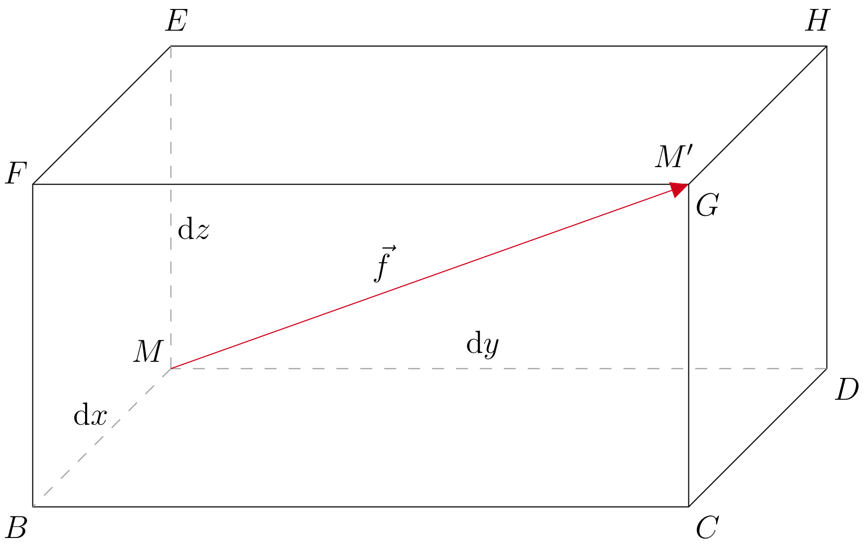

Figure 6.129: **Move of a vector through a parallelepiped**

We can decompose the movement (flow) through each face of the parallelepiped (decompositions in the orthonormal basis). For example, if we are interested at the decomposed part of the flow through the face $(\mathrm{d}y, \mathrm{d}z)$ described by the peaks vertices $BCFG$ we have obviously $\vec{n} = (1,0,0)$.

We still need to determine how to represent the flow $\vec{f}$ for this direction. As the flow is a function, that is to say that each of its components may be dependent of the three components of the space (if we take the case of a function in $\mathbb{R}^3$) we have:

$$\vec{f}=\begin{pmatrix} f_x(x,y,z)\\ f_y(x,y,z)\\ f_z(x,y,z)\end{pmatrix} \tag{6.5.295}$$

Remark

Those who are not convinced can go read the beginning of section Electrodynamics where we take the electric field as an (excellent) example (see page 3969).

While the variation of the flow according to x is given by:

$$\vec{f}_x=\begin{pmatrix} f_x(x+\mathrm{d}x,y,z)\\ f_y(x+\mathrm{d}x,y,z)\\ f_z(x+\mathrm{d}y,y,z)\end{pmatrix}-\begin{pmatrix} f_x(x,y,z)\\ f_y(x,y,z)\\ f_z(x,y,z)\end{pmatrix} \tag{6.5.296}$$

which give us:

$$\begin{aligned}
\mathrm{d}\Phi_x&=((\vec{f})_x\circ\vec{n}_x)\mathrm{d}y\mathrm{d}z=\Big(f_x(x+\mathrm{d}x,y,z)-f_x(x,y,z)\Big)\mathrm{d}y\mathrm{d}z=\frac{\partial f_x}{\partial x}\mathrm{d}x\mathrm{d}y\mathrm{d}z\\
\mathrm{d}\Phi_y&=((\vec{f})_y\circ\vec{n}_y)\mathrm{d}x\mathrm{d}z=\Big(f_y(x,y+\mathrm{d}y,z)-f_x(x,y,z)\Big)\mathrm{d}x\mathrm{d}z=\frac{\partial f_y}{\partial y}\mathrm{d}x\mathrm{d}y\mathrm{d}z\\
\mathrm{d}\Phi_z&=((\vec{f})_z\circ\vec{n}_z)\mathrm{d}x\mathrm{d}y=\Big(f_z(x,y,z+\mathrm{d}z)-f_x(x,y,z)\Big)\mathrm{d}x\mathrm{d}y=\frac{\partial f_z}{\partial z}\mathrm{d}x\mathrm{d}y\mathrm{d}z
\end{aligned} \tag{6.5.297}$$

therefore by summing:

$$\mathrm{d}\Phi=\left(\frac{\partial f_x}{\partial x}+\frac{\partial f_y}{\partial y}+\frac{\partial f_z}{\partial z}\right)\mathrm{d}x\mathrm{d}y\mathrm{d}z=\mathrm{div}(\vec{f})\mathrm{d}V=\vec{\nabla}\circ\vec{f}\mathrm{d}V \tag{6.5.298}$$

Compared to the first expression of Φ, the term $\mathrm{d}x\mathrm{d}y\mathrm{d}z$ is then a volume element and not more of surface. We also have an interesting result:

$$\Phi=\int\limits_V\left(\vec{\nabla}\circ\vec{f}\right)\mathrm{d}V=\int\limits_S\left(\vec{f}\circ\vec{n}\right)\mathrm{d}S \tag{6.5.299}$$

whose more explicit and rigorous writing should be (to highlight well that the considered closed surface is the boundary of the closed studied volume):

$$\Phi=\iiint_V(\vec{\nabla}\circ\vec{f})\mathrm{d}V=\oiint_S(\vec{f}\circ\vec{n})\mathrm{d}x\mathrm{d}y \tag{6.5.300}$$

or more commonly written:

$$\boxed{\Phi=\iiint_V(\vec{\nabla}\circ\vec{f})\mathrm{d}V=\oiint_S\vec{f}\circ\mathrm{d}\vec{S}} \tag{6.5.301}$$

Remark

See the practical cases in the section Electrodynamics where for example the electric field divergence is zero for a free spherical charge as the vectors point in different directions (directional divergence) and where the norms decrease as the inverse of the square of the radius (modular convergence). Both contributions are in opposition and so the total divergence is zero.

The development above is named "Ostrogradsky theorem" or "Gauss-Ostrogradsky theorem" or more simply "divergence theorem" and actually defines the total divergence of $\vec{f}$ in a volume as the flow $\vec{f}$ through the "walls" of the closed volume (Gauss closed surface), which expresses well the name "divergence".

Now reconsider the previous relation but extracting a unitary vector from the vector field $\vec{f}$ such that:

$$\iiint_V (\vec{\nabla}\circ(f\vec{u}))\mathrm{d}V=\oiint_S (f\vec{u})\circ\mathrm{d}\vec{S} \tag{6.5.302}$$

where now f is a scalar field. This can be rewritten obviously using chain rule derivatives and dot product commutativity:

$$\iiint_V (\vec{\nabla}(f)\circ\vec{u}+f\vec{\nabla}\circ\vec{u})\mathrm{d}V=\left(\oiint_S f\mathrm{d}\vec{S}\right)\circ\vec{u} \tag{6.5.303}$$

In the special case of a uniform field we have:

$$\vec{\nabla}\circ\vec{u}=0 \tag{6.5.304}$$

Then it remains:

$$\iiint_V \vec{\nabla}(f)\circ\vec{u}\mathrm{d}V=\left(\oiint_S f\mathrm{d}\vec{S}\right)\circ\vec{u} \tag{6.5.305}$$

The dot product being distributive on the sum of vectors we can rewrite this as:

$$\left(\iiint_V \vec{\nabla}(f)\mathrm{d}V\right)\circ\vec{u}=\left(\oiint_S f\mathrm{d}\vec{S}\right)\circ\vec{u} \tag{6.5.306}$$

and therefore we get the "gradient theorem[17]":

$$\boxed{\iiint_V \vec{\nabla}(f)\mathrm{d}V=\oiint_S f\mathrm{d}\vec{S}} \tag{6.5.307}$$

We define the operator "divergence" by the following relation (the tensor notation has been used to shorten the writing) in an n-dimensional space:

$$\mathrm{div}(\vec{f})=\vec{\nabla}\circ\vec{f}=\sum_{i=0}^{n}\frac{\partial f_i}{\partial x_i} \tag{6.5.308}$$

---

[17] As it is applicable only for uniform field it is not used a lot in practice. Its most well-known application is to prove the Archimedes principle in the most general case.

Thus we have for the operator "divergence in Cartesian coordinates":

$$\boxed{\vec{\nabla}=\left(\frac{\partial}{\partial x},\frac{\partial}{\partial y},\frac{\partial}{\partial z}\right)} \tag{6.5.309}$$

If the divergence of a vector field is identically zero in all the points of an Eulerian frame[18], the triple integral flux of this field through a volume V will be:

$$\Phi=\iiint_V(\vec{\nabla}\circ\vec{f})\mathrm{d}V=0 \tag{6.5.310}$$

It follows that the flow of this vector field through the edges of the volume is zero, that is to say that the incoming flow compensates the output flow. We say that such a field vectors having a null divergence has a "conservation flow".

To determine the expression of the divergence operator in polar coordinates let us recall the relations proved earlier above:

$$\begin{aligned}\vec{e}_r&=\frac{\vec{r}}{r}=\frac{x\vec{e}_x+y\vec{e}_y}{r}=\vec{e}_x\cos(\phi)+\vec{e}_y\sin(\phi)\\ \vec{e}_\phi&=\frac{\vec{e}_z\times\vec{e}_r}{\sin(\theta)}=-\vec{e}_x\sin(\phi)+\vec{e}_y\cos(\phi)\end{aligned} \tag{6.5.311}$$

Given now a vectorial function $\vec{f}:\mathbb{R}^2\rightarrow\mathbb{R}^2$. We have:

$$\vec{f}=f_x\vec{e}_x+f_y\vec{e}_y=f_r\vec{e}_r+f_\theta\vec{e}_\theta \tag{6.5.312}$$

Knowing the expression of $\vec{e}_r,\vec{e}_\phi$ depending on $\vec{e}_x,\vec{e}_y$, from the expression above we deduce:

$$\begin{aligned}f_x&=\cos(\phi)f_r-\sin(\phi)f_\phi\\ f_y&=\sin(\phi)f_r+\cos(\phi)f_\phi\end{aligned} \tag{6.5.313}$$

The divergence of $\vec{f}$ being defined in the two dimensional case by:

$$\vec{\nabla}\circ\vec{f}=\frac{\partial f_x}{\partial x}+\frac{\partial f_y}{\partial y} \tag{6.5.314}$$

we then have:

$$\vec{\nabla}\circ\vec{f}=\vec{\nabla}(f_x)\circ\vec{e}_x+\vec{\nabla}(f_y)\circ\vec{e}_y \tag{6.5.315}$$

The first term is (application of the gradient in polar coordinates!):

$$\begin{aligned}\vec{\nabla}(f_x)\circ\vec{e}_x&=\left(\frac{\partial f_x}{\partial r}\vec{e}_r+\frac{1}{r}\frac{\partial f_x}{\partial\phi}\vec{e}_\phi\right)\circ\vec{e}_x\\ &=\frac{\partial f_x}{\partial r}\vec{e}_r\circ\vec{e}_x+\frac{1}{r}\frac{\partial f_x}{\partial\phi}\vec{e}_\phi\circ\vec{e}_x\\ &=\frac{\partial f_x}{\partial r}\cos(\phi)-\frac{1}{r}\frac{\partial f_x}{\partial\phi}\sin(\phi)\end{aligned} \tag{6.5.316}$$

---

[18] The Eulerian specification of the flow field is a way of looking at fluid motion that focuses on specific locations in the space through which the fluid flows as time passes. This can be visualized by sitting on the bank of a river and watching the water pass the fixed location.

in the same way we get for the second term (we can as always give more details on request):

$$\begin{aligned}\vec{\nabla}(f_y)\circ\vec{e}_y&=\frac{\partial f_y}{\partial r}\vec{e}_r\circ\vec{e}_y+\frac{1}{r}\frac{\partial f_y}{\partial\phi}\vec{e}_\phi\circ\vec{e}_y\\&=\frac{\partial f_y}{\partial r}\sin(\phi)+\frac{1}{r}\frac{\partial f_y}{\partial\phi}\cos(\phi)\end{aligned}\tag{6.5.317}$$

By adding the two terms and expressing the partial derivatives of the functions f_x, f_y in function of the partial derivatives of the functions f_r, f_ϕ using the relations:

$$\begin{aligned}f_x&=\cos(\phi)f_r-\sin(\phi)f_\phi\\f_y&=\sin(\phi)f_r+\cos(\phi)f_\phi\end{aligned}\tag{6.5.318}$$

We get:

$$\begin{aligned}\vec{\nabla}\circ\vec{f}=&\frac{\partial f_x}{\partial r}\cos(\phi)-\frac{1}{r}\frac{\partial f_x}{\partial(\phi)}\sin(\phi)+\frac{\partial f_y}{\partial r}\sin(\phi)+\frac{1}{r}\frac{\partial f_y}{\partial\phi}\cos(\phi)\\=&\cos^2(\phi)\frac{\partial f_r}{\partial r}-\cos(\phi)\sin(\phi)\frac{\partial f_\phi}{\partial r}-\frac{1}{r}\sin(\phi)\left(-\sin(\phi)f_r+\cos(\phi)\frac{\partial f_r}{\partial\phi}-\cos(\phi)f_\phi-\sin(\phi)\frac{\partial f_\phi}{\partial\phi}\right)\\&+\sin^2(\phi)\frac{\partial f_r}{\partial r}+\sin(\phi)\cos(\phi)\frac{\partial f_\phi}{\partial r}+\frac{1}{r}\cos(\phi)\left(\cos(\phi)f_r+\sin\phi\frac{\partial f_r}{\partial\phi}-\sin(\phi)f_\phi+\cos(\phi)\frac{\partial f_\phi}{\partial\phi}\right)\end{aligned}\tag{6.5.319}$$

After simplification:

$$\vec{\nabla}\circ\vec{f}=\frac{\partial f_r}{\partial r}+\frac{1}{r}f_r+\frac{1}{r}\frac{\partial f_\phi}{\partial\phi}=\frac{1}{r}\frac{\partial(rf_r)}{\partial r}+\frac{1}{r}\frac{\partial f_\phi}{\partial\phi}\tag{6.5.320}$$

The expression of the operator "divergence in polar coordinates" is then:

$$\boxed{\vec{\nabla}=\left(\frac{1}{r}\frac{\partial(r}{\partial r},\frac{1}{r}\frac{\partial}{\partial\phi}\right)}\tag{6.5.321}$$

To determine the expression of the divergence operator in cylindrical coordinates let us recall the relations:

$$\begin{aligned}\vec{e}_r&=\frac{\vec{r}}{r}=\frac{x\vec{e}_x+y\vec{e}_y}{r}=\vec{e}_x\cos(\phi)+\vec{e}_y\sin(\phi)\\\vec{e}_\phi&=\frac{\vec{e}_z\times\vec{e}_r}{\sin(\phi)}=-\vec{e}_x\sin(\phi)+\vec{e}_y\cos(\phi)\\\vec{e}_z&=\vec{e}_z\end{aligned}\tag{6.5.322}$$

Given now a vector function $\vec{f}:\mathbb{R}^3\rightarrow\mathbb{R}^3$. We have:

$$\vec{f}=f_x\vec{e}_x+f_y\vec{e}_y+f_z\vec{e}_z=f_r\vec{e}_r+f_\phi\vec{e}_\phi+f_z\vec{e}_z\tag{6.5.323}$$

As we know the expressions of $\vec{e}_r,\vec{e}_\phi,\vec{e}_z$ in function of the $\vec{e}_x,\vec{e}_y,\vec{e}_z$, from the above expressions we deduce:

$$\begin{aligned}f_x&=\cos(\phi)f_r-\sin(\phi)f_\phi\\f_y&=\sin(\phi)f_r+\cos(\phi)f_\phi\\f_z&=f_z\end{aligned}\tag{6.5.324}$$

The divergence of $\vec{f}$ being defined in the three dimensional case by:

$$\vec{\nabla}\circ\vec{f}=\frac{\partial f_x}{\partial x}+\frac{\partial f_y}{\partial y}+\frac{\partial f_z}{\partial z} \tag{6.5.325}$$

we then have:

$$\vec{\nabla}\circ\vec{f}=\vec{\nabla}(f_x)\circ\vec{e}_x+\vec{\nabla}(f_y)\circ\vec{e}_y+\vec{\nabla}(f_z)\circ\vec{e}_z \tag{6.5.326}$$

The first term is equal to (application of the gradient in cylindrical coordinates):

$$\begin{aligned}\vec{\nabla}(f_x)\circ\vec{e}_x&=\left(\frac{\partial f_x}{\partial r}\vec{e}_r+\frac{1}{r}\frac{\partial f_x}{\partial\phi}\vec{e}_\phi+\frac{\partial f_x}{\partial z}\vec{e}_z\right)\circ\vec{e}_x\\&=\frac{\partial f_x}{\partial r}\vec{e}_r\circ\vec{e}_x+\frac{1}{r}\frac{\partial f_x}{\partial\phi}\vec{e}_\phi\circ\vec{e}_x+\frac{\partial f_x}{\partial z}\vec{e}_z\circ\vec{e}_x\\&=\frac{\partial f_x}{\partial r}\cos(\phi)-\frac{1}{r}\frac{\partial f_x}{\partial\phi}\sin(\phi)\end{aligned} \tag{6.5.327}$$

in the same way we get for the second component (we can give the details on request):

$$\begin{aligned}\vec{\nabla}(f_y)\circ\vec{e}_y&=\frac{\partial f_y}{\partial r}\vec{e}_r\circ\vec{e}_y+\frac{1}{r}\frac{\partial f_y}{\partial\phi}\vec{e}_\phi\circ\vec{e}_y+\frac{\partial f_y}{\partial z}\vec{e}_z\circ\vec{e}_y\\&=\frac{\partial f_y}{\partial r}\sin(\phi)+\frac{1}{r}\frac{\partial f_y}{\partial\phi}\cos(\phi)\end{aligned} \tag{6.5.328}$$

and for the last one:

$$\begin{aligned}\vec{\nabla}(f_z)\circ\vec{e}_z&=\frac{\partial f_z}{\partial r}\vec{e}_r\circ\vec{e}_z+\frac{1}{r}\frac{\partial f_z}{\partial\phi}\vec{e}_\phi\circ\vec{e}_z+\frac{\partial f_z}{\partial z}\vec{e}_z\circ\vec{e}_z\\&=\frac{\partial f_z}{\partial z}\end{aligned} \tag{6.5.329}$$

By adding the three terms and expressing the partial derivatives of the functions f_x,f_y,f_z in function of the partial derivatives of the functions f_r,f_ϕ,f_z using the relations:

$$\begin{aligned}f_x&=\cos(\phi)f_r-\sin(\phi)f_\phi\\f_y&=\sin(\phi)f_r+\cos(\phi)f_\phi\\f_z&=f_z\end{aligned} \tag{6.5.330}$$

we get:

$$\begin{aligned}&\vec{\nabla}\circ\vec{f}=\frac{\partial f_x}{\partial r}\cos(\phi)-\frac{1}{r}\frac{\partial f_x}{\partial\phi}\sin(\phi)+\frac{\partial f_y}{\partial r}\sin(\phi)+\frac{1}{r}\frac{\partial f_y}{\partial\phi}\cos(\phi)+\frac{\partial f_z}{\partial z}\\&=\cos^2(\phi)\frac{\partial f_r}{\partial r}-\cos(\phi)\sin(\phi)\frac{\partial f_\phi}{\partial r}-\frac{1}{r}\sin(\phi)\left(-\sin(\phi)f_r+\cos(\phi)\frac{\partial f_r}{\partial\phi}-\cos(\phi)f_\phi-\sin(\phi)\frac{\partial f_\phi}{\partial\phi}\right)\\&+\sin^2(\phi)\frac{\partial f_r}{\partial r}+\sin(\phi)\cos(\phi)\frac{\partial f_\phi}{\partial r}+\frac{1}{r}\cos(\phi)\left(\cos\phi f_r+\sin(\phi)\frac{\partial f_r}{\partial\phi}-\sin(\phi)f_\phi+\cos(\phi)\frac{\partial f_\phi}{\partial\phi}\right)+\frac{\partial f_z}{\partial z}\end{aligned} \tag{6.5.331}$$

After simplification:

$$\vec{\nabla}\circ\vec{f}=\frac{f_r}{\partial r}+\frac{1}{r}f_r+\frac{1}{r}\frac{f_\phi}{\partial\phi}+\frac{f_z}{\partial z}=\frac{1}{r}\frac{\partial(rf_r)}{\partial r}+\frac{1}{r}\frac{f_\phi}{\partial\phi}+\frac{f_z}{\partial z} \tag{6.5.332}$$

The expression of the operator "divergence in cylindrical coordinates" is then:

$$\boxed{\vec{\nabla}=\left(\frac{1}{r}\frac{\partial(r}{\partial r},\frac{1}{r}\frac{\partial}{\partial\phi},\frac{\partial}{\partial z}\right)} \tag{6.5.333}$$

To find the expression of the divergence in spherical coordinates, let us recall the relations:

$$\begin{aligned}\vec{e}_r&=\sin(\theta)\cos(\phi)\vec{e}_x+\sin(\theta)\sin(\phi)\vec{e}_y+\cos(\theta)\vec{e}_z\\ \vec{e}_\phi&=-\vec{e}_x\sin(\phi)+\vec{e}_y\cos(\phi)\\ \vec{e}_\theta&=-\vec{e}_x\cos(\theta)\cos(\phi)-\vec{e}_y\cos(\theta)\sin(\phi)-\vec{e}_z\sin(\theta)\end{aligned} \tag{6.5.334}$$

Given now a vector function $\vec{f}:\mathbb{R}^3\rightarrow\mathbb{R}^3$. We have:

$$\vec{f}=f_x\vec{e}_x+f_y\vec{e}_y+f_z\vec{e}_z=f_r\vec{e}_r+f_\theta\vec{e}_\theta+f_\phi\vec{e}_\phi \tag{6.5.335}$$

Knowing the expression of $\vec{e}_r,\vec{e}_\theta,\vec{e}_\phi$ depending on $\vec{e}_x,\vec{e}_y,\vec{e}_z$, from the expression above we deduce:

$$\begin{aligned}f_x&=\sin(\theta)\cos(\phi)f_r+\cos(\theta)\sin(\phi)f_\theta-\sin(\phi)f_\phi\\ f_y&=\sin(\theta)\sin(\phi)f_r+\cos(\theta)\sin(\phi)f_\theta+\cos(\phi)f_\phi\\ f_z&=\cos(\theta)f_r-\sin(\theta)f_\theta\end{aligned} \tag{6.5.336}$$

The divergence of $\vec{f}$ being defined in the three dimensional case by:

$$\vec{\nabla}\circ\vec{f}=\frac{\partial f_x}{\partial x}+\frac{\partial f_y}{\partial y}+\frac{\partial f_z}{\partial z} \tag{6.5.337}$$

we then have:

$$\vec{\nabla}\circ f=\vec{\nabla}(f_x)\circ\vec{e}_x+\vec{\nabla}(f_y)\circ\vec{e}_y+\vec{\nabla}(f_z)\circ\vec{e}_z \tag{6.5.338}$$

The first component is equal to (application of the gradient in spherical coordinates):

$$\begin{aligned}\vec{\nabla}(f_x)\circ\vec{e}_x&=\left(\frac{\partial f_x}{\partial r}\vec{e}_r+\frac{1}{r}\frac{\partial f_x}{\partial\theta}\vec{e}_\theta+\frac{1}{r\sin(\theta)}\frac{\partial f_x}{\partial\phi}\vec{e}_\phi\right)\circ\vec{e}_x\\ &=\frac{\partial f_x}{\partial r}\vec{e}_r\circ\vec{e}_x+\frac{1}{r}\frac{\partial f_x}{\partial\theta}\vec{e}_\theta\circ\vec{e}_x+\frac{1}{r\sin(\theta)}\frac{\partial f_x}{\partial\phi}\vec{e}_\phi\circ\vec{e}_x\\ &=\frac{\partial f_x}{\partial r}\sin(\theta)\cos(\phi)+\frac{1}{r}\frac{\partial f_x}{\partial\theta}\cos(\theta)\cos(\phi)-\frac{\sin(\phi)}{r\sin(\theta)}\frac{\partial f_x}{\partial\phi}\end{aligned} \tag{6.5.339}$$

in the same way we get for the second component (we can give the details on request):

$$\vec{\nabla}(f_y)\circ\vec{e}_y=\frac{\partial f_y}{\partial r}\sin(\theta)\sin(\phi)+\frac{1}{r}\frac{\partial f_y}{\partial\theta}\cos(\theta)\sin(\phi)+\frac{\cos(\phi)}{r\sin\theta}\frac{\partial f_y}{\partial\phi} \tag{6.5.340}$$

and finally for the third and last one:

$$\vec{\nabla}(f_z)\circ\vec{e}_z=\frac{\partial f_z}{\partial r}\cos(\theta)-\frac{1}{r}\frac{\partial f_z}{\partial\theta}\sin(\theta) \tag{6.5.341}$$

By adding the three terms and expressing the partial derivatives of the functions f_x,f_y,f_z in function of the partial derivatives of the functions f_r,f_θ,f_ϕ using the relations:

$$\begin{aligned}
f_x&=\sin(\theta)\cos(\phi)f_r+\cos(\theta)\cos(\phi)f_\theta-\sin(\phi)f_\phi\\
f_y&=\sin(\theta)\sin(\phi)f_r+\cos(\theta)\sin(\phi)f_\theta+\cos(\phi)f_\phi\\
f_z&=\cos(\theta)f_r-\sin(\theta)f_\theta
\end{aligned}\tag{6.5.342}$$

we get (we can develop the intermediate details on request):

$$\vec{\nabla}\circ\vec{f}=\frac{1}{r\sin(\theta)}\frac{\partial f_\phi}{\partial\phi}+\frac{\cos(\theta)}{r\sin(\theta)}f_\theta+\frac{1}{r}\frac{\partial f_\theta}{\partial\theta}+\frac{\partial f_r}{\partial r}+\frac{2}{r}f_r\tag{6.5.343}$$

We notice that we can regroup terms depending on the same variable using the property of the derivative, so we get for the expression of the divergence in spherical coordinates:

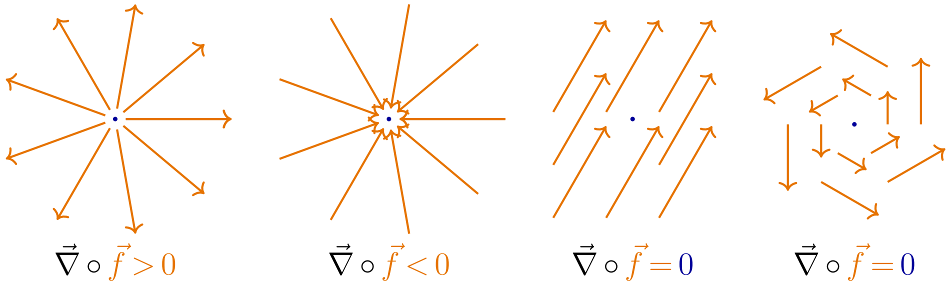
$$\vec{\nabla}\circ\vec{f}=\frac{1}{r\sin(\theta)}\frac{\partial f_\phi}{\partial\phi}+\frac{1}{r\sin(\theta)}\frac{\partial(f_\theta\sin(\theta))}{\partial\theta}+\frac{1}{r^2}\frac{\partial(r^2f_r)}{\partial r}\tag{6.5.344}$$

and therefore the operator of "divergence in spherical coordinates" is:

$$\boxed{\vec{\nabla}=\left(\frac{1}{r^2}\frac{\partial(r^2}{\partial r},\frac{1}{r\sin(\theta)}\frac{\partial(\sin(\theta)}{\partial\theta},\frac{1}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)}\tag{6.5.345}$$

So we finally saw all the expressions of the divergence operator of a vector field in Cartesian, polar, cylindrical and spherical systems.

Keep in mind that way to "see" divergence on a vector field plot is to look at what happens to the magnitude of vectors as you move along the flow of the vector field. If the vector field is increasing in magnitude as you move along the flow of a vector field, then the divergence is positive. If the vector field is decreasing in magnitude as you move along the flow of a vector field, then the divergence is negative. If the vector field does not change in magnitude as you move along the flow of the vector field, then the divergence is zero. Also, remember that the divergence of a vector field is often a variable quantity and will change depending on location!



$\vec{\nabla}\circ\vec{f}>0$
$\vec{\nabla}\circ\vec{f}<0$
$\vec{\nabla}\circ\vec{f}=0$
$\vec{\nabla}\circ\vec{f}=0$

6.5.8.4 Rotationals of a Vector Field (Curl)

The "curl" or "rotationnal" of a vector field can be seen (this is a simplification!) as the vector field whose field lines are perpendicular to those we have calculated the rotational as shown in the special example below (we will see more academic detailed further below):

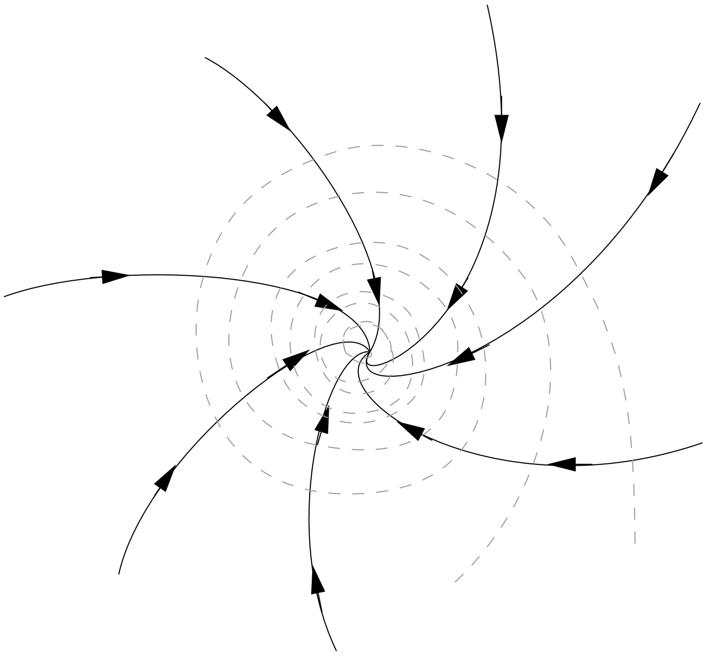

Figure 6.131: **Example of rotational (curl) of a vector field**

In a little bit more technical way the rotational is a vector operator that describes the infinitesimal rotation of a 3-dimensional vector field. At every point in the field, the rotational of that point is represented by a vector. The attributes of this vector (length and direction) characterize the rotation at that point. he direction of the rotational is the axis of rotation, as determined by the right-hand rule, and the magnitude of the rotational is the magnitude of rotation.

The rotational transforms a vector field in another vector field. For most people it is more difficult to accurately represent than the gradient and divergence, it intuitively reflects the tendency of a field to rotate around a point (the way it is twisted).

Let us give before tackling with the mathematical stuff and also mathematical examples two every-day life examples:

✍**Examples:**

E1. In a tornado, the wind turns around the eye of the storm and the wind velocity vector field has a non-zero rotational around the eye.

E2. The rotational of the velocity field of a disc that rotates at a constant speed is constant, directed along the axis of rotation and oriented such that the rotation takes place, in relation to it, in the direct sense.

A vector field is said to be "irrotational" when the rotational of this field is identically zero at all points of space. Otherwise, we say it is a "vortex".

In the usual case where $\mathrm{d}x$ is an element of length, the measurement unit of the rotational is then the unit of the considerated field divided by a unit length. For example, in fluid mechanics: the unity of the rotational of a velocity field is radians per unit time, as an angular velocity as we divide a velocity ([ms^{-1}] by the length [m]!

The divergence gives some indication of the behaviour of a vector or a vector field: how it moves in relation to the normal and how it crosses the surface, but it is insufficient. Take a field which would have the shape of a cylinder and another field which have a helicoidal form of the same diameter as the cylinder. If the move in the same direction the divergence will be the same even if the movements are quite different This requires that we determine how the field is bent as it passes through a surface: this will be determined by the circulation (as the work of a force, for example) of the vector along a closed curve, obtained with the sum of dot products $\vec{f}\circ\mathrm{d}\vec{r}$ on the closed contour (see section Differential and Integral Calculus page 1583):

$$\oint \vec{f}\circ\mathrm{d}\vec{r} \tag{6.5.346}$$

In fact it's the same to look at how twisted is the vector with respect to the normal vector of the surface which leads us to define the "rotational" or "swirl vector" by writing:

$$\oint \vec{f}\circ\mathrm{d}\vec{r}=\int\limits_S \mathrm{rot}(\vec{f})\circ\mathrm{d}\vec{S} \tag{6.5.347}$$

that thus establishes a relation between the line integral and the surface integral (we then transform a line integral on a closed path in a surface integral delimited by the given path).

Theorem 6.37. In other words, the rotational is calculated by using the fact that the flow around a closed basic path of a vector field is equal to the flux of its rotational through the immediate elementary surface generated by this path.

This is the "Stokes' theorem" (which is more rigorously demonstrable with a heavy mathematical formalism) which is in fact a definition of the rotational operator which we will seek the explicit mathematical expression right now!

Proof 6.37.1. Given $\vec{f}$ a vector field defined in a given space. We want to calculate the circulation of $\vec{f}$ around a closed path (contour) C:

$$\oint \vec{f}\circ\mathrm{d}\vec{r} \tag{6.5.348}$$

We choose for contour C the edge of an infinitesimal rectangle $(\mathrm{d}x,\mathrm{d}y)$ that is into $\mathbb{R}^3$ and parallel to the xy-plane (note that we travel the contour so as to always have the surface to our left!):

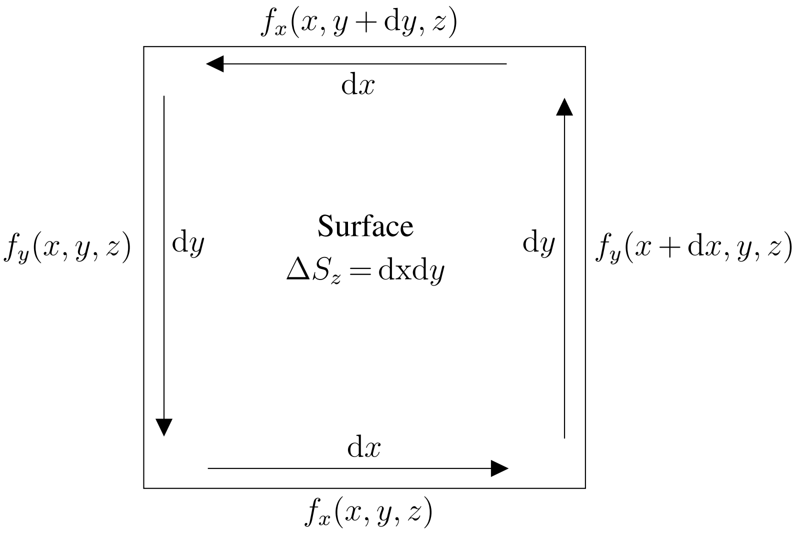

Figure 6.132: **Contour (path) of integration**

For the two horizontal sides (edges), the contribution to the circulation is:

$$f_x(x,y,z)\mathrm{d}x-f_x(x,y+\mathrm{d}y,z)\mathrm{d}x \tag{6.5.349}$$

Which authorizes us to write:

$$\frac{f_x(x,y,z)-f_x(x,y+\mathrm{d}y,z)}{\mathrm{d}y}\mathrm{d}x\mathrm{d}y=-\frac{\partial f_x}{\partial y}\mathrm{d}S_z \tag{6.5.350}$$

Same for the vertical sides (edges) we have also:

$$\frac{f_y(x+\mathrm{d}x,y,z)-f_y(x,y,z)}{\mathrm{d}x}\mathrm{d}x\mathrm{d}y=-\frac{\partial f_y}{\partial x}\mathrm{d}S_z \tag{6.5.351}$$

Therefore we have the circulation following z:

$$(\vec{f}\circ\mathrm{d}\vec{r})_z=\left(\frac{\partial f_y}{\partial x}-\frac{\partial f_x}{\partial y}\right)\mathrm{d}S_z \tag{6.5.352}$$

Which can also be written in the following more general and important form:

$$\boxed{\oint\limits_C(f_x\mathrm{d}x+f_y\mathrm{d}y)=\int\limits_S\left(\frac{\partial f_y}{\partial x}-\frac{\partial f_x}{\partial y}\right)\mathrm{d}S_z} \tag{6.5.353}$$

and that is nothing less than the famous "Green's theorem" or also known as the "Green-Riemann theorem" that we will see again in the section of Complex Analysis.

Green's theorem is a special case of Stokes (general manifold) theorem, but a generalisation to 2-dimension of the fundamental theorem of calculus. But stated in another way: The total spin outside of a function (closed curve) is equal to the sum of little spins on the inside of the function (closed curve).

And that we will write in the situation that interest us:

$$\int\limits_S\left(\frac{\partial f_y}{\partial x}-\frac{\partial f_x}{\partial y}\right)\mathrm{d}S_z:=\int\limits_S\mathrm{rot}(\vec{f})_z\mathrm{d}S_z \tag{6.5.354}$$

By circular permutation we then get:

$$\text{rot}(\vec{f}) = \left(\frac{\partial f_z}{\partial y} - \frac{\partial f_y}{\partial z}\right)\vec{e}_x + \left(\frac{\partial f_x}{\partial z} - \frac{\partial f_z}{\partial x}\right)\vec{e}_y + \left(\frac{\partial f_y}{\partial x} - \frac{\partial f_x}{\partial y}\right)\vec{e}_z \tag{6.5.355}$$

Either in vector condensed form:

$$\boxed{\text{rot}(\vec{f}) = \begin{pmatrix} \dfrac{\partial f_z}{\partial y} - \dfrac{\partial f_y}{\partial z} \\ \dfrac{\partial f_x}{\partial z} - \dfrac{\partial f_z}{\partial x} \\ \dfrac{\partial f_y}{\partial x} - \dfrac{\partial f_x}{\partial y} \end{pmatrix}} \tag{6.5.356}$$

This allows us to better understand the notation, or the non intuitive definition of the rotational in many books and that is:

$$\text{rot}(\vec{f}) = \vec{\nabla} \times \vec{f} \tag{6.5.357}$$

that is to say the cross product of the gradient operator by the vector field!

So finally we have proved the Stokes theorem or also named in this form "curl theorem" that gives well:

$$\boxed{\oint \vec{f} \circ \mathrm{d}\vec{r} = \int\limits_S \left(\vec{\nabla} \times \vec{f}\right) \circ \mathrm{d}\vec{S}} \tag{6.5.358}$$

and at the same time the rotational in Cartesian coordinates.

The above classical Stokes theorem can be stated in one sentence: The line integral of a vector field over a loop is equal to the flux of its curl through the enclosed surface.

■ Q.E.D.

Remark

The above relation is in fact not the "Stokes theorem" but a special case of it named the "Kelvin–Stokes theorem". The stokes theorem is given by (without proof):

$$\int_{\partial\Omega} \omega = \int_{\Omega} \mathrm{d}\omega \tag{6.5.359}$$

and says that the integral of a differential form ω over the boundary of some orientable manifold Ω is equal to the integral of its exterior derivative $\mathrm{d}\omega$ over the whole of Ω. It is the generalization of the fundamental theorem of calculus to N dimensions.

This is the most general and conceptually pure form of Stokes' theorem, of which the fundamental theorem of calculus (1D case), the fundamental theorem of line integrals, Green's theorem (2D case), Stokes' (original) theorem (3D case) and the divergence theorem are all special cases!

✍**Examples:**

E1. Let us take the vector field, which depends on x and y linearly:

$$\vec{f}(x,y,z)=y\vec{e}_x-x\vec{e}_y \tag{6.5.360}$$

Its plot look like this in Maple™ 4.00b:

```
 >with(DEtools):  with(plots):
>fieldplot([y, -x], x=-5..5, y=-5..5,arrows = medium,
color = sqrt(x ^2 + y^2),thickness=2,labels=[‘x‘,‘y‘],
title=‘Simple vector field‘);
```

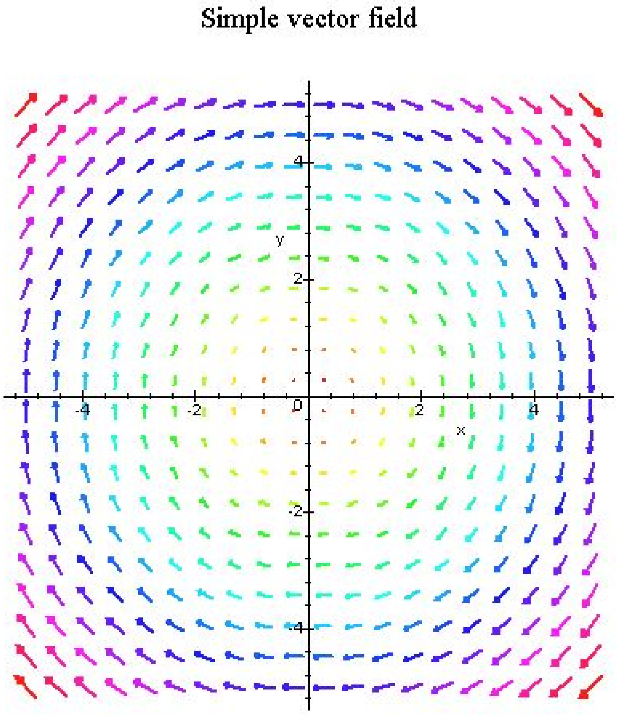

Figure 6.133: Vector field example in Maple™ 4.00b

Simply by visual inspection, we can see that the field is rotating. If we place a paddle wheel anywhere, we see immediately its tendency to rotate clockwise. Using the right-hand rule, we expect the rotational to be into the page. If we are to keep a right-handed coordinate system, into the page will be in the negative z direction. The lack of x and y directions is analogous to the cross product operation.

If we calculate the rotational:

$$\vec{\nabla}\times\vec{f}=0\cdot\vec{e}_x+0\cdot\vec{e}_y+\left(\frac{\partial}{\partial x}(-x)-\frac{\partial}{\partial y}y\right)\vec{e}_z=-2\vec{e}_z \tag{6.5.361}$$

With Maple™ 4.00b we get this algebraic result with the following commands:

```
>with(linalg):
>f:=[y,-x,0];v:=[x,y,z];
>curl(f,v);
```

As we did yet not have the time to find an easy way to plot the resulting rotational vector field in the release 4.00b of Maple™ we will take the picture provided by Wikipedia:

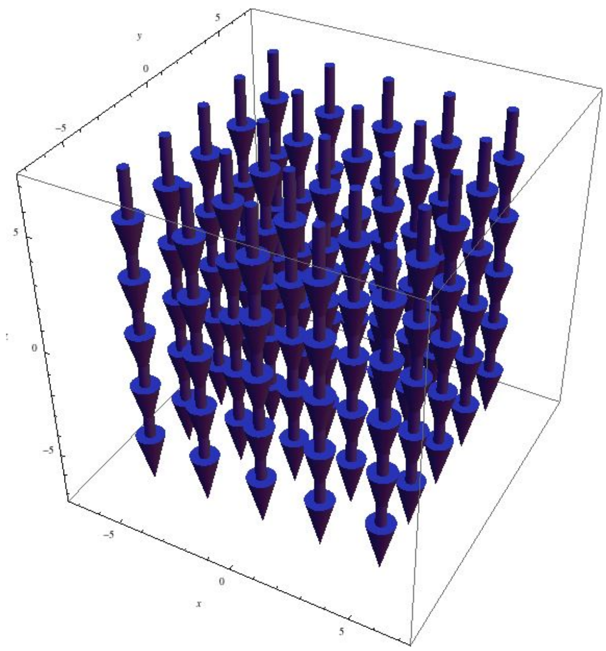

Figure 6.134: **Rotational of previous vector field (source: Wikipedia)**

E2. Suppose we now consider a slightly more complicated vector field:

$$\vec{f}(x,y,z)=-x^2\vec{e}_y \tag{6.5.362}$$

Its plot:

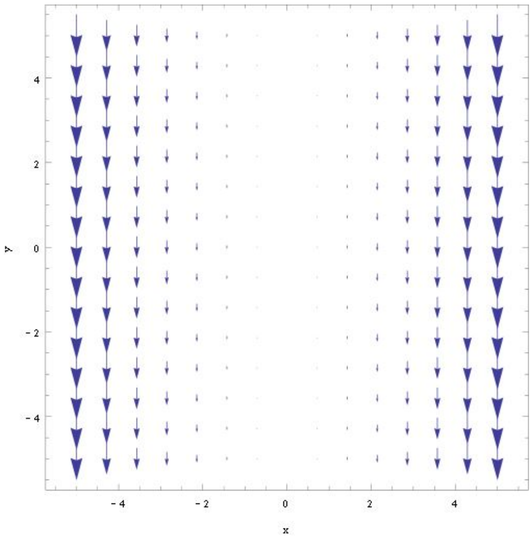

Figure 6.135: **Second vector field example (source: Wikipedia)**

We might not see any rotation initially, but if we closely look at the right, we see a larger field at, say, $x=4$ than at $x=3$. Intuitively, if we placed a small paddle wheel there, the larger "current" on its right side would cause the paddle-wheel to rotate clockwise, which corresponds to a rotational in the negative z direction. By contrast, if we look at a point on the left and placed a small paddle wheel there, the larger "current" on its left side would cause the paddle-wheel to rotate counter-clockwise, which corresponds to a rotational in the positive z direction. Let's check out our guess by doing the math:

$$\vec{\nabla}\times\vec{f}=0\cdot\vec{e}_x+0\cdot\vec{e}_y+\frac{\partial}{\partial x}(-x^2)\vec{e}_z=-2x\vec{e}_z \qquad (6.5.363)$$

Indeed the rotational is in the positive z direction for negative x and in the negative z direction for positive x, as expected. Since this rotational is not the same at every point, its plot is a bit more interesting:

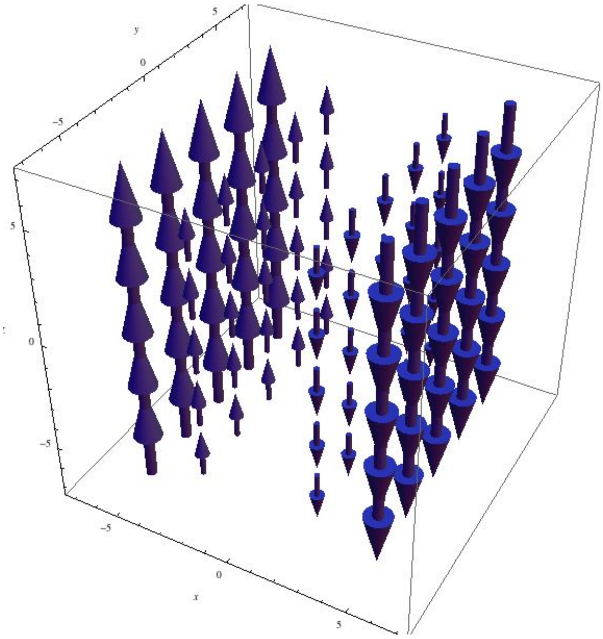

Figure 6.136: **Rotational of previous vector field (source: Wikipedia)**

Let us now determine the expression of the rotational in cylindrical coordinates (the rotational in polar coordinates is not defined in $\mathbb{R}^2$).

Using the same technique as for the rotational in Cartesian coordinates, we write the circulation of $\vec{f}$ along a contour corresponding to a small piece $P_1P_2P_3P_4$ of an orthogonal cylinder (oriented in the direction of the z-axis):

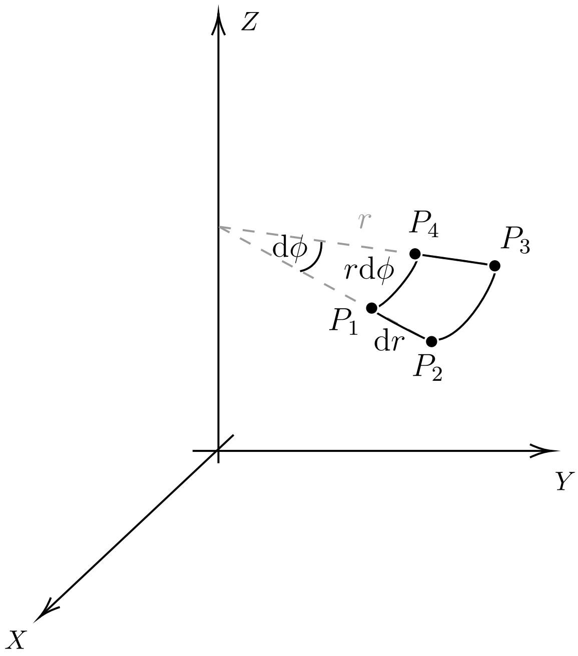

Figure 6.137: **Representation of the cylinder piece** $P_1P_2P_3P_4$

We have then by fixing z (caution! the $\mathrm{d}\vec{r}$ has nothing to do with the cylinder radius r... the notation can be confusing I'm sorry!):

$$\begin{aligned}(\vec{f}\circ\mathrm{d}\vec{r})_{P_1P_2} &= f_r(r,\phi,z)\mathrm{d}r\\(\vec{f}\circ\mathrm{d}\vec{r})_{P_2P_3} &= f_\phi(r+\mathrm{d}r,\phi,z)(r+\mathrm{d}r)\mathrm{d}\phi\\(\vec{f}\circ\mathrm{d}\vec{r})_{P_3P_4} &= -f_r(r,\phi+\mathrm{d}\phi,z)\mathrm{d}r\\(\vec{f}\circ\mathrm{d}\vec{r})_{P_4P_1} &= -f_\phi(r,\phi,z)r\mathrm{d}\phi\end{aligned} \tag{6.5.364}$$

The total circulation thus gives after regrouping terms:

$$\begin{aligned}&\vec{f}\circ\mathrm{d}\vec{r}= f_r(r,\phi,z)\mathrm{d}r+f_\phi(r+\mathrm{d}r,\phi,z)(r+\mathrm{d}r)\mathrm{d}\phi-f_r(r,\phi+\mathrm{d}phi,z)\mathrm{d}r-f_\phi(r,\phi,z)r\mathrm{d}\phi\\&=r\left[f_\phi(r+\mathrm{d}r,\phi,z)-f_\phi(r,\phi,z)\right]\mathrm{d}\phi+f_\phi(r+\mathrm{d},\phi,z)\mathrm{d}\phi\mathrm{d}r-\left[f_r(r,\phi+\mathrm{d}\phi,z)\right]\mathrm{d}r\end{aligned} \tag{6.5.365}$$

We can not at this stage compare with the rotational because it is difficult to us to make appearing the differential of the surface if we look at the differentials that currently appear in circulation. The best is then to divide everything by $r\mathrm{d}\phi\mathrm{d}r$:

$$\begin{aligned}&\frac{1}{r\mathrm{d}\phi\mathrm{d}r}\vec{f}\circ\mathrm{d}\vec{r}\\&=\frac{f_\phi(r+\mathrm{d}r,\phi,z)-f_\phi(r,\phi,z)}{\mathrm{d}r}-\frac{1}{r}\frac{f_r(r,\phi+\mathrm{d}\phi,z)-f_r(r,\phi,z)}{\mathrm{d}\phi}+\frac{1}{r}f_\phi(r+\mathrm{d}r,\phi,z)\\&\underset{\substack{\mathrm{d}r\to 0\\ \mathrm{d}\phi\to 0}}{=}\left(\frac{\partial f_\phi}{\partial r}+\frac{1}{r}f_\phi(r,\phi,z)-\frac{1}{r}\frac{\partial f_r}{\partial\phi}\right)=\frac{1}{r}\frac{\partial(rf_\phi)}{\partial r}-\frac{1}{r}\frac{\partial f_r}{\partial\phi}\end{aligned} \tag{6.5.366}$$

Therefore:

$$\text{rot}(\vec{f})_z = \frac{1}{r}\frac{\partial(rf_\phi)}{\partial r} - \frac{1}{r}\frac{\partial f_r}{\partial \phi} \tag{6.5.367}$$

Now we determine the rotational by fixing ϕ. The problem is like having a rectangle in the space that we travel to determine the circulation. But we already know what is the result of the rotational for a rectangle in Cartesian coordinates following the z-axis:

$$\text{rot}(\vec{f})_z = \frac{\partial f_y}{\partial x} - \frac{\partial f_x}{\partial y} \tag{6.5.368}$$

except that in cylindrical coordinates we have to replace z by ϕ, x by y, y by r and f_y by f_r and finally f_x by f_z (this choice is always appropriate simply because the circulation is such that the surface is always on our left). This gives us:

$$\text{rot}(\vec{f})_\phi = \frac{\partial f_r}{\partial z} - \frac{\partial f_z}{\partial r} \tag{6.5.369}$$

It therefore only remains to us to find the component of the rotational on r (therefore when r is fixed). The calculation is more difficult as we have to follow (positively always!) a curved surface by the variation of the angle ϕ.

We then have by fixing r:

$$\begin{aligned}(\vec{f}\circ \mathrm{d}\vec{r})_{P_1P_2} &= f_\phi(r,\phi,z)r\mathrm{d}\phi\\(\vec{f}\circ \mathrm{d}\vec{r})_{P_2P_3} &= f_z(r,\phi+\mathrm{d}\phi,z)\mathrm{d}z\\(\vec{f}\circ \mathrm{d}\vec{r})_{P_3P_4} &= -f_\phi(r,\phi,z+\mathrm{d}z)r\mathrm{d}\phi\\(\vec{f}\circ \mathrm{d}\vec{r})_{P_4P_1} &= -f_z(r,\phi,z)\mathrm{d}z\end{aligned} \tag{6.5.370}$$

the total circulation thus gives after regrouping terms:

$$\begin{aligned}\vec{f}\circ \mathrm{d}\vec{r} &= f_z(r,\phi+\mathrm{d}\phi,z)\mathrm{d}z - f_z(r,\phi,z)\mathrm{d}z - rf_\phi(r,\phi,z+\mathrm{d}z)\mathrm{d}\phi + rf_\phi(r,\phi,z)\mathrm{d}\phi\\&= \left[f_z(r,\phi+\mathrm{d}\phi,z) - f_z(r,\phi,z)\right]\mathrm{d}z - r\left[f_\phi(r,\phi,z+\mathrm{d}z) - f_\phi(r,\phi,z)\right]\mathrm{d}\phi\end{aligned} \tag{6.5.371}$$

We can not at this stage compare with the rotational because it is difficult to us to make appearing the differential of the surface if we look at the differentials that currently appear in circulation. The best is then to divide everything by $r\mathrm{d}\phi\mathrm{d}z$:

$$\frac{1}{r\mathrm{d}\phi\mathrm{d}z}\vec{f}\circ \mathrm{d}\vec{r} = \frac{1}{r}\frac{f_z(r,\phi+\mathrm{d}\phi,z) - f_z(r,\phi,z)}{\mathrm{d}\phi} - \frac{f_\phi(r,\phi,z+\mathrm{d}z) - f_\phi(r,\phi,z)}{\mathrm{d}z} = \frac{1}{r}\frac{\partial f_z}{\partial \phi} - \frac{\partial f_\phi}{\partial z} \tag{6.5.372}$$

Then finally:

$$\text{rot}(\vec{f})_r = \frac{1}{r}\frac{\partial f_z}{\partial \phi} - \frac{\partial f_\phi}{\partial z} \tag{6.5.373}$$

And finally we have the "rotational in cylindrical coordinates" given in its globality by:

$$\boxed{\text{rot}(\vec{f}) = \begin{pmatrix}\dfrac{1}{r}\dfrac{\partial f_z}{\partial \phi} - \dfrac{\partial f_\phi}{\partial z}\\ \dfrac{\partial f_r}{\partial z} - \dfrac{\partial f_z}{\partial r}\\ \dfrac{1}{r}\dfrac{\partial(rf_\phi)}{\partial r} - \dfrac{1}{r}\dfrac{\partial f_r}{\partial \phi}\end{pmatrix}} \tag{6.5.374}$$

The reader can check verify that this result is simply the gradient in cylindrical coordinates applied to the vector field $\vec{f}$.

To be convinced, let us now show directly the expression of the rotational in spherical coordinates by showing this through the cross product of the gradient in spherical coordinates with the vector field $\vec{f}$.

First let us recall that we have obtained for the gradient in spherical coordinates:

$$\vec{\nabla}=\left(\frac{\partial}{\partial r},\frac{1}{r}\frac{\partial}{\partial\theta},\frac{1}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right) \tag{6.5.375}$$

Therefore we have:

$$\vec{\nabla}\times\vec{f}=\begin{pmatrix}\dfrac{\partial}{\partial r}\\ \dfrac{1}{r}\dfrac{\partial}{\partial\theta}\\ \dfrac{1}{r\sin(\theta)}\dfrac{\partial}{\partial\phi}\end{pmatrix}\times\begin{pmatrix}f_r\\ f_\theta\\ f_\phi\end{pmatrix} \tag{6.5.376}$$

what we can write using the decomposition in basis vectors:

$$\begin{aligned}\vec{\nabla}\times\vec{f}=&\left(\vec{e}_r\frac{\partial}{\partial r}+\frac{\vec{e}_\theta}{r}\frac{\partial}{\partial\theta}+\frac{\vec{e}_\phi}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)\times(f_r\vec{e}_r+f_\theta\vec{e}_\theta+f_\phi\vec{e}_\phi)\\ &\left(\vec{e}_r\frac{\partial}{\partial r}+\frac{\vec{e}_\theta}{r}\frac{\partial}{\partial\theta}+\frac{\vec{e}_\phi}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)\times\vec{f}=\vec{e}_r\times\frac{\partial\vec{f}}{\partial r}+\frac{\vec{e}_\theta}{r}\times\frac{\partial\vec{f}}{\partial\theta}+\frac{\vec{e}_\phi}{r\sin(\theta)}\times\frac{\partial\vec{f}}{\partial\phi}\\ &=\vec{e}_r\times\left(\frac{\partial f_r}{\partial r}\vec{e}_r+\frac{\partial f_\theta}{\partial r}\vec{e}_\theta+\frac{\partial f_\phi}{\partial r}\vec{e}_\phi+f_r\frac{\partial\vec{e}_r}{\partial r}+f_\theta\frac{\partial\vec{e}_\theta}{\partial r}+f_\phi\frac{\partial\vec{e}_\phi}{\partial r}\right)\\ &+\frac{\vec{e}_\theta}{r}\times\left(\frac{\partial f_r}{\partial\theta}\vec{e}_r+\frac{\partial f_\theta}{\partial\theta}\vec{e}_\theta+\frac{\partial f_\phi}{\partial\theta}\vec{e}_\phi+f_r\frac{\partial\vec{e}_r}{\partial\theta}+f_\theta\frac{\partial\vec{e}_\theta}{\partial\theta}+f_\phi\frac{\partial\vec{e}_\phi}{\partial\theta}\right)\\ &+\frac{\vec{e}_\phi}{r\sin(\theta)}\times\left(\frac{\partial f_r}{\partial\phi}\vec{e}_r+\frac{\partial f_\theta}{\partial\phi}\vec{e}_\theta+\frac{\partial f_\phi}{\partial\phi}\vec{e}_\phi+f_r\frac{\partial\vec{e}_r}{\partial\phi}+f_\theta\frac{\partial\vec{e}_\theta}{\partial\phi}+f_\phi\frac{\partial\vec{e}_\phi}{\partial\phi}\right)\end{aligned} \tag{6.5.377}$$

Thanks to the partial derivatives that we proved earlier during our introduction to the spherical coordinates, it comes:

$$\begin{aligned}&\vec{\nabla}\times\vec{f}=\\ &=\vec{e}_r\times\left(\frac{\partial f_r}{\partial r}\vec{e}_r+\frac{\partial f_\theta}{\partial r}\vec{e}_\theta+\frac{\partial f_\phi}{\partial r}\vec{e}_\phi+\vec{0}+\vec{0}+\vec{0}\right)\\ &+\frac{\vec{e}_\theta}{r}\times\left(\frac{\partial f_r}{\partial\theta}\vec{e}_r+\frac{\partial f_\theta}{\partial\theta}\vec{e}_\theta+\frac{\partial f_\phi}{\partial\theta}\vec{e}_\phi+f_r\vec{e}_\theta+f_\theta(-\vec{e}_r)+\vec{0}\right)\\ &+\frac{\vec{e}_\phi}{r\sin(\theta)}\times\left(\frac{\partial f_r}{\partial\phi}\vec{e}_r+\frac{\partial f_\theta}{\partial\phi}\vec{e}_\theta+\frac{\partial f_\phi}{\partial\phi}\vec{e}_\phi+f_r\sin(\theta)\vec{e}_\phi+f_\theta\cos(\theta)\vec{e}_\phi+f_\phi\left[-(\vec{e}_r\sin(\theta)+\vec{e}_\theta\cos(\theta))\right]\right)\end{aligned} \tag{6.5.378}$$

The cross products with the collinear vectors cancelled. Therefore it remains:

$$\begin{aligned}\vec{\nabla}\times\vec{f}=&\vec{e}_r\times\left(\frac{\partial f_\theta}{\partial r}\vec{e}_\theta+\frac{\partial f_\phi}{\partial r}\vec{e}_\phi\right)\\ &+\frac{\vec{e}_\theta}{r}\times\left(\frac{\partial f_r}{\partial\theta}\vec{e}_r+\frac{\partial f_\phi}{\partial\theta}\vec{e}_\phi+f_\theta(-\vec{e}_r)\right)\\ &+\frac{\vec{e}_\phi}{r\sin(\theta)}\times\left(\frac{\partial f_r}{\partial\phi}\vec{e}_r+\frac{\partial f_\theta}{\partial\phi}\vec{e}_\theta+f_\phi\left[-(\vec{e}_r\sin(\theta)+\vec{e}_\theta\cos(\theta))\right]\right)\end{aligned} \tag{6.5.379}$$

As the cross product of two basis vectors give the corresponding orthogonal vector (positively or negatively) then we have:

$$\begin{aligned}\vec{\nabla}\times\vec{f}=&\left(\frac{\partial f_\theta}{\partial r}\vec{e}_\phi-\frac{\partial f_\phi}{\partial r}\vec{e}_\theta\right)\\&+\left(-\frac{1}{r}\frac{\partial f_r}{\partial\theta}\vec{e}_\phi+\frac{1}{r}\frac{\partial f_\phi}{\partial\theta}\vec{e}_r-\frac{f_\theta}{r}\vec{e}_\phi\right)\\&+\left(\frac{1}{r\sin(\theta)}\frac{\partial f_r}{\partial\phi}\vec{e}_\theta-\frac{1}{r\sin(\theta)}\frac{\partial f_\theta}{\partial\phi}\vec{e}_r-\frac{f_\phi}{r}\vec{e}_\theta+\frac{f_\phi\vec{e}_r\cos(\theta)}{r\sin(\theta)}\right)\end{aligned}\qquad(6.5.380)$$

By regrouping the terms it comes:

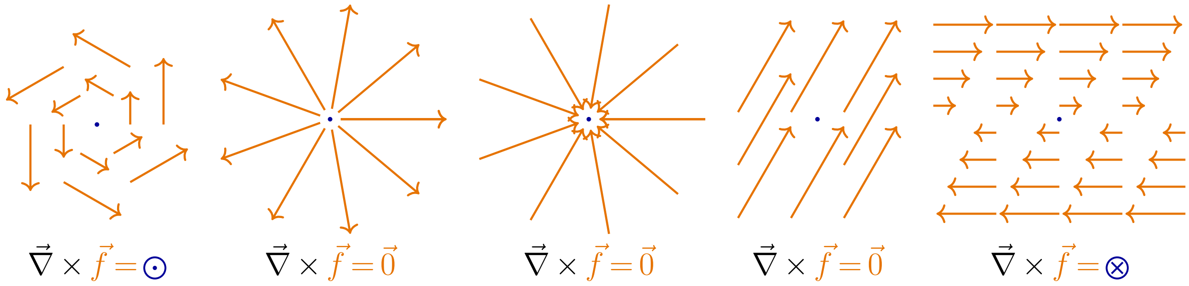
$$\begin{aligned}\vec{\nabla}\times\vec{f}=\vec{e}_r&\left(\frac{1}{r}\frac{\partial f_\phi}{\partial\theta}-\frac{1}{r\sin(\theta)}\frac{\partial f_\theta}{\partial\phi}+\frac{f_\phi\cos(\theta)}{r\sin(\theta)}\right)+\vec{e}_\theta\left(-\frac{f_\phi}{\partial r}+\frac{1}{r\sin(\theta)}\frac{\partial f_r}{\partial\phi}-\frac{f_\phi}{r}\right)\\&+\vec{e}_\phi\left(\frac{\partial f_\theta}{\partial r}-\frac{1}{r}\frac{\partial f_r}{\partial\theta}-\frac{f_\theta}{r}\right)\end{aligned}\qquad(6.5.381)$$

Thus by simplifying:

$$\vec{\nabla}\times\vec{f}=\frac{\vec{e}_r}{r\sin(\theta)}\left(\frac{\partial}{\partial\theta}(\sin(\theta)f_\phi)-\frac{\partial f_\theta}{\partial\phi}\right)+\frac{\vec{e}_\theta}{r\sin(\theta)}\left(\frac{\partial f_r}{\partial\phi}-\sin(\theta)\frac{\partial}{\partial r}(rf_\phi)\right)+\frac{e_p\vec{h}i}{r}\left(\frac{\partial}{\partial r}(rf_\theta)-\frac{\partial f_r}{\partial\theta}\right)\qquad(6.5.382)$$

Thus finally we get the "rotational in spherical coordinates":

$$\boxed{\vec{\nabla}\times\vec{f}=\begin{pmatrix}\dfrac{1}{r\sin(\theta)}\dfrac{\partial}{\partial\theta}(\sin(\theta)f_\phi)-\dfrac{1}{r\sin(\theta)}\dfrac{\partial f_\theta}{\partial\phi}\\\dfrac{1}{r\sin(\theta)}\dfrac{\partial f_r}{\partial\phi}-\dfrac{1}{r}\dfrac{\partial}{\partial r}(rf_\phi)\\\dfrac{1}{r}\dfrac{\partial}{\partial r}(rf_\theta)-\dfrac{1}{r}\dfrac{\partial f_r}{\partial\theta}\end{pmatrix}}\qquad(6.5.383)$$



$\vec{\nabla}\times\vec{f}=\odot$
$\vec{\nabla}\times\vec{f}=\vec{0}$
$\vec{\nabla}\times\vec{f}=\vec{0}$
$\vec{\nabla}\times\vec{f}=\vec{0}$
$\vec{\nabla}\times\vec{f}=\otimes$

6.5.8.5 Laplacians of Scalar Fields (Laplace Operator)

The Laplacian of a scalar field $\phi(x_1,x_2,x_3)$ give also a scalar field that gives the difference between the value of the function ϕ on one point and it average around this point. In other words: the second partial derivative measure the variations of the slope on the study point in its immediate neighbourhood and following one direction at a time. If the second partial derivative is null following x, then the slope is constant in its immediate neighbourhood and following this dimension (direction), this implies that the value of the function at the study point is the average of its neighbourhood (following one dimension).

The reader will be able to see again major practical applications of this differential operator in the sections of Complex Analysis, Quantum Chemistry, Astronomy, Electrodynamics, Weather & Marine Engineering, Wave Mechanics, Wave Quantum Physic and Quantum Field Theory.

This operator is defined from the divergence and the gradient and we denote it by (tensor notations):

$$\boxed{\Delta\cdot f=\vec{\nabla}^2 f=\mathrm{div}(\overrightarrow{\mathrm{grad}}(f))=\vec{\nabla}\circ(\vec{\nabla}\cdot\phi)=\sum_{i=1}^{n}\frac{\partial^2 f}{\partial x_i^2}} \tag{6.5.384}$$

The Laplacian is null, or quite small, when the function varies. The functions satisfying the "Laplace equation":

$$\Delta\cdot\phi=0 \tag{6.5.385}$$

are named "harmonic function".

Thus the "scalar Laplacian operator in cartesian coordinates" is by this definition, given by:

$$\vec{\nabla}^2=\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial y^2}\right) \tag{6.5.386}$$

The Laplacian of a scalar field in other coordinate systems is a little bit more hard to get that for the other differential operators. There are more than one possible proof but among the existing one we have try to choose (as always) this that seem to us the most interesting in the point of view of the tools used (and not of simplicity!).

Given the Laplacian in cartesian coordinates in $\mathbb{R}^2$ of a scalar field f:

$$\vec{\nabla}^2 f=\left(\frac{\partial^2 f}{\partial x^2}+\frac{\partial^2 f}{\partial y^2}\right) \tag{6.5.387}$$

To determine this expression in polar coordinates, we will use the total exact differential and the multivariate chain rule in polar coordinates (see section Differential and Integral Calculus page 1483):

$$\mathrm{d}f=\frac{\partial f}{\partial r}\mathrm{d}r+\frac{\partial f}{\partial\phi}\mathrm{d}\phi\Rightarrow\frac{\mathrm{d}f}{\mathrm{d}x}=\frac{\partial f}{\partial r}\frac{\mathrm{d}r}{\mathrm{d}x}+\frac{\partial f}{\partial\phi}\frac{\mathrm{d}\phi}{\mathrm{d}x} \tag{6.5.388}$$

therefore for a second derivative:

$$\begin{aligned}\frac{\mathrm{d}^2 f}{\mathrm{d}x^2} &= \frac{d}{\mathrm{d}x}\left(\frac{\partial f}{\partial r}\frac{\mathrm{d}r}{\mathrm{d}x}+\frac{\partial f}{\partial \phi}\frac{\mathrm{d}\phi}{\mathrm{d}x}\right)=\frac{\partial}{\partial x}\left(\frac{\partial f}{\partial r}\right)\frac{\mathrm{d}r}{\mathrm{d}x}+\frac{\partial f}{\partial r}\frac{\mathrm{d}^2 r}{\mathrm{d}x^2}+\frac{\partial}{\partial x}\left(\frac{\partial f}{\partial \phi}\right)\frac{\mathrm{d}\phi}{\mathrm{d}x}+\frac{\partial f}{\partial \phi}\frac{\mathrm{d}^2\phi}{\mathrm{d}x^2}\\ &=\left(\frac{\partial^2 f}{\partial r^2}\frac{\partial r}{\partial x}+\frac{\partial^2 f}{\partial r\partial\phi}\right)\frac{\mathrm{d}r}{\mathrm{d}x}+\frac{\partial f}{\partial r}\frac{\mathrm{d}^2 r}{\mathrm{d}x^2}+\left(\frac{\partial^2 f}{\partial\phi\partial r}\frac{\partial r}{\partial x}+\frac{\partial^2 f}{\partial\phi^2}\frac{\partial\phi}{\partial x}\right)\frac{\mathrm{d}\phi}{\mathrm{d}x}+\frac{\partial f}{\partial\phi}\frac{\mathrm{d}^2\phi}{\mathrm{d}x^2}\end{aligned}\tag{6.5.389}$$

but we know that we have in polar coordinates:

$$r=\sqrt{x^2+y^2}\quad\text{and}\quad\phi=\arctan\left(\frac{y}{x}\right)\tag{6.5.390}$$

hence for the first derivative:

$$\frac{\mathrm{d}r}{\mathrm{d}x}=\frac{x}{\sqrt{x^2+y^2}}=\frac{x}{r}\qquad\text{and}\qquad\frac{\mathrm{d}\phi}{\mathrm{d}x}=\frac{-y}{x^2+y^2}=-\frac{y}{r^2}\tag{6.5.391}$$

and for the second derivative:

$$\frac{\mathrm{d}^2}{\mathrm{d}x^2}=\frac{r-\frac{\mathrm{d}r}{\mathrm{d}x}}{r^2}=\frac{r-\left(\frac{x}{r}\right)x}{r^2}=\frac{y^2}{r^3}\quad\text{and}\quad\frac{\phi^2}{\mathrm{d}x^2}=\frac{\mathrm{d}}{\mathrm{d}x}\left(-\frac{y}{r^2}\right)=-y\frac{\mathrm{d}}{\mathrm{d}x}\left(r^2\right)=-y\left(-\frac{2x}{r^4}\right)=\frac{2xy}{r^4}\tag{6.5.392}$$

therefore:

$$\begin{aligned}\frac{\mathrm{d}^2 f}{\mathrm{d}x^2}=\frac{\partial^2 f}{\partial r^2}\left(\frac{x}{r}\right)^2+\frac{\partial^2 f}{\partial r\partial\phi}\left(\frac{x}{r}\right)\left(-y\frac{y}{r^2}\right)+\frac{\partial f}{\partial r}\left(\frac{y^2}{r^3}\right)+\frac{\partial^2 f}{\partial\phi\partial r}\left(\frac{x}{r}\right)\left(-\frac{y}{r^2}\right)\\+\frac{\partial^2 f}{\partial\phi^2}\left(-\frac{y}{r^2}\right)^2+\frac{\partial f}{\partial\phi}\left(\frac{2xy}{r^4}\right)\end{aligned}\tag{6.5.393}$$

and given that the second partial derivatives are continuous, then the cross derivatives are equal according to the Schwarz's theorem (see section Differential and Integral Calculus page 1469):

$$\frac{\partial^2 f}{\partial r\partial r}=\frac{\partial^2 f}{\partial\phi\partial r}\tag{6.5.394}$$

Therefore:

$$\frac{\mathrm{d}^2 f}{\mathrm{d}x^2}=\frac{\partial^2 f}{\partial r^2}\left(\frac{x^2}{r^2}\right)+\frac{\partial^2 f}{\partial r\partial\phi}\left(-\frac{2xy}{r^3}\right)+\frac{\partial f}{\partial r}\left(\frac{y^2}{r^3}\right)+\frac{\partial^2 f}{\partial\phi^2}\left(\frac{y^2}{r^4}\right)+\frac{\partial f}{\partial\phi}\left(\frac{2xy}{r^4}\right)\tag{6.5.395}$$

Similarly, we will have:

$$\frac{\mathrm{d}^2 f}{\mathrm{d}y^2}=\frac{\partial^2 f}{\partial r^2}\left(\frac{y^2}{r^2}\right)+\frac{\partial^2 f}{\partial r\partial\phi}\left(\frac{2xy}{r^3}\right)+\frac{\partial f}{\partial r}\left(\frac{x^2}{r^3}\right)+\frac{\partial^2 f}{\partial\phi^2}\left(\frac{x^2}{r^4}\right)+\frac{\partial f}{\partial\phi}\left(-\frac{2xy}{r^4}\right)\tag{6.5.396}$$

hence the expression of the Laplace operator in polar coordinates by adding the last two expressions:

$$\vec{\nabla}^2 f=\frac{\partial^2 f}{\partial r^2}+\frac{1}{r}\frac{\partial f}{\partial r}+\frac{1}{r^2}\frac{\partial^2 f}{\partial\phi^2}\tag{6.5.397}$$

Therefore the "scalar Laplacian in polar coordinates" is finally given by:

$$\boxed{\vec{\nabla}^2 = \left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{1}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial \phi^2}\right)} \tag{6.5.398}$$

To find the expression of the scalar Laplacian operator in spherical coordinates, we will use the intuition of the physicist and the concepts of similarity.

We will first of all help us with the below figure to find out what we mean:

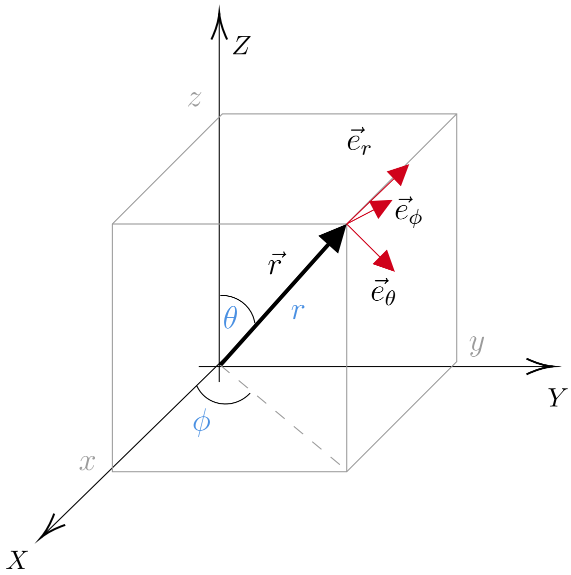

Figure 6.139: **Recall of the spherical coordinate system representation**

Recall that the relation between cartesian and spherical coordinates are given by the relations:

$$\begin{aligned} r &= \sqrt{x^2+y^2+z^2} \\ \tan(\phi) &= \frac{y}{x} \\ \cos(\theta) &= \frac{z}{x^2+y^2+z^2} \end{aligned} \tag{6.5.399}$$

We will now consider the following similarities:

1. Cylindrical coordinates:

$$x = \rho\cos(\phi) \quad \text{and} \quad y = \rho\sin(\phi) \tag{6.5.400}$$

2. Spherical coordinates:

$$z = r\cos(\theta) \quad \text{and} \quad \rho = r\sin(\theta) \tag{6.5.401}$$

Let us build a correspondence table:

$$\begin{array}{lcccc} \text{Cyl:} & x & \rho & \phi & y \\ & \downarrow & \downarrow & \downarrow & \downarrow \\ \text{Sph:} & z & r & \theta & \rho \end{array} \tag{6.5.402}$$

The goal is to play with this correspondence with in a first time the Laplacian in cylindrical coordinates where we have subtracted from both sides of the equality the term $\dfrac{\partial^2 f}{\partial z^2}$. Therefore:

$$\frac{\partial^2 f}{\partial x^2}+\frac{\partial^2 f}{\partial y^2}=\frac{\partial^2 f}{\partial \rho^2}+\frac{1}{\rho}\frac{\partial f}{\partial \rho}+\frac{1}{\rho^2}\frac{\partial^2 f}{\partial \phi^2} \tag{6.5.403}$$

Let us now use our small correspondence table and we get:

$$\frac{\partial^2 f}{\partial z^2}+\frac{\partial^2 f}{\partial \rho^2}=\frac{\partial^2 f}{\partial r^2}+\frac{1}{r}\frac{\partial f}{\partial r}+\frac{1}{r^2}\frac{\partial^2 f}{\partial \theta^2} \tag{6.5.404}$$

The second term of the equality of the latter relation is the spherical equivalent of the term #1 of the Laplacian in cylindrical coordinates:

$$\frac{\partial^2 f}{\partial x^2}+\frac{\partial^2 f}{\partial y^2}+\frac{\partial^2 f}{\partial z^2}=\underbrace{\frac{\partial^2 f}{\partial \rho^2}+\frac{\partial^2 f}{\partial z^2}}_{\#1}+\frac{1}{\rho}\frac{\partial f}{\partial \rho}+\frac{1}{\rho^2}\frac{\partial f}{\partial \phi^2} \tag{6.5.405}$$

Now let us examine and focus on the term: $\dfrac{1}{\rho}\dfrac{\partial f}{\partial \rho}$

Identically as when we determined the relation:

$$\mathrm{d}f=\frac{\partial f}{\partial \rho}\mathrm{d}\rho+\frac{\partial f}{\partial \phi}\mathrm{d}\phi\Rightarrow\frac{\mathrm{d}f}{\mathrm{d}x}=\frac{\partial f}{\partial \rho}\frac{\mathrm{d}\rho}{\mathrm{d}x}+\frac{\partial f}{\partial \phi}\frac{\mathrm{d}\phi}{\mathrm{d}x} \tag{6.5.406}$$

we get:

$$\mathrm{d}u=\frac{\partial u}{\partial rho}\mathrm{d}\rho+\frac{\partial u}{\partial \phi}\mathrm{d}\phi\Rightarrow\frac{\mathrm{d}u}{\mathrm{d}y}=\frac{\partial u}{\partial \rho}\frac{\mathrm{d}\rho}{\mathrm{d}y}+\frac{\partial u}{\partial phi}\frac{\mathrm{d}\phi}{\mathrm{d}y} \tag{6.5.407}$$

with:

$$\frac{\mathrm{d}\rho}{\mathrm{d}y}=\frac{y}{\sqrt{x^2+y^2}}=\frac{y}{\rho}\quad\text{and}\quad\frac{\mathrm{d}\phi}{\mathrm{d}y}=\frac{x}{x^2+y^2}=\frac{x}{\rho^2} \tag{6.5.408}$$

Which gives us the possibility to write:

$$\frac{\mathrm{d}f}{\mathrm{d}y}=\frac{y}{\rho}\frac{\partial f}{\partial \rho}+\frac{x}{\rho^2}\frac{\partial f}{\partial \rho} \tag{6.5.409}$$

If we play again with our small correspondence table we get:

$$\frac{\mathrm{d}f}{\mathrm{d}\rho}=\frac{\rho}{r}\frac{\partial f}{\partial r}+\frac{z}{r^2}\frac{\partial f}{\partial \theta} \tag{6.5.410}$$

We divide the latter relation by ρ and we get:

$$\frac{1}{\rho}\frac{\mathrm{d}f}{\mathrm{d}\rho}=\frac{1}{r}\frac{\partial f}{\partial r}+\frac{z}{\rho r^2}\frac{\partial f}{\partial \theta}=\frac{1}{r}\frac{\partial f}{\partial r}+\frac{\cot(\theta)}{r^2}\frac{\partial f}{\partial \theta} \tag{6.5.411}$$

We have therefore above the spherical equivalent of the second term #2 of the Laplacian in cylindrical coordinates:

$$\frac{\partial^2 f}{\partial x^2}+\frac{\partial^2 f}{\partial y^2}+\frac{\partial^2 f}{\partial z^2}=\underbrace{\frac{\partial^2 f}{\partial \rho^2}+\frac{\partial^2 f}{\partial z^2}}_{\#1}+\underbrace{\frac{1}{\rho}\frac{\partial f}{\partial \rho}}_{\#2}+\frac{1}{\rho^2}\frac{\partial^2 f}{\partial \phi^2} \tag{6.5.412}$$

The last and third term is quite simple to determine. We just have to replace ρ by $r\sin(\theta)$ to get:

$$\frac{1}{\rho^2}\frac{\partial^2 f}{\partial\phi^2} \rightarrow \frac{1}{r^2\sin^2(\theta)}\frac{\partial^2 u}{\partial\phi^2} \tag{6.5.413}$$

By bringing together all terms obtained previously, we finally get the extended form of the Laplacian in spherical coordinates used so much in physics (see corresponding sections of this textbook):

$$\vec{\nabla}^2 = \frac{\partial^2 f}{\partial r^2} + \frac{1}{r}\frac{\partial f}{\partial r} + \frac{1}{r^2}\frac{\partial^2 f}{\partial\theta^2} + \frac{1}{r}\frac{\partial f}{\partial r} + \frac{\cot(\phi)}{r^2}\frac{\partial f}{\partial\theta} + \frac{1}{r^2\sin^2(\theta)}\frac{\partial^2 f}{\partial\phi^2} \tag{6.5.414}$$

We can shorten this expression by factoring the terms:

$$\vec{\nabla}^2 = \frac{\partial^2 f}{\partial r^2} + 2\frac{1}{r}\frac{\partial f}{\partial r} + \frac{1}{r^2}\frac{\partial^2 f}{\partial\theta^2} + \frac{\cot(\phi)}{r^2}\frac{\partial f}{\partial\theta} + \frac{1}{r^2\sin^2(\theta)}\frac{\partial^2 f}{\partial\phi^2} \tag{6.5.415}$$

If we condense even a little bit more, we get the final expression of the "scalar Laplacian in spherical coordinates" named also "spherical Laplacian":

$$\boxed{\vec{\nabla}^2 = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) + \frac{1}{r^2\sin(\theta)}\frac{\partial}{\partial\theta}\left(\sin(\theta)\frac{\partial}{\partial\theta}\right) + \frac{1}{r^2\sin^2(\theta)}\frac{\partial^2}{\partial\phi^2}} \tag{6.5.416}$$

6.5.8.6 Laplacians of Vector Fields

As to the Laplacian of a scalar field, the Laplacian of a vector field is only a very convenient notation system for condensing the writing of the components of a vector field.

The reader will also find practical applications of this operator in the sections of Electrokinetics, Electrodynamics and Continuum Mechanics.

Thus, the vector Laplacian is often defined by (introducing at the same time the different existing notations):

$$\Delta\vec{f} = \vec{\nabla}^2\vec{v} = \vec{\nabla}\left(\vec{\nabla}\circ\vec{f}\right) - \vec{\nabla}\times\left(\vec{\nabla}\times\vec{f}\right) \tag{6.5.417}$$

We also prove that in the specific case of the Cartesian coordinates, the Laplacian of a vector field has for components the scalar Laplacian of each of the components.

So we have therefore in Cartesian coordinates:

$$\begin{aligned}
\Delta\vec{f} &= \vec{\nabla}\left(\vec{\nabla}\circ\vec{f}\right) - \vec{\nabla}\times\left(\vec{\nabla}\times\vec{f}\right) = \vec{\nabla}\left(\partial_x f_1 + \partial_y f_2 + \partial_z f_3\right) - \vec{\nabla}\times\begin{pmatrix}\partial_y f_3 - \partial_z f_2\\ \partial_z f_1 - \partial_x f_3\\ \partial_x f_2 - \partial_y f_1\end{pmatrix}\\
&= \begin{pmatrix}\partial_x\partial_x f_1 + \partial_x\partial_y f_2 + \partial_x\partial_z f_3\\ \partial_y\partial_x f_1 + \partial_y\partial_y f_2 + \partial_y\partial_z f_3\\ \partial_z\partial_x f_1 + \partial_z\partial_y f_2 + \partial_z\partial_z f_3\end{pmatrix} - \begin{pmatrix}\partial_y(\partial_x f_2 - \partial_y f_1) - \partial_z(\partial_z f_1 - \partial_x f_3)\\ \partial_z(\partial_y f_3 - \partial_z f_2) - \partial_x(\partial_x f_2 - \partial_y f_1)\\ \partial_x(\partial_z f_1 - \partial_x f_3) - \partial_y(\partial_y f_3 - \partial_z f_3)\end{pmatrix}\\
&= \begin{pmatrix}\partial_x\partial_x f_1 + \partial_x\partial_y f_2 + \partial_x\partial_z f_3 - \partial_y\partial_x f_2 + \partial_y\partial_y f_1 + \partial_z\partial_z f_1 - \partial_z\partial_x f_3\\ \partial_y\partial_x f_1 + \partial_y\partial_y f_2 + \partial_y\partial_z f_3 - \partial_z\partial_y f_3 + \partial_z\partial_z f_2 + \partial_x\partial_x f_2 - \partial_x\partial_y f_1\\ \partial_z\partial_x f_1 + \partial_z\partial_y f_2 + \partial_z\partial_z f_3 - \partial_x\partial_z f_1 + \partial_x\partial_x f_3 - \partial_y\partial_y f_3 + \partial_y\partial_z f_2\end{pmatrix}\\
&= \begin{pmatrix}\partial_x\partial_x f_1 + \partial_y\partial_y f_1 + \partial_z\partial_z f_1\\ \partial_x\partial_x f_1 + \partial_y\partial_y f_2 + \partial_z\partial_z f_2\\ \partial_x\partial_x f_1 + \partial_y\partial_y f_2 + \partial_z\partial_z f_3\end{pmatrix}
\end{aligned} \tag{6.5.418}$$

and thus the "vector Laplacian of a vector field in Cartesian coordinates" is indeed the scalar Laplacian of each component:

$$\boxed{\Delta\vec{f}=\begin{pmatrix}\displaystyle\sum_{i=1}^{3}\frac{\partial^2 f_1}{\partial x_i^2}\\ \displaystyle\sum_{i=1}^{3}\frac{\partial^2 f_2}{\partial x_i^2}\\ \displaystyle\sum_{i=1}^{3}\frac{\partial^2 f_3}{\partial x_i^2}\end{pmatrix}} \tag{6.5.419}$$

Or more explicitly:

$$\vec{\nabla}=\begin{pmatrix}\dfrac{\partial^2 f_1}{\partial x^2}+\dfrac{\partial^2 f_1}{\partial y^2}+\dfrac{\partial^2 f_1}{\partial z^2}\\ \dfrac{\partial^2 f_2}{\partial x^2}+\dfrac{\partial^2 f_2}{\partial y^2}+\dfrac{\partial^2 f_2}{\partial z^2}\\ \dfrac{\partial^2 f_3}{\partial x^2}+\dfrac{\partial^2 f_3}{\partial y^2}+\dfrac{\partial^2 f_3}{\partial z^2}\end{pmatrix} \tag{6.5.420}$$

The Laplacian of a vector field, frequently named "vectorial laplacian", in other coordinates systems is quite simple to get once we know the Laplacian of a scalar field in the same coordinates!

We have first in cylindrical coordinates:

$$\begin{gathered}\Delta\vec{f}=\vec{\nabla}(\vec{\nabla}\circ\vec{f})-\vec{\nabla}\times(\vec{\nabla}\times\vec{f})=\vec{\nabla}\left(\frac{1}{r}\partial_r r f_r+\frac{1}{r}\partial_\phi f_\phi+\partial_z f_z\right)-\nabla\times\begin{pmatrix}\frac{1}{r}\partial_\phi f_z-\partial_z f_\phi\\ \partial_z f_r-\partial_r f_z\\ \frac{1}{r}\partial_r r f_\phi-\frac{1}{r}\partial_\phi f_r\end{pmatrix}\\ =\begin{pmatrix}\partial_r\left(\frac{1}{r}\partial_r r f_r\right)+\partial_r\left(\frac{1}{r}\partial_\phi f_\phi\right)+\partial_r(\partial_z f_z)\\ \frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_r r f_r\right)+\frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_\phi f_\phi\right)+\frac{1}{r}\partial_\phi(\partial_z f_z)\\ \partial_z\left(\frac{1}{r}\partial_r r f_r\right)+\partial_z\left(\frac{1}{r}\partial_\phi f_\phi\right)+\partial_z\partial_z f_z\end{pmatrix}\\ -\begin{pmatrix}\frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_r r f_\phi-\frac{1}{r}\partial_\phi f_r\right)-\partial_z(\partial_z f_r-\partial_r f_z)\\ \partial_z\left(\frac{1}{r}\partial_\phi f_z-\partial_z f_\phi\right)-\partial_r\left(\frac{1}{r}\partial_r r f_\phi-\frac{1}{r}\partial_\phi f_r\right)\\ \frac{1}{r}\partial_r r(\partial_z f_r-\partial_r f_z)-\frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_\phi f_z-\partial_z f\phi\right)\end{pmatrix}\end{gathered} \tag{6.5.421}$$

To simplify (because of a lack of space) let us focus first on the first line:

$$\begin{aligned}
&\partial_r\left(\frac{1}{r}\partial_r r f_r\right)+\partial_r\left(\frac{1}{r}\partial_\phi f_\phi\right)+\partial_r(\partial_z f_z)-\frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_r r f_\phi-\frac{1}{r}\partial_\phi f_r\right)+\partial_z(\partial_z f_r-\partial_r f_z)\\
&=\partial_r\left(\frac{1}{r}\partial_r r f_r\right)+\partial_r\left(\frac{1}{r}\partial_\phi f_\phi\right)-\frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_r r f_\phi-\frac{1}{r}\partial_\phi f_r\right)+\partial_z^2 f_r\\
&=-\frac{1}{r^2}\partial_r r f_r+\frac{1}{r}\partial_r^2 r f_r-\frac{1}{r^2}\partial_\phi f_\phi+\frac{1}{r}\partial_r\partial_\phi f_\phi-\frac{1}{r^2}\partial_\phi\partial_r r f_\phi+\frac{1}{r^2}\partial_\phi^2 f_r+\partial_z^2 f_r\\
&=-\frac{1}{r^2}f_r-\frac{1}{r}\partial_r f_r+\frac{1}{r}\partial_r^2 r f_r-\frac{1}{r^2}\partial_\phi f_\phi+\frac{1}{r}\partial_r\partial_\phi f_\phi-\frac{1}{r^2}\partial_\phi\partial_r f_\phi+\frac{1}{r^2}\partial_\phi^2 f_r+\partial_z^2 f_r\\
&=-\frac{1}{r^2}f_r-\frac{1}{r}\partial_r f_r+\frac{1}{r}\partial_r^2 r f_r-\frac{2}{r^2}\partial_\phi f\phi+\frac{1}{r^2}\partial_\phi^2 f_r+\partial_z^2 f_r\\
&=-\frac{1}{r^2}f_r-\partial 1 r\partial_r f_r+\frac{1}{r}\partial_r f_r+\frac{1}{r}\partial_r r\partial_r f_r-\frac{2}{r^2}\partial_\phi f_\phi+\frac{1}{r^2}\partial_\phi^2 f_r+\partial_z^2 f_r\\
&=-\frac{1}{r^2}f_r+\frac{1}{r}\partial_r r\partial_r f_r-\frac{2}{r^2}\partial_\phi f_\phi+\frac{1}{r^2}\partial_\phi^2 f_r+\partial_z^2 f_r\\
&=-\frac{1}{r^2}f_r+\frac{1}{r}\partial_r f_r+\partial_r^2 f_r-\frac{2}{r^2}\partial_\phi f_\phi+\frac{1}{r^2}\partial_\phi^2 f_r+\partial_z^2 f_r
\end{aligned}\tag{6.5.422}$$

and after for the second line:

$$\begin{aligned}
&=\frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_r r f_r\right)+\frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_\phi f_\phi\right)+\frac{1}{r}\partial_\phi(\partial_z f_z)-\partial_z\left(\frac{1}{r}\partial_\phi f_z-\partial_z f_\phi\right)+\partial_r\left(\frac{1}{r}\partial_r r f_\phi-\frac{1}{r}\partial_\phi f_r\right)\\
&=\frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_r r f_r\right)+\frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_\phi f_\phi\right)+\frac{1}{r}\partial_\phi\partial_z f_z-\partial_z\frac{1}{z}\partial_\phi f_z+\partial_z^2 f_\phi+\partial_r\frac{1}{r}\partial_r r f_\phi-\partial_r\frac{1}{r}\partial_\phi f_r\\
&=\frac{1}{r^2}\partial_\phi\partial_r r f_r+\frac{1}{r^2}\partial_\phi^2 f_\phi+\frac{1}{r}\partial_\phi\partial_z f_z-\frac{1}{r}\partial_z\partial_\phi f_z+\partial_z^2 f_\phi+\partial_r\frac{1}{r}\partial_r r f_\phi-\partial_r\frac{1}{r}\partial_\phi f_r\\
&=\frac{1}{r^2}\partial_\phi\partial_r r f_r+\frac{1}{r^2}\partial_\phi^2 f_\phi+\partial_z^2 f_\phi+\partial_r\frac{1}{r}r f_\phi-\partial_r\frac{1}{r}\partial_\phi f_r\\
&=\frac{1}{r^2}\partial_\phi f_r+\frac{1}{r^2}\partial_\phi r\partial_r f_r+\frac{1}{r^2}\partial_\phi^2 f_\phi+\partial_z^2 f_\phi-\frac{1}{r^2}\partial_r r f_\phi+\frac{1}{r}\partial_r^2 r f_\phi+\frac{1}{r^2}\partial_\phi f_r-\frac{1}{r}\partial_r\partial_\phi f_r\\
&=\frac{2}{r^2}\partial_\phi f_r+\frac{1}{r}\partial_\phi\partial_r f_r+\frac{1}{r^2}\partial_\phi^2 f_\phi f_\phi+\partial_z^2 f_\phi-\frac{1}{r^2}f_\phi-\frac{1}{r}f_\phi+\frac{1}{r}\partial_r^2 r f_\phi-\frac{1}{r}\partial_r\partial_\phi f_r\\
&=\frac{2}{r^2}\partial_\phi f_r+\frac{1}{r^2}\partial_\phi^2 f_\phi+\partial_z^2 f_\phi+\partial_z^2 f_\phi-\frac{1}{r^2}f_\phi+\frac{1}{r}\partial_r r\partial_r f_\phi\\
&=\frac{2}{r^2}\partial_\phi f_r+\frac{1}{r^2}\partial_\phi^2 f_\phi+\partial_z^2 f_\phi+\partial_z^2 f_\phi-\frac{1}{r^2}f_\phi+\frac{1}{r}\partial_r f_\phi+\partial_r^2 f_\phi
\end{aligned}\tag{6.5.423}$$

and finally the third one:

$$\begin{aligned}
&=\partial_z\left(\frac{1}{r}\partial_r r f_r\right)+\partial_z\left(\frac{1}{r}\partial_\phi f_\phi\right)+\partial_z\partial_z f_z-\frac{1}{r}\partial_r r(\partial_z f_r-\partial_r f_z)+\frac{1}{r}\partial_\phi\left(\frac{1}{r}\partial_\phi f_z-\partial_z f_\phi\right)\\
&=\frac{1}{r}\partial_z\partial_r r f_r+\partial 1r\partial_z\partial_\phi f_\phi+\partial_z^2 f_z-\partial 1r\partial_r r\partial_z f_r+\frac{1}{r}\partial_r r\partial_r f_z+\frac{1}{r^2}\partial_p hi^2 f_z-\frac{1}{r}\partial_\phi\partial_z f_\phi\\
&=\frac{1}{r}\partial_z\partial_r r f_r+\partial_z^2 f_z-\frac{1}{r}\partial_r r\partial f_r+\frac{1}{r}\partial_r r\partial_r f_z+\frac{1}{r^2}\partial_\phi^2 f_z\\
&=\frac{1}{r}\partial_z f_r+\frac{1}{r}\partial_z r\partial_r f_r+\partial_z^2 f_z-\frac{1}{r}\partial_z f_r-\partial_r\partial_z f_r+\frac{1}{r}\partial_r f_z+\partial_r^2 f_z+\partial 1r^2\partial_\phi^2 f_z\\
&=\frac{1}{r}\partial_z r\partial_r f_r+\partial_z^2 f_z-\partial_r\partial_z f_r+\frac{1}{r}\partial_r f_z+\partial_r^2 f_z+\frac{1}{2}\partial_\phi^2 f_z\\
&=\partial_z\partial_r f_r+\partial_z^2 f_z-\partial_r\partial_z f_r+\frac{1}{r}\partial_r f_z+\partial_r^2 f_z+\frac{1}{r^2}\partial_\phi^2 f_z\\
&=\partial_z^2 f_z+\frac{1}{r}\partial_r f_z+\partial_r^2 f_z+\frac{1}{r^2}\partial_\phi^2 f_z
\end{aligned}\tag{6.5.424}$$

So what gives for us for the "vector Laplacian in cylindrical coordinates" as we can find it in tables or forms:

$$\boxed{\Delta\vec{f}=\begin{pmatrix}-\dfrac{1}{r^2}f_r+\dfrac{1}{r}\partial_r f_r+\partial_r^2 f_r-\dfrac{2}{r^2}\partial_\phi f_\phi+\dfrac{1}{r^2}\partial_\phi^2 f_r+\partial_z^2 f_r\\ \dfrac{2}{r^2}\partial_\phi f_r+\dfrac{1}{r^2}\partial_\phi^2 f_\phi+\partial_z^2 f_\phi+\partial_z^2 f_\phi-\dfrac{1}{r^2}f_\phi+\dfrac{1}{r}\partial_r f_\phi+\partial_r^2 f_\phi\\ \partial_z^2 f_z+\dfrac{1}{r}\partial_r f_z+\partial_r^2 f_z+\dfrac{1}{r^2}\partial_\phi^2 f_z\end{pmatrix}}\tag{6.5.425}$$

To finish and in the joy (...) let us make the merry and detailed calculations of the vector Laplacian operator in spherical coordinates (it's quite long but it's just to make sure that we fall back on what is in tables and forms):

$$\begin{aligned}
\Delta\vec{f}&=\vec{\nabla}(\vec{\nabla}\circ\vec{f})-\vec{\nabla}\times(\vec{\nabla}\times\vec{f})=\vec{\nabla}\left(\frac{1}{r^2}\partial_r(r^2 f_r)+\frac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta)f_\theta)+\frac{1}{r\sin(\theta)}\partial_\phi f_\phi\right)\\
&-\vec{\nabla}\times\begin{pmatrix}\dfrac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta)f_\phi)-\dfrac{1}{r\sin(\theta)}\partial_\phi f_\theta\\ \dfrac{1}{r\sin(\theta)}\partial_\phi f_r-\dfrac{1}{r}\partial_r(rf_\phi)\\ \dfrac{1}{r}\partial_r(rf_\theta)-\dfrac{1}{r}\partial_\theta f_r\end{pmatrix}\\
&=\begin{pmatrix}\partial_r\left(\dfrac{1}{r^2}\partial_r(r^2 f_r)\right)+\partial_r\left(\dfrac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta)f_\theta)\right)+\partial_r\left(\dfrac{1}{r\sin(\theta)}\partial_\phi f_\phi\right)\\ \dfrac{1}{r}\partial_\theta\left(\dfrac{1}{r^2}\partial_r(r^2 f_r)\right)+\dfrac{1}{r}\partial_\theta\left(\dfrac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta)f_\theta)\right)+\dfrac{1}{r}\partial_\theta\left(\dfrac{1}{r\sin(\theta)\partial_\phi f_\phi}\right)\\ \dfrac{1}{r\sin(\theta)}\partial_\phi\left(\dfrac{1}{r^2}\partial_r(r^2 f_r)\right)+\dfrac{1}{r\sin(\theta)}\partial_\phi\left(\dfrac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta)f_\theta)\right)+\dfrac{1}{r\sin(\theta)}\partial_\phi\left(\dfrac{1}{r\sin(\theta)}\right)\end{pmatrix}\\
&-\begin{pmatrix}\dfrac{1}{r\sin(\theta)}\partial_\theta\left(\sin(\theta)\left(\dfrac{1}{r}\partial_r(rf_\theta)-\dfrac{1}{r}\partial_\theta f_r\right)\right)-\dfrac{1}{r\sin(\theta)}\partial_\phi\left(\dfrac{1}{r}\partial_\phi f_r-\dfrac{1}{r}\partial_r(rf_\phi)\right)\\ \dfrac{1}{r\sin(\theta)}\partial_\phi\left(\dfrac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta)f_\phi)-\dfrac{1}{r\sin(\theta)}\partial_\phi f_\theta\right)-\dfrac{1}{r}\partial_r\left(r\left(\dfrac{1}{r}\partial_r(rf_\theta)-\dfrac{1}{r}\partial_\theta f_r\right)\right)\\ \dfrac{1}{r}\partial_r\left(r\left(\dfrac{1}{r\sin(\theta)}\partial_\phi f_r-\dfrac{1}{r}\partial_r(rf_\phi)\right)\right)-\dfrac{1}{r}\partial_\theta\left(\dfrac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta f_\phi)-\dfrac{1}{r\sin(\theta)}\partial_\phi f_\theta\right)\end{pmatrix}
\end{aligned}\tag{6.5.426}$$

Let us focus on the first line (caution! this will be quite long...):

$$
\begin{aligned}
&-\frac{1}{r\sin(\theta)}\cos(\theta)\partial_r f_\theta-\frac{1}{r\sin(\theta)}\sin(\theta)\partial_\theta\partial_r f_\theta+\frac{1}{r\sin(\theta)}\frac{\cos(\theta)}{r}\partial_\theta f_r+\frac{1}{r\sin(\theta)}\frac{\sin(\theta)}{r}\partial_\theta\partial_\theta f_\theta\\
&+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_r-\frac{2}{r^2\sin(\theta)}\partial_\phi f_\phi\\
&=\partial_r\left(\frac{1}{r^2}\partial_r(r^2 f_r)\right)-\frac{1}{r^2\sin(\theta)}\partial_\theta(\sin(\theta)f_\theta)+\frac{1}{r\sin(\theta)}\partial_r\partial_\theta(\sin(\theta)f_\theta)\\
&-\frac{\cot(\theta)}{r^2}f_\theta-\frac{1}{r^2}\partial_\theta f_\theta-\frac{\cot(\theta)}{r}\partial_r f_\theta-\frac{1}{r}\partial_\theta\partial_r f_\theta+\frac{\cot(\theta)}{r^2}\partial_\theta f_r+\frac{1}{r^2}\partial_\theta^2 f_r\\
&+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_r-\frac{2}{r^2\sin(\theta)}\partial_\phi f_\phi\\
&=\partial_r\left(\frac{1}{r^2}\partial_r(r^2 f_r)\right)-\frac{1}{r^2\sin(\theta)}\cos(\theta)f_\theta-\frac{1}{r^2\sin(\theta)}\partial_\theta f_\theta+\frac{1}{r\sin(\theta)}\partial_r f_\theta+\frac{1}{r\sin(\theta)}\partial_r\partial_\theta f_\theta\\
&-\frac{\cot(\theta)}{r^2}f_\theta-\frac{1}{r^2}\partial_\theta f_\theta-\frac{\cot(\theta)}{r}\partial_r f_\theta-\frac{1}{r}\partial_\theta\partial_r f_\theta+\frac{\cot(\theta)}{r^2}\partial_\theta f_r+\frac{1}{r^2}\partial_\theta^2 f_r\\
&+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_r-\frac{2}{r^2\sin(\theta)}\partial_\phi f_\phi\\
&=\partial_r\left(\frac{1}{r^2}\partial_r(r^2 f_r)\right)-\frac{\cot(\theta)}{r^2}f_\theta-\frac{1}{r^2}\partial_\theta f_\theta+\frac{\cot(\theta)}{r}\partial_r f_\theta+\frac{1}{r}\partial_r\partial_\theta f_\theta\\
&-\frac{\cot(\theta)}{r^2}f_\theta-\frac{1}{r^2}\partial_\theta f_\theta-\frac{\cot(\theta)}{r}\partial_r f_\theta-\frac{1}{r}\partial_\theta\partial_r f_\theta+\frac{\cot(\theta)}{r^2}\partial_\theta f_r+\frac{1}{r^2}\partial_\theta^2 f_r\\
&+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_r-\frac{2}{r^2\sin(\theta)}\partial_\phi f_\phi\\
&=\partial_r\left(\frac{1}{r^2}\partial_r(r^2 f_r)\right)-\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_r-\frac{2}{r^2\sin(\theta)}\partial_\phi f_\phi\\
&=-\frac{2}{r^3}\partial_r(r^2 f_r)+\left(\frac{1}{r^2}\partial_r^2(r^2 f_r)\right)\\
&-\frac{2\cot(\theta)}{r^2}f_\theta-\frac{2}{r^2}\partial_\theta f_\theta\frac{\cot(\theta)}{r^2}\partial_\theta f_r+\frac{1}{r^2}\partial_\theta^2 f_r+\frac{1}{r^2\sin^2(\theta)}\partial_\phi f_r-\frac{2}{r^2\sin(\theta)}\partial_\phi f_\phi\\
&=-\frac{2}{r^3}2rf_r-\frac{2}{r^3}r^2\partial_r f_r+\left(\frac{1}{r^2}\partial_r(2rf_2+r^2\partial_r f_r)\right)\\
&-\frac{2\cot(\theta)}{r^2}f_\theta-\frac{2}{r^2}\partial_\theta f_\theta+\frac{\cot(\theta)}{r^2}\partial_\theta f_r+\frac{1}{r^2}\partial_\theta^2 f_r+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_r-\frac{2}{r^2\sin(\theta)}\partial_\phi f_\phi\\
&=-\frac{4}{r^2}f_r-\frac{2}{r}\partial_r f_r+\frac{1}{r^2}2f_r+\frac{1}{r^2}2r\partial_r f_r+\frac{1}{r^2}2r\partial_r^2 f_r\\
&-\frac{2\cot(\theta)}{r^2}f_\theta-\frac{2}{r^2}\partial_\theta f_\theta+\frac{\cot(\theta)}{r^2}\partial_\theta f_r+\frac{1}{r^2}\partial_\theta^2 f_r+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_r-\frac{2}{r^2\sin(\theta)}\partial_\phi f_\phi\\
&=-\frac{2}{r^2}f_r+\frac{2}{r}\partial_r f_r+\underbrace{\partial_r^2 f_r}_{=\frac{1}{r}\partial_r^2(rf_r)}-\frac{2\cot(\theta)}{r^2}f_\theta-\frac{2}{r^2}\partial_\theta f_\theta+\frac{\cot(\theta)}{r^2}\partial_\theta f_r+\frac{1}{r^2}\partial_\theta^2 f_r\\
&+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_r-\frac{2}{r^2\sin(\theta)}\partial_\phi f_\phi
\end{aligned}
\tag{6.5.427}
$$

$$
\begin{aligned}
&=-\frac{2}{r^2}f_r+\frac{1}{r}\partial_r^2(rf_r)\\
&-\frac{2\cot(\theta)}{r^2}f_\theta-\frac{2}{r^2}\partial_\theta f_\theta+\frac{\cot(\theta)}{r^2}\partial_\theta f_r+\frac{1}{r^2}\partial_\theta^2 f_r+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_r-\frac{2}{r^2\sin(\theta)}\partial_\phi f_\phi
\end{aligned}
\tag{6.5.428}
$$

That's it for the first line ... Let us get on to the second line always with joy...:

$$
\begin{aligned}
&=\frac{1}{r}\left(\frac{1}{r^2}\partial_r(r^2f_r)\right)+\frac{1}{r}\partial_\theta\left(\frac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta)f_\theta)\right)+\frac{1}{r}\partial_\theta\left(\frac{1}{r\sin(\theta)}\partial_\phi f_\phi\right)\\
&-\frac{1}{r\sin(\theta)}\partial_\phi\left(\frac{1}{\sin(\theta)}\partial_\theta(\sin(\theta f_\phi)-\frac{1}{r\sin(\theta)}\partial_\phi f_\theta\right)+\frac{1}{r}\partial_r\left(r\left(\frac{1}{r}\partial_r(rf_\theta)-\frac{1}{r}\partial_\theta f_r\right)\right)\\
&=\frac{1}{r^3}\partial_\theta\partial_r r^2 f_r-\frac{1}{r^2}\frac{\cos(\theta)}{\sin^2(\theta)}\partial_\phi f_\phi+\frac{1}{r^2\sin(\theta)}\partial_\theta\partial_\phi f_\phi-\frac{1}{r^2}\frac{\cos(\theta)}{\sin^2(\theta)}\partial_\phi f_\phi+\frac{1}{r^2\sin(\theta)}\partial_\theta\partial_\phi f_\phi\\
&+\frac{1}{r^2\sin(\theta)}\partial_\theta\partial_\phi f_\phi-\frac{1}{r^2\sin^2(\theta)}\partial_\phi\partial_\theta\sin(\theta)f_\phi+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_\theta+\frac{1}{r}\partial_r(\partial_r(rf_\theta)-\partial_\theta f_r)\\
&=\frac{1}{r^3}\partial_\theta 2rf_r+\frac{1}{r^3}\partial_\theta r^2\partial_r f_r-\frac{1}{r^2}\frac{\cot(\theta)}{\sin(\theta)}\partial_\theta\sin(\theta)f_\theta+\frac{1}{r^2\sin(\theta)}\partial_\theta^2(\sin(\theta)f_\theta)-\frac{1}{r^2}\frac{\cot(\theta)}{\sin(\theta)}\partial_\phi f_\phi\\
&+\frac{1}{r^2\sin(\theta)}\partial_\theta\partial_\phi f_\phi-\frac{1}{r^2\sin^2(\theta)}\partial_\phi\partial_\theta\sin(\theta)f_\phi+\frac{1}{r^2\sin(\theta)}\partial_\phi^2 f_\theta+\frac{1}{r}\partial_r(f_\theta+r\partial_r f_\theta-\partial_\theta f_r)\\
&=\frac{2}{r^2}\partial_\theta f_r+\frac{1}{r}\partial_\theta\partial_r f_r-\frac{1}{r^2}\frac{\cot(\theta)}{\sin(\theta)}\cos(\theta)f_\theta-\frac{1}{r^2}\frac{\cot(\theta)}{\sin(\theta)}\sin(\theta)\partial_\theta f_\theta+\frac{1}{r^2\sin(\theta)}\partial_\theta^2(\sin(\theta)f_\theta)\\
&-\frac{1}{r^2}\frac{\cot(\theta)}{\sin(\theta)}\partial_\phi f_\phi+\frac{1}{r^2\sin(\theta)}\partial_\theta\partial_\phi f_\phi-\frac{1}{r^2\sin^2(\theta)}\partial_\phi\cos(\theta)f_\phi-\\
&\frac{1}{r^2\sin^2(\theta)}\partial_\phi\sin(\theta)\partial_\theta f_\phi+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_\theta+\frac{1}{r}\partial_r f_\theta+\frac{1}{r}\partial_r r\partial_r f_\theta-\frac{1}{r}\partial_r\partial_\theta f_r\\
&=\frac{2}{r^2}\partial_\theta f_r-\frac{1}{r^2}\cot^2(\theta)f_\theta-\frac{\cot(\theta)}{r^2}\partial_\theta f_\theta+\frac{1}{r^2\sin(\theta)}\partial_\theta\cos(\theta)f_\theta+\frac{1}{r^2\sin(\theta)}\partial_\theta\sin(\theta)\partial_\theta f_\theta\\
&-\frac{2}{r^2}\frac{\cot(\theta)}{\sin(\theta)}\partial_\phi f_\phi+\frac{1}{r^2\sin(\theta)}\partial_\theta\partial_\phi f_\phi-\frac{1}{r^2\sin(\theta)}\partial_\phi\partial_\theta f_\phi+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_\theta+\frac{1}{r}\partial_r^2(rf_\theta)\\
&=\frac{2}{r^2}\partial_\theta f_r-\frac{1}{r^2}\cot^2(\theta)f_\theta-\frac{\cot(\theta)}{r^2}\partial_\theta f_\theta-\frac{1}{r^2\sin(\theta)}\sin(\theta)f_\theta+\frac{1}{r^2\sin(\theta)}\cos(\theta)\partial_\theta f_\theta\\
&+\frac{1}{r^2\sin(\theta)}\cos(\theta)\partial_\theta f_\theta+\frac{1}{r^2\sin(\theta)}\sin(\theta)\partial_\theta^2 f_\theta-\frac{2}{r^2}\frac{\cot(\theta)}{\sin(\theta)}\partial_\phi f_\phi+\frac{1}{r^2\sin(\theta)}\partial_\theta\partial_\phi f_\phi\\
&-\frac{1}{r^2\sin(\theta)}\partial_\phi\partial_\theta f_\phi+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_\theta+\frac{1}{r}\partial_r^2(rf_\theta)\\
&=\frac{2}{r^2}\partial_\theta f_r-\frac{\cot^2(\theta)}{r^2}f_\theta+\frac{\cot(\theta)}{r^2}\partial_\theta f_\theta-\frac{1}{r^2}f_\theta+\frac{1}{r^2}\partial_\theta^2 f_\theta-\frac{2}{r^2}\frac{\cot(\theta)}{\sin(\theta)}\partial_\phi f_\phi+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_\theta+\frac{1}{r}\partial_r^2(rf_\theta)\\
&=\frac{2}{r^2}\partial_\theta f_r-\frac{1}{r^2}(\cot^2(\theta)-1)f_\theta+\frac{\cot(\theta)}{r^2}\partial_\theta f_\theta+\frac{1}{r^2}\partial_\theta^2 f_\theta-\frac{2}{r^2}\frac{\cot(\theta}{\sin(\theta)}\partial_\phi f_\phi+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_\theta+\frac{1}{r}\partial_r^2(rf_\theta)\\
&=\frac{2}{r^2}\partial_\theta f_r-\frac{1}{r^2\sin^2(\theta)}f_\theta+\frac{\cot(\theta)}{r^2}\partial_\theta f_\theta+\frac{1}{r^2}\partial_\theta^2 f_\theta-\frac{2}{r^2}\frac{\cot(\theta)}{\sin(\theta)}\partial_\phi f_\phi+\frac{1}{r^2\sin^2(\theta)}\partial_\phi^2 f_\theta+\frac{1}{r}\partial_r^2(rf_\theta)
\end{aligned}
\tag{6.5.429}
$$

and finally a last effort for the third and last line:

$$
\begin{aligned}
&=\frac{1}{r\sin(\theta)}\partial_\phi\left(\frac{1}{r^2}\partial_r(r^2f_r)\right)+\frac{1}{r\sin(\theta)}\partial_\phi\left(\frac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta)f_\theta)\right)+\frac{1}{r\sin(\theta)}\partial_\phi\left(\frac{1}{r\sin(\theta)}\partial_\phi f_\phi\right)\\
&-\frac{1}{r}\partial_r\left(r\left(\frac{1}{r\sin(\theta)}\partial_\phi f_r-\frac{1}{r}\partial_r(rf_\phi)\right)\right)+\frac{1}{r}\partial_\theta\left(\frac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta)f_\phi)-\frac{1}{r\sin(\theta)}\partial_\phi f_\theta\right)\\
&=\frac{1}{r^3\sin(\theta)}\partial_\phi\partial_r r^2f_r+\frac{1}{r^2\sin^2(\theta)}\partial_\phi\partial_\theta\sin(\theta)f_\theta+\frac{1}{r^2\sin^2(\theta)}\partial^2_\phi f_\phi\\
&-\frac{1}{r}\partial_r\left(\frac{1}{\sin(\theta)}\partial_\phi f_r-\partial_r rf_\phi\right)+\frac{1}{r}\partial_\theta\frac{1}{r\sin(\theta)}\partial_\theta f_\theta\\
&=\frac{1}{r^3\sin(\theta)}\partial_\phi 2rf_r+\frac{1}{r^3\sin(\theta)}\partial_\phi r^2\partial_r f_r+\frac{1}{r^2\sin^2(\theta)}\partial_\phi+\cos(\theta)f_\theta+\frac{1}{r^2\sin^2(\theta)}\partial_\phi\sin(\theta)\partial_\theta f_\theta\\
&+\frac{1}{r^2\sin^2(\theta)}\partial^2_\phi f_\phi-\frac{1}{r\sin(\theta)}\partial_r\partial_\phi f_r+\frac{1}{r}\partial_r\partial_r f_\phi\\
&-\frac{1}{r}\frac{\cos(\theta)}{r\sin^2(\theta)}\partial_\theta(\sin(\theta)f_\phi)+\frac{1}{r^2\sin(\theta)}\partial_\theta\partial_\theta(\sin(\theta)f_\phi)+\frac{1}{r}\frac{\cos(\theta)}{r\sin^2(\theta)}\partial_\phi f_\theta-\frac{1}{r^2\sin(\theta)}\partial_\theta\partial_\phi f_\theta\\
&=\frac{2}{r^2\sin(\theta)}\partial_\phi f_r+\frac{1}{r\sin(\theta)}\partial_\phi\partial_r f_r+\frac{\cot(\theta)}{r^2\sin(\theta)}\partial_\phi f_\theta+\frac{1}{r^2\sin(\theta)}\partial_\phi\partial_\theta f_\theta\\
